The National Portrait Gallery at present occupies 19,040 square feet, partly in the two floors of the eastern wing A (a portion of the freehold), and partly in the eastern section of the central block C (the leasehold portion), of the south galleries. A space of 7500 square feet in the upper floor of the central leasehold block C, is also reserved for examination-rooms.

A portion of the ground floor of the western gallery, D, has been, up to the present time, occupied by the Pitt-Rivers Loan Collection, but this collection is in course of removal to Oxford.

10. The Science collections are now contained in the western part of the ground floor of the leasehold central block C; in the ground floor and in part of the upper floor of the western freehold wing B; in the northern end spurs A′ and B′; in the two floors of the western gallery D; and in an unsightly wooden passage K.

This passage runs outside the southern wall of the south gallery, and forms the only approach from Exhibition Road to the Science collections, it not being possible to allow the public to use the Portrait Gallery as a thoroughfare.

The "Patent Museum" is contained in the temporary building E.

11. The total floor-space now occupied by the Science collections is therefore about as follows:—

		Square feet
Total space in C		22,000
,, ,, A, B, and A′, B′		29,500
,, ,, D		36,560
,, ,, E		7,500
		95,560
Deduct Portrait Gallery	19,040	
,, Examination-Rooms ...	7,500	
		26,540
Total occupied by the Collections ...		69,020

12. The Drawing No. I. also shows (marked G and coloured red) the area of land which belongs to the Government south of the present south galleries, which land is implied in our instructions to be available for buildings to house the collections.

SCOPE OF THE COLLECTIONS, AND SPACE REQUIRED FOR THEM

13. We may now proceed to report on the first subject submitted to us, namely:—

The scope of the Scientific and Technical Collections, including the Patent Museum, and the space required for them, immediately and prospectively.

14. A Museum of Science was contemplated as an integral part of the Science and Art Department from its creation in 1853.

Objects were gradually collected, and when the Department was removed to South Kensington in 1858 these objects were, for the first time, arranged together in the Museum for public inspection. They were mentioned by a House of Commons Committee in 1860 as "well worth preserving."

These collections, however, were not developed as much as the Art collections. Some objects were sent away to other establishments; and for want of space in the South Kensington Museum, the greater portion of the remainder were removed to the galleries on the western side of the Exhibition Road, where they have remained till now.

But public attention was frequently called to the subject.

The Royal Commission on Scientific Instruction and the Advancement of Science, in their Fourth Report (1874), treated somewhat largely of these collections; they noticed many interesting objects which they contained, but they pointed out the striking contrast between them and other British National collections. They expressed their regret that there was no National collection of the instruments used in the investigation of mechanical, chemical, or physical laws, although such collections were of great importance to persons interested in the experimental sciences. This defect in our collections was, they said, already keenly felt by teachers of science, and high authorities had assured them that, on the Continent, collections of scientific apparatus, when combined with lectures accessible to workmen, had exerted a very beneficial influence on the development of the skill of artisans.

The Commission suggested, in conclusion, that the collections should be completed and consolidated, and placed under the authority of a Minister of State.

In 1876 a Loan Collection of Scientific Instruments and Apparatus was exhibited in the galleries of the Horticultural Gardens. It excited much attention, and a memorial was presented to the Lord President, signed by 140 of the best known men of science in the country, suggesting that it might be utilised in the formation of a National Science Museum. Some of the objects were left in the care of the Department, but no general action was taken.

The question of the development of the Science Collections of the Department remained in abeyance till 1881, when the Lord President, Earl Spencer, stating that "the importance of having a Museum for Scientific Apparatus was amply established," set on foot a series of inquiries to which we proceed to refer.

15. For the purpose of these inquiries, the existing collections were divided into six heads:—Objects for the illustration of Science generally; Naval Models; Objects illustrating Building Construction; Objects bearing on Fish Culture; Educational Objects; and Mechanical Objects.

Committees, composed of persons having specific knowledge in each of these branches, were appointed to examine the several collections, and expressed opinions on their condition, on the development which it would be advisable to give to them, and on the space required.

As copies of the Reports on each head are reprinted in an Appendix (B), it will suffice to give here a general outline of the opinions and recommendations they contain.

Collections of Objects for the Illustration of Science generally

16. The Committee consisted of Mr. Wm. Spottiswoode, President of the Royal Society, Professors Frankland, Goodeve, Guthrie, Huxley, Judd, Chandler Roberts, and Warington Smyth, Mr. Norman Lockyer, and the chief officers of the Science Department. They expressed the opinion that this question was of great importance in relation to the education, the industry, and the science of the country; they reported that the present collection was suitable for a nucleus of the contemplated Museum, and they recommended an examination, by the several Professors and other members of the Council of the Normal School, of the various classes of apparatus and appliances relating to their own subjects respectively.

This examination was afterwards undertaken by a Committee of the various Professors, and the results, as already stated, are given in the Reports. Recommendations were made as to the objects in each department of science, and the following estimate was given of space necessary to be provided:—

	Square feet
Chemistry	6000
Physics	6000
Mechanics	5000
Metallurgy	2500
Geology and Mineralogy	2500
Astronomy, Meteorology, and Geography ...	7000
Agriculture	4000
Biology	4000
	37,000

The Committee also estimated that a further space of 3000 square feet (making 40,000 in all) would probably be sufficient for any reasonable increase within ten years.

Naval Models

17. A Committee consisting of Lord Ravensworth, Sir E. J. Reed, K.C.B., M.P., Mr. W. Baskcomb, Mr. J. H. Morrison, and Mr. Joseph D. A. Samuda, considered this collection, and reported on it on March 1, 1883. They expressed a strong opinion as to the utility of such a collection, gave some general suggestions upon it, and proposed to have it carefully examined in detail.

This examination was carried out, and on April 4, 1883, the Committee based upon it a statement that a space of 10,500 square feet was at once required, and that 10,000 square feet additional should be provided for the increase during the next ten years, making 20,500 square feet in all.

Structural Collection

18. The Committee for this consisted of Mr. (now Sir) Charles Hutton Gregory, Past-President of the Institution of Civil Engineers, Mr. G. E. Street, President of the Royal Institute of British Architects, Mr. James Abernethy, President of the Institution of Civil Engineers, and Major H. C. Seddon, R.E., Examiner for the Science and Art Department in Building Construction. They reported, in 1881, that this collection was of great value in many respects, and recommended its maintenance, revision, and development.

In July 1883 another Committee, consisting of Mr. C. H. Gregory, Mr. Horace Jones, President of the Royal Institute of British Architects, Mr. James Brunlees, President of the Institution of Civil Engineers, and Major Seddon, took up the matter. They put forward detailed proposals in regard to the constitution and arrangement of the collection, and gave an estimate of 15,000 square feet of floor-space for it, to be increased to 25,000 square feet in ten years.

Fish Culture

19. The Committee for this collection were Prof. Huxley (Government Inspector of Fisheries), Sir J. R. G. Maitland, Bart., Mr. E. Birkbeck, and Dr. Francis Day.

They expressed the opinion that it was highly desirable that the existing specimens should be developed into an economic Fish Museum, and they estimated about 5000 square feet as the space required.

Educational Objects

20. The Committee for this were Dr. J. H. Gladstone, Rev. J. W. Sharpe, Mr. J. S. Fitch, Mr. J. Iselin, and Mr. H. A. Bowler.

They stated that the collections would be of great value to School Boards, managers, and teachers, and they estimated 7000 square feet of surface as necessary, not including any allowance for the library.

Mechanical Collections

21. The Committee appointed to consider these collections were Mr. John Slagg, M.P., Sir W. G. Armstrong, Sir J. W. Bazalgette, Mr. James Brunlees, Mr. E. A. Cowper, Prof. T. M. Goodeve, Sir Charles Hutton Gregory, Mr. John Hick, Mr. James Howard, M.P., Mr. Charles Manby, Mr. J. Hinde Palmer, Sir E. J. Reed, M.P., and Mr. (now Sir) B. Samuelson, M.P.

They carefully examined the collections, including the "Patent Museum" (which, under the Patent Act, 1883, had been transferred to the care of this Department on January 1, 1884), and made a comprehensive report, embodying suggestions for the improvement and the arrangement of the whole.

They estimated that from 40,000 to 50,000 square feet of space would be required.

22. Considering that the members of these Committees were selected, on the responsibility of the Government, for their competence as authorities in their respective branches of science, and considering the detailed nature of their inquiries, we assume their conclusions as the basis of our recommendations.

We may also add that similar Committees are permanently retained, under the name of "Committees of Advice and Reference" for the several collections.

23. We need not enlarge on the desirability that such a country as Great Britain should possess a thoroughly good and complete National Collection of Scientific and Technical objects, any more than that it should possess a Museum of objects of Art or of Natural History.

When it is considered how much the prosperity of the nation is bound up with industrial enterprises and occupations, and how largely these depend, for their success, on practical applications of science, it needs no elaborate reasoning to prove that the public exhibition of well-selected and judiciously arranged scientific and technical collections, particularly when used in connection with efficient courses of instruction, justifies its cost.

24. There has long been a National Scientific and Technical Museum in France, well known under the name of the Conservatoire des Arts et Métiers, and this has often been referred to as a type of the institution of a similar nature which ought to be established in England.

We reprint, in Appendix C, an article published in the *Times* newspaper of October 5, 1876, which gives a full account of the nature and scope of the Conservatoire, and we have also received, through the courtesy of the Directors, full information as to the present contents and arrangements of the Museum.

The premises are situated in an area contained between the four streets, Rue St. Martin, Rue Vaucanson, Rue du Vert Bois, and Rue Réaumur. This area is about 200 metres wide by 140 metres deep, thus containing 28,000 square metres, or about 7 acres. These 7 acres are not at present entirely occupied by the Conservatoire, but an enlargement of the buildings is in progress, which will extend them, including the necessary courtyards, passages, &c., over the whole area.

The objects exhibited belong to a great variety of subjects, the following being only a brief indication of their general classification:—

Motors.—Horse-machines, water-motors, wind-motors, steam-engines, hot-air engines. Details and accessories.

Hydraulic Machines.—Pumps, &c.

Descriptive Geometry.—Forms of curves; teeth of wheels. Machines for producing special forms.

Metallurgy.—Working of mines. Minerals. Metallurgical processes. Metals.

Calculating and Counting Machines.

Instruments for Surveying.

Astronomy, &c.—Almanacs and Calendars.

Chronometry, ancient and modern; movements; tools.

Arts of Construction.—Materials, processes, workmen's tools, &c. Constructions under water.

Kinematics.—Machinery. Mechanism. Elements of machines.

Dynamometers and instruments for mechanical observations.

Cranes and other constructions for lifting and removing weights.

Machine Tools of various kinds. Presses, &c.

Engraving, Lithography, Typography, Printing, &c., and paper-making.

Porcelain, Glass, and Pottery.

Physics.—Mechanics. Molecular actions. Heat. Magnetism. Electricity. Acoustics. Optics. Meteorology. Electro-chemistry. Telegraphy.

Agriculture.—Apparatus of all kinds.

Weights and Measures.—French and foreign. Weighing-machines. Instruments of comparison.

Locomotion and Transport on ordinary roads, on railways, and on rivers, canals, and the sea.

Manufactures, various.—Gunpowder. Arms. Chemicals. Bread. Sugar. Cements. Cutlery. India-rubber.

Spinning and Weaving.—Textile manufactures generally.

Preparation, Dyeing, and Printing of Fabrics.

Chemical Arts and Products.—Preservation of Timber. Gas. Distilling. Brewing. Tanning, &c.

Industrial and Fine Arts.—Prints; designs. Photography.

Pictures and Drawings, illustrative of Scientific and Technical matters; a very large collection.

There are in all about 10,000 objects. The collection is remarkably rich, both in historic apparatus and in the most recent inventions. The machinery is shown in motion two days in the week. The objects are used, when required, for the lectures given in the Conservatoire.

Nothing is added unless it can be utilised for teaching; sometimes orders are given for models to be made, and sometimes objects are purchased. When anything is offered as a gift, it is not accepted unless one of the professors will state that it is really required.

The collection is not in any way a Patent Museum. Formerly certain models of patented inventions were exhibited there, but this is no longer done.

(*To be continued.*)

NOTES

THE meetings held yesterday at St. James's Palace and the Mansion House, to which we have not time to refer at length this week, indicate that from the Prince of Wales downwards all interested in the proposed memorial are willing to allow the necessity of making the Institute one on a broad scientific basis. An admirable speech by Prof. Huxley at the Mansion House, following that of the Prince of Wales at the first meeting, shows that there is now no chance of the importance and of the necessity of collecting and arranging *knowledge* being overlooked.

FRENCH geologists have cause to regret the blow which their science has received in the premature death of the well-known geologist of Lyons, C. F. Fontannes, on December 29, at the age of forty-eight. He is best known by his important monograph on the "Stratigraphy and Palæontology of the Tertiary Deposits of the Basin of the Rhone"—a work of laborious research and of great value from the minuteness and accuracy of its details. He established a claim on the gratitude of geologists by the infinite pains he took in the organisation and working of the International Geological Congress, the success of which has been in large measure due to his active help. His pleasant smile and cheery way of smoothing over personal friction will long be remembered by those who witnessed them at the meetings of the Congress.

SIR FRANCIS BOLTON died at Bournemouth on Wednesday, the 5th inst. He was born in 1831, and entered the army at the age of twenty-six. For some time he served on the staff as Deputy-Assistant Quartermaster-General, and in 1881 he retired with the rank of colonel. He was the inventor of the system of telegraphic and visual signalling which was introduced into the army and navy in 1863, and for these services and other improvements and inventions in regard to warlike material he received in 1883 the honour of knighthood. In 1870 he founded the Society of Telegraph-Engineers and Electricians.

LAST year some of the leading statisticians of Europe combined to form a new Society, the International Statistical Institute. If we may judge from its aims, as set forth in the first article of its statutes, the Institute is likely to do work which will be of the highest service to Governments. It proposes to foster the progress of administrative and scientific statistics: "(1) by introducing as much as possible uniformity of method and classification and of handling statistical material, in order to make the results obtained in different countries comparable; (2) by calling the attention of Governments to those questions which require to be solved by statistical observation, and requesting from them information on subjects which have not yet been treated statistically, or have been only insufficiently treated; (3) by creating international publications intended to establish permanent relations among statisticians of all countries; (4) by striving, through its publications, and, if possible, by public instruction and other means, to promote the spread of sound ideas as to statistics, and to interest Governments and peoples in the investigation of the phenomena of society." The Institute intended to have held its first general meeting in Rome in September last, but was compelled by the spread of cholera in Italy to abandon its design. It has now decided to hold its first meeting in Rome in Easter week of this year, from April 12 to 16. Nearly fifty members have expressed their intention of being present, and it is expected that the attendance will be considerably larger. The Italian Government deserves the greatest credit for the generous and enlightened manner in which it is supporting the Institute. It allows Prof. Boris, the Director-General of the Statistics of the Kingdom of Italy, to act as Secretary, and in this capacity to use the services of his official staff. With the sanction of the Italian Parliament, it has granted a sum equal to 600*l.* to aid the Institute in printing its publications, and another sum of 400*l.* has been contributed to the expenses of the approaching meeting. Moreover, it has been arranged that for the benefit of members who attend the meeting the fares on the public railways to and from Rome shall be reduced by one-half. Signor Grimaldi, the Italian Minister of Commerce, is trying to induce other Governments to act in a similar spirit, and it may be hoped that his efforts will not be wholly unsuccessful.

ON Saturday evening last, Sir John Lubbock delivered, at Toynbee Hall, a lecture on "Savages," the first of a new course. He pointed out that modern savages do not in all respects reproduce the condition of our ancestors in early times. Even the Australians hold now a system of complex rules and stringent customs, which have grown up gradually, and cannot have existed originally. From the study of modern savages, however, we may gain a fairly correct idea of man as he existed in ancient times, and of the stages through which our civilisation has been evolved. The lecturer gave a remarkably vivid and interesting account of some of the leading facts known about the customs, beliefs, and institutions of savage races.

ON Friday evening last the Drapers' Company set an admirable example to other City Companies by entertaining at its Hall in Throgmorton Street the students associated with the Whitechapel centres of the University Extension Scheme. The classes connected with this Scheme at Toynbee Hall are attended by no fewer than 631 students, who receive instruction in physiology, astronomy, history, and English literature. The fee for a course of twelve lectures is one shilling.

THE presidential address delivered at the annual meeting of the American Neurological Association in June last by Dr. Burt G. Wilder has been reprinted from the *Journal of Nervous and Mental Disease.* In this address Dr. Wilder discusses the question as to the need of some improvement in the nomenclature of the brain. He is convinced that the current nomenclature is to a large extent an obstacle rather than an aid to the advancement and dissemination of knowledge concerning a complex organ; and, with regard to the encephalic cavities in particular, he holds that it would be better for the student if the incongruous and misleading *quasi*-descriptive terms, *first, second, third, fourth,* and *fifth ventricle,* could be displaced by totally meaningless, but easily remembered, Chinese monosyllables, like *pran, pren, prin, pron,* and *prun.* Dr. Wilder has obtained an alphabetical list of nearly all the names which have been applied to the parts of the central nervous system, and, allowing for some omissions and duplicates, the numbers are as follows:—Latin, 2600; English, 1300; German, 2400; French, 1800; Italian and Spanish, 900; total, 9000. The number of parts designated by these names is considerably less than 500.

REFERRING to the death of Sir W. W. Heughes, which took place near London on New Year's Day, the *Colonies and India* mentions that practically he initiated the Adelaide University by contributing 20,000*l.* in 1872 for the endowment of two professorships. He also contributed largely to the expedition under Colonel Warburton for the exploration of the interior of the Australian continent. He received the honour of knighthood in 1880.

M. JANSSEN, the Director of the Meudon Observatory, who has been nominated Vice-President of the Paris Academy of Sciences for 1887, will be President in 1888, according to the constant rule.

IT is said that M. Chevreul will resign his membership of the Academy of Sciences, and will return to his native place to spend the last years of his life in retirement. He has already sent in his resignation of the Directorship of the Museum.

ONE of the last letters written by M. Paul Bert was read at the meeting of the French Academy of Sciences on the 3rd inst. In this letter M. Bert complained of the darkness in the town of Hanoï at night. Gas was too dear, and he had tried the use of petroleum. This, however, was a barbarous expedient, and he was anxious to know whether it would not be possible for him to make the Red River, which flows past Hanoï, produce the required illumination. "Would the expense be great?" he wrote. "Only think, if we succeeded we should be ahead of England and Japan!" "Answer," he added, "and answer quickly; my days are numbered." The Academy decided that the letter should be preserved among its archives.

A LARGE number of French scientific Societies are anxious that a building should be erected in Paris for their common use. A circular on the subject has been issued. The lead in the matter is being taken by the Geographical Society.

A GOOD deal of canvassing has been going on recently in Paris, in the Sorbonne, the Medical School, and the Academy of Sciences, for professorships and seats in the Institute of France. Many superannuated professors have been removed, in consequence of the enforcement of a recent law; others have died. In the Medical School, Prof. Sappey's place has been given to M. Farabeuf, a distinguished anatomist, although entirely devoid of philosophical tendencies. Prof. Gavarret, whose well-known researches, conducted many years ago with Audral, have been of the utmost importance for the physiology of respiration, has seen his place filled by M. Gariel, who has been his assistant for a long time. Prof. Peter has taken the place of M. Hardy, in the Professorship of Clinical Medicine. He is an obstinate opponent of M. Pasteur's theories, but, nevertheless, a good physician, well trained, and skilled in his part of science. Prof. Pagot, the well-known Professor of Obstetrics, resigned his appointment on the day of his seventieth anniversary, and it is likely that M. Pinard will be his successor. M. Pinard is an able obstetrician, a good teacher, an original worker, and is much liked by students and professors. The vacancy caused at the Sorbonne by the death of Milne-Edwards has been filled by the appointment of M. Yves Delage, who has been for a short time Professor of Zoology in Caen. M. Yves Delage, although a very young man, has done a good deal of excellent personal work. His principal investigations bear upon the circulatory system of Crustacea, the life-history and anatomy of Sacculina, a parasitic Crustacean, and the anatomy of the whale. In the Academy of Sciences, M. Sappey was elected soon after his removal from the Medical School. His personal work has been good, and bears upon human anatomy, upon the anatomy of the lymphatic vessels, of the air-reservoirs of birds, and many other points of comparative anatomy. M. Ranvier, the able histologist of the Collège de France, will very likely be elected to the seat of Ch. Robin. One of the competitors for Paul Bert's seat is M. Ch. Rochet, the physiologist, and editor of the *Revue Scientifique*.

A VERY good little guide to the most picturesque streets and buildings in the capital of Egypt, by Major E. T. Plunkett, R.E., has just been published. It is entitled "Walks in Cairo." Major Plunkett's object is to call attention to "sights" which have hitherto been neglected by the writers of guide-books, —out-of-the-way mosques, in which the most graceful Arabesque forms may be found, with choice bits of marble mosaic and fine specimens of cabinet-work, and street corners made picturesque by minarets, overhanging stories, and windows of lace-like lattice-work. If any visitor is in doubt whether he would or would not enjoy the "Walks" described, he is advised to try one of them, and if he finds that uninteresting to try no more.

ON July 28 last, Miss Eleanor A. Ormerod, F.E.S., Consulting Entomologist to the Royal Agricultural Society, received from Revell's Hall, Hertford, specimens of injured barley, which on examination precisely corresponded with the condition caused by attack of the *Cecidomyia destructor*, commonly known as the Hessian fly. A paper setting forth the results of her observations, with the opinions of high authorities in England and America, was read at the Entomological Society of London on December 1 last. An abstract of this paper will be found in the *Entomologist* for January.

IN the January *Zoologist* there is a very good representation of the Greater Horse-shoe Bat (*Rhinolophus ferrum-equinum*). It illustrates an article on "Horse-shoe Bats" by the editor, who remarks that as few really good figures of bats are accessible, those in Bell's work being almost too small to be of much use, it is very desirable that no opportunity should be lost of obtaining correct drawings of the rarer species whenever they can be procured alive or in a fresh condition, so as to secure an accurate delineation of the natural features before they become distorted or shrunk in the process of drying. The plate which he offers as a first contribution to such a series is from a living specimen obtained by the Rev. H. A. Macpherson in South Devon in August last. This specimen weighed little more than half an ounce the day after death.

SEVERAL Arctic species of birds, which do not breed in England or Ireland, breed in Scotland. This fact is explained by Mr. Henry Seebohm in an article in the January *Zoologist*. Most, if not all, of the species in question breed in July, and, roughly speaking, they draw the line a few degrees below 60° F. They do not breed in any locality where the mean temperature for July is as high as 60°, the reason probably having relation to the supply of food. Now, in a map of the world, in Keith Johnston's "Physical Atlas," giving the mean temperature for July in various parts of the earth, the isothermal line of 59° is drawn. This line separates England and Ireland from Scotland, passes north of the Gulf of Bothnia, through the town of Archangel, extends nearly straight across Russia and Western Siberia, but, east of the valley of the Yenesei, again rises until it almost reaches the coast near the delta of the Lena. Farther east in Siberia it plunges south again, much more rapidly than it rose in Western Europe, and, passing south of Kamchatka, it embraces the Kurile Islands in the latitude of the Pyrenees. This line is almost exactly parallel with what is known of the southern breeding-ranges of the various Arctic birds under consideration. It is not, therefore, surprising that these birds should breed in Scotland; and there is no reason, Mr. Seebohm concludes, for attempting to explain by any other causes than the ascertained climatic cause, the interesting fact that British ornithologists are able to study the breeding habits of so many species which their Continental fellow-students can only observe by travelling 500 miles or more farther north.

THE Journal of the Society of Arts prints an interesting letter from Mr. T. F. Peppe, on the cultivation of the so-called wild silks of India. Mr. Peppe points out that in many parts of India the jungle consists of the plants on which the tussur worm feeds, and that the supply of labour is practically unlimited. At present the work is carried on only by a few tribes who have been accustomed to it from time immemorial; but nearly all the aboriginal tribes of India might be available, if their services were in demand. The chief obstacle to the rapid development of the industry is the difficulty of procuring seed-cocoons, which have to be sought for in the wild state in the jungles. This difficulty, however, Mr. Peppe thinks, will be gradually overcome, since in every cultivated tract there are always a few cocoons which escape detection and collection, and which add to the number of wild cocoons found in the next brood. The industry is precarious, but there are several crops in the season, and if one fails the others may succeed. Mr. Peppe has cultivated tussur for three years, yet he is not prepared to say how many broods are possible in a year. Each brood so overlaps the succeeding one, that it is very difficult to distinguish one brood from another.

A COURSE of five lectures on "Molecular Forces" will be delivered by Prof. A. W. Rücker, M.A., F.R.S., at the Royal Institution, beginning on Thursday, the 20th inst. The remaining lectures will be delivered on the 27th inst., and on February 3, 10, and 17.

MESSRS. W. WESLEY AND SON have issued the seventy-ninth number of their "Natural History and Scientific Book Circular." The most important part of the Catalogue appears under the heading "Ornithology."

WE have received the "Year-book of Photography and the Topographic News Almanac for 1887," edited by Mr. Thomas Bolas, F.C.S It contains, besides a calendar for the year and lists of photographic societies, a large number of notes and articles likely to be interesting and useful both to beginners in photography and to advanced practitioners.

THE Severn Fishery Board has issued an Almanac for the year 1887, which is intended to show the law as to fishing in the Severn fishery district, and to indicate to water-bailiffs, fishermen, and others interested in fishing, what they may look for in different months of the year. The information on which the statements in the Almanac are based was collected by the Board's officers.

THE seventh volume of the Transactions of the Sanitary Institute of Great Britain, 1885-86, presents a full report of the proceedings of the Congress of the Institute held at Leicester from September 22 to 26, 1885. The papers read at the Congress were divided into three sections—(1) Sanitary Science and Preventive Medicine; (2) Engineering and Architecture; (3) Chemistry, Meteorology, and Geology. Mr. John F. J. Sykes, Honorary Secretary for the first section, recommends that a special day, or part of a day, should be devoted to the consideration of domestic sanitation and ambulance. In both of these subjects ladies take great interest, and Mr. Sykes is of opinion that his suggestion, if adopted, would add immensely to the success of future Congresses.

THE amount of the rainfall at Ben Nevis Observatory during 1886 was 107·85 inches, the greatest monthly fall being 14·57 inches in November, and the least 2·84 inches in February. In 1885 the annual rainfall was (see vol. xxxiii. p. 347) 145·50 inches, the largest monthly fall being 24·33 inches, and the least 4·97 inches, the rainfall of 1886 being thus very much less.

WE understand that complaints have been made to the Fishery Board for Scotland that steam-vessels have been recently prosecuting beam-trawling overnight in the waters closed by the Board's by-law against this mode of fishing. Some time since the Board instituted legal proceedings against parties who had infringed the by-law, some of whom were fined, and they also posted placards at the different harbours and creeks in the prescribed waters giving notice of the terms of the by-law, and it was hoped that the illegal practice would have been thereafter discontinued. The Board's cruiser *Vigilant* has done what she could to protect these waters, but owing to her being a sailing-vessel she cannot do this so effectively as a vessel with steam power. In the circumstances the Board have instructed H.M.S. *Jackal*, at present cruising on the west coast, at once to proceed to the east coast and protect the inclosed areas there, as well as to take a general superintendence of the fisheries. The prescribed waters include the Firth of Forth, St. Andrews Bay, and Aberdeen Bay. The present *Jackal* is a new, powerful, and swift vessel, and is provided with the electric light, which will enable her to sight vessels at a considerable distance on dark nights. The Board's cruiser *Vigilant* will at once proceed to the west coast and take up fishery duty there, assisted by H.M.C. *Daisy* tender.

THE Report of the Swiss Commission for the Reform of Gymnasial Instruction has just been issued. The Commission recommend that the teaching of Latin shall begin in the fifth class, and shall be continued, for five hours weekly, up to the highest class; that instruction in Greek shall depend upon the expressed desire of parents or guardians, and shall begin in the fourth class; and that all scholars who do not learn Greek shall learn either English or Italian. Two spare hours gained by pupils in English or Italian are to be spent in the study of natural science and mathematics.

MR. EDISON, the electrician, of New York, is reported to be seriously ill.

THE additions to the Zoological Society's Gardens during the past week include two Barn Owls (*Strix flammea*) from South Africa, presented by Mr. E. Hume; a Black-headed Gull (*Larus ridibundus*), British, presented by Mr. W. S. Rawlinson; two Eyed Lizards (*Lacerta ocellata*), European, deposited; four Bramblings (*Fringilla montifringilla*), British, purchased.

OUR ASTRONOMICAL COLUMN

THE SIX INNER SATELLITES OF SATURN.—Appendix I. to the volume of Washington Observations for 1883 contains an important memoir by Prof. Asaph Hall on the orbits of the six inner satellites of Saturn. Of these, the two innermost have been known to us about 100 years, but the other four for more than 200. Owing, however, to the difficulty of making accurate observations of them, their orbits were but rough approximations until the publication of Bessel's work on the orbit of Titan, which appeared in vols. ix. and xi. of the *Astronomische Nachrichten*, and from which that value of the mass of Saturn was derived which has been generally used up to the present time in computing the perturbations produced by this planet. Bessel likewise commenced, but did not live to complete, a memoir on the "Theorie des Saturns Systems," of which Prof. Hall justly remarks that it "is still the most comprehensive investigation we have of the differential equations of this system, and of the various forms of the perturbative function arising from the figure of the planet, the ring, the action of the satellites on each other, and the action of the sun." M. Tisserand has shown, however, in a short but important paper, "Sur le mouvement des absides des satellites de Saturne et sur la détermination de la masse de l'anneau," that Bessel's determination of the mass of the ring from the motion of the line of apsides of the orbit of Titan was seriously in error, since he neglected the influence of the figure of the planet. We were, therefore, ignorant of the true value of the mass of the ring, but if the inner satellites moved in orbits which were decidedly eccentric, so that the motions of the lines of apsides could be accurately determined, the mass of the ring and figure of the planet could be deduced. It was therefore a matter of great interest to determine these orbits as accurately as possible; and Prof. Hall therefore undertook the observation of those satellites with the great refractor of the Naval Observatory, Washington. The observations of Titan, given in Prof. Hall's paper, were made at Washington during the eleven years, 1874 (in which year Prof. Newcomb observed the satellite) to 1884. During the years 1875, 1876, and 1877, Prof. Hall observed differences of R.A. and declination of Saturn and Titan at the same time and in the same manner as he observed Iapetus, to which satellite he found the method well adapted. Rhea, Dione, and Tethys were observed by Prof. Newcomb in 1874 and by Prof. Hall in 1875, whilst for Mimas and Enceladus observations extending over the years from 1874 to 1879 have been used. In the reduction of the observations of Rhea, Dione, and Tethys, the observed places have been compared with places computed from the elements for these satellites given by Dr. W. Meyer, of Geneva, and corrections to his elements are deduced therefrom. The corrected orbits show in each case a practically insensible eccentricity, and the observations of Mimas and Enceladus also can be satisfied within the limits of their probable errors by circular elements. Prof. Hall, however, draws attention to the fact that for the three innermost satellites the eccentricity of the orbit, and consequently the position of the line of apsides, cannot be determined with any certainty from the observations at his disposal. Some more accurate method of observation than that of the filar micrometer should be adopted; possibly observing the conjunctions of the satellites with the ends of the ring, the Cassinian division, and with the sides of the ball, might prove more efficient. A heliometer, if one existed of sufficient aperture, would probably furnish the most satisfactory means of all.

The orbits of the five inner satellites being thus sensibly circular, any consideration of the motions of their lines of apsides is placed out of the question. These five satellites also appear to move in the plane of the ring. It is therefore easy to furnish tables of their motions, and Prof. Hall supplies them for the period 1875-1950, together with the elements of the ring, at the close of his paper. For the mass of Saturn, from the motions of Titan, Rhea, Dione, and Tethys, he finds the reciprocal to be $3478·7 \pm 1·10$. The best previous determinations have been as follows:—Bessel 3501·6, Leverrier 3529·6, Meyer 3487·45, and Prof. Hall, from the motion of Iapetus, 3481·3 ± 0·54.

Prof. Hall carefully searched for additional satellites moving in the remarkable gaps between Rhea and Titan, and Hyperion and Iapetus, but without result.

STELLAR PARALLAX.—The second Appendix to the Washington Observations for 1883, contains a second memoir by Prof. Asaph Hall, not less interesting and valuable than the above. It will be remembered that Prof. Hall published a volume in 1882, containing determinations of the parallaxes of Vega and 61 Cygni from observations made by himself with the great 26-inch refractor at the Washington Observatory. Prof. Peters, of Clinton, U.S.A., has since pointed out to Prof. Hall that the temperature correction to his observations had been applied with the wrong sign. Prof. Hall has therefore now reduced his observations afresh, and given a new solution of the equations of condition. For 61 Cygni, Prof. Hall now finds a parallax of 0″·270 ± 0·0101 from 101 observations extending from October 24, 1880, to January 26, 1886. This value is notably smaller than he obtained before, viz. 0″·4783, or than most other investigators have deduced. Thus Sir R. S. Ball had found 0″·4756, Auwers 0″·564, and Struve, Woldstedt, and others values closely according. Prof. Hall appears, however, satisfied with his results, and it should be remembered that Dr. C. A. F. Peters obtained 0″·349 for his absolute value of the parallax, the others being only relative parallaxes. Prof. Hall's value for Vega is also rather small, viz. + 0″·134 ± 0·0055 from 128 observations, but agrees very much better with other modern determinations; Brünnow in 1869 from the same comparison-star, but by measures of distance and position, and not of differences of declination only, having obtained π = 0″·212 ± 0″·0098. Prof. Hall also attacked the parallax of two other stars, 6 (Bode) Cygni, the parallax of which has recently been determined at Dunsink, being one, and the curious star 40 (o^2) Eridani the other. For the former he finds a negative value, whereas Sir R. S. Ball gave π = + 0″·422 ± 0″·054, but only as a "merely provisional" value. The parallax obtained for 40 Eridani, π = + 0″·223 ± 0″·0202 is in fairly close agreement with Dr. Gill's, viz. π = 0″·166. In the early part of this important paper Prof. Hall gives a full discussion, in his usual thorough and painstaking manner, of the value of a revolution of the micrometer-screw employed in the observations.

ASTRONOMICAL PRIZES OF THE ACADEMY OF SCIENCES. The Paris Académie des Sciences have decreed the Lalande Prize to M. O. Backlund for his labours on the motion of Encke's comet; the Valz Prize to M. Bigourdan for his researches on personality in the observation of double stars; and the Damoiseau Prize, for the revision of the theory of the satellites of Jupiter, to M. Souillart, with an *encouragement* to M. Obrecht of a thousand francs from the Damoiseau fund.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 JANUARY 16-22

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 16

Sun rises, 8h. 1m.; souths, 12h. 9m. 58·8s.; sets, 16h. 19m.; decl. on meridian, 20° 56′ S.: Sidereal Time at Sunset, 0h. 2m.

Moon (at Last Quarter) rises, 23h. 47m.*; souths, 5h. 41m.; sets, 11h. 24m.; decl. on meridian, 4° 14′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	7 23	11 13	15 3	23 55 S.
Venus	8 39	12 55	17 11	19 54 S.
Mars	9 4	13 42	18 20	16 24 S.
Jupiter	1 23	6 27	11 31	11 42 S.
Saturn	15 29	23 35	7 41*	22 1 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

Occultations of Stars by the Moon (visible at Greenwich)

Jan.	Star	Mag.	Disap. h. m.	Reap. h. m.	Corresponding angles from vertex to right for inverted image ° °
16	65 Virginis	6	2 5	3 5	61 193
16	66 Virginis	6	2 48	3 57	44 221
16	l^2 Virginis	5	7 44	8 35	44 318

Jan.	h.	
16	21	Mars at least distance from the Sun.
17	3	Jupiter in conjunction with and 3° 40′ south of the Moon.
17	4	Mercury at greatest distance from the Sun.

Variable Stars

Star	R.A. h. m.	Decl. ° ′		h. m.	
U Cephei	0 52·3	81 16 N.	Jan. 16,	23 2	*m*

δ Cephei	22 25·0	57 50 N.	,, 18,	23 0	*M*

M signifies maximum; *m* minimum; m_2 secondary minimum.

Meteor-Showers

Near γ Orionis, R.A. 72°, Decl. 4° N. From Coma Berenices, R.A. 181°, Decl. 35° N.; swift streak-bearing meteors. Near χ Cygni, R.A. 295°, Decl. 53° N.; somewhat slow meteors.

GEOGRAPHICAL NOTES

THE opinions of Dr. Junker, who is now in Cairo, as to the best route by which to reach Emin Pasha do not help us much. Indeed, Dr. Junker does not commit himself further than to suggest that by the shortest route, through Masai Land, there would be difficulties as to food. Not more, we are inclined to think, than by any other route. Mr. Thomson passed through the country at an exceptionally bad time, when the cattle of the Masai were dying by hundreds from disease. The country is one of the richest game regions in Africa, and by any route an expedition must, as far as possible, be independent of local supplies. For an expedition of hundreds of men to attempt to cross the Victoria Nyanza in boats would be extremely hazardous. Meantime it is evident both from what Dr. Junker says and from the letter of Mr. Ashe, who has just returned from Uganda, that Emin Pasha is in an exceedingly perilous condition, and that every week's delay risks his life and the lives of those who are with him, for he has no ammunition. We hear, on good authority, that Mr. Stanley has decided to go by the Masai Land route; if so, it seems a pity that the only white man who has explored this route will not be in the expedition.

IT is said that great administrative changes are about to be made in Russian Central Asia. According to the St. Petersburg Correspondent of the *Times*, the whole system of arbitrary military mixed with native government, formerly considered necessary for high political purposes of further conquest, is to be gradually modified and almost abolished by the introduction of Russian civil administration and justice, and the subordination of the various departments to the Ministers in St. Petersburg. There is a proposal that Turkestan and the new Transcaspian province should be amalgamated, the reason alleged being that they will be closely connected by the Transcaspian railway, which, after passing through Bokhara, will terminate at Tashkend. The Transcaspian province will therefore, it is considered, be nearer to Turkestan than to the Caucasus. The scheme is said to have been suggested by General Rosenbach, the Governor-General at Tashkend. It is opposed by General Shepeleff, Director of the Chancery of the Governor-General of the Caucasus, who is of opinion that it would be highly inconvenient to remove the Transcaspian further from the control of the central Government, and that, if alterations are considered necessary, it would be better to make the newly-acquired territory an independent province.

ACCORDING to the *Novoe Vremya*, the trading caravan lately despatched by the Central Asian Commercial Company Koudrine has passed through Kashgar and entered Tibet. This company is likely to play an important part in Central Asia. It has established permanent agencies at Merv and Askabad and in the Persian cities of Kutchan and Meshed, and now it proposes to do the like in Tibet. It has received from the Ameer of

Bokhara a large tract of land on the banks of the Amu-daria, near the Chardjui station of the Transcaspian Railway, for the cultivation of cotton. In the Transcaspian there seems to be a great district suitable for cotton-growing, and there is a general opinion among the commercial classes of Russia that the development of this industry ought to be steadily encouraged by the Government.

THE *Bollettino* of the Italian Geographical Society for November contains an account of a second expedition by Signor E. Modigliani to Nias, which has proved much more successful than his first visit to that island, reported in NATURE, November 16, 1886, p. 60. His primary object was to discover and ascend the Mount Matsua, 600 metres high, seen by Von Rosenberg from the west coast, and figured on his map as the culminating point of the island. But, although no trace could be found of this mountain, the hitherto unexplored south-western district was traversed from Serombu on the west to Lagundi Bay on the south coast. This district was carefully surveyed, and the explorer succeeded in making rich zoological, botanical, and ethnological collections, most of which have been forwarded to the Natural History Museum of Genoa. They include no less than twenty-six human skulls (fifteen of which were obtained at Hili Horo in exchange for a rifle), about 120 birds, 2000 butterflies, 1500 other insects, monkeys, fishes, reptiles, and plants. The journey was made during the summer of 1886, Signor Modigliani's last communication being dated August 10, and forwarded to Europe from Gunung Sitoli, in the north of Nias, where he was then stationed with the intention of continuing his scientific researches in the island.

ON Tuesday evening last Captain Cameron delivered at the London Institution a lecture on "Urua: its People, Government, and Religion." In closing his lecture Captain Cameron said that Urua would shortly come into great prominence, for lately some of the officers of the Congo Free State had followed the river due east, across the great bend of the Congo, showing that it was a navigable river, and that if followed up it would lead to Kasongo's capital. They were frequently hearing of the London Missionary Society's agents pushing up the new great tributary of the Congo on the south, so there could be little doubt that in a short time the Somami would be followed up to Urua, and that traders, missionaries, and others would soon come into the great kingdom of Urua, where there was a great work before them. However, they would have to bear in mind that they would not have to do with a little chief ruling over 200 or 300 natives, but with a powerful monarch who ruled absolutely over his people, and who would allow of no agreement which had not been approved by him. It was to be hoped that, as Stanley had been successful before, he might be successful in his expedition for the relief of Emin Pasha, and also that those who went into Urua would bring civilisation and peace, and be able to do away with the horrors of the slave trade which obtained there owing to the Portuguese and the Arabs. Urua was rich in many kinds of minerals and other products, and the people were a fine race. When the Europeans came into constant contact with them, if they were wisely managed, there would be a great future for them.

WAR AND BALLOONING[1]

THE object which stimulated the practical invention of the balloon was its use in war. I say practical invention, because in theory the balloon was invented before the experiment of Montgolfier. Theory is ever the soil of practice. The idea of the balloon has its starting-point in the principle of the pressure of fluids elucidated by Archimedes, of Syracuse, 200 years before the Christian era. The discovery of hydrogen gas by Mr. Henry Cavendish, in 1760, led Joseph Black, the Professor of Chemistry at the University of Edinburgh, to suggest in one of his lectures that a weight might be lifted from the ground by attaching to it a sphere of hydrogen gas. A fruitful idea once expressed is rarely lost, however casual its first expression. Some years later, Tiberius Cavallo, an Italian merchant, remembered the remark of Dr. Black, and, in 1782, tested its truth by experiment. He first manufactured some paper bags, which he filled with hydrogen gas: to his disappointment, the subtle gas escaped through the pores of the paper. He then collected the gas in soapy water, and the bubble of gas ascended. A soap-bubble filled with hydrogen was therefore the first balloon. The experiment seems to have been repeated by Cavallo at one of the meetings of the Royal Society, and described in the Transactions of that Society; but neither Cavallo nor his colleague pursued the experiment further, and there was still to be found the peculiar kind of energy that would transform the laboratory experiment into a practical reality. Books are indeed the carriers of thought. It is probably due to a work of Priestley, in which were described those discoveries of Cavallo, and which was translated into French, that Montgolfier, the paper-maker of Annonay, was fired to perform an experiment that is historical. He, as most of you know, filled a paper bag with heated air, the consequence being that the bag rose to the ceiling of the room. Montgolfier was not content with such trifling efforts: a patriotic motive stimulated him to attain greater results—the desire to make the invention of use to France in her wars; and the paper bag of 40 cubic feet capacity was succeeded by one of 680 cubic feet; this, again, by one of 23,000 cubic feet. Montgolfier seemed on the high-road to a brilliant success. There was, however, another brain actively employed in eclipsing the fame of Montgolfier—that of Charles, the Parisian, who realised that heated air would never become a satisfactory method of filling balloons, heated air being three-fourths the weight of the air at the ordinary temperature. He therefore took up the experiments with hydrogen gas where Cavallo had left off. Hydrogen gas being thirteen times lighter than air, its superiority in filling balloons was, to his mind, indisputable. He succeeded in making a material gas-proof, and consequently produced the first practical gas-balloon.

From the efforts of Montgolfier and Charles began the history of ballooning. I do not propose to discuss its general history this evening, with its startling incidents of adventure, nor to enumerate the good service the balloon has rendered to science in the hands of such men as Benedict de Saussure, Robertson, and Glaisher, but to make a few remarks upon its use as an adjunct of war.

By many persons, those who advocate its use in war are looked upon as enthusiasts. With many persons, an enthusiast is synonymous with a fanatic. Now, I agree that enthusiasm is sometimes expended on improper subject-matter—on wild incoherent schemes; but give enthusiasm proper subject-matter, truth, and coherency, and it becomes a noble thing; it is, in fact, the life-blood of science and art. It is, in other words, earnestness of purpose. I think the use of balloons in war is worthy of this earnestness of purpose.

I have to bring before your notice this evening, in particular, a somewhat new departure in balloons, in which electricity is so combined with a captive balloon as to render it valuable for signalling-purposes. Before I describe this special use for balloons in war, which I have had the honour of introducing to the English Government, and for which I hold patents in the principal foreign countries, I will say a few words concerning the general use of balloons in time of war.

The way in which balloons have been chiefly utilised in war is for taking observations of the enemy. In such cases the balloons are captive. As early as 1793 the French Government adopted the use of captive balloons. Such balloons were employed with great success in those wars which the French Goverment carried on soon after the French Revolution. There was a regular company formed, called "Aërostiers," and it seems to me that more practical work with captive balloons was done in actual war at this period than has been accomplished since. It was Napoleon who put an end to their career of usefulness in France, and who closed the Aëronautical School at Meudon.

It is this use of captive balloons for observations that has lately been revived by the English Government, and experiments are frequently carried on at Chatham under a Committee of the Royal Engineers. Notably amongst those who have been prominent in the revival of balloons for war purposes we may mention the names of Major Templer, Major Elsdale, and Lieut. Mackenzie, and the country, I think, has reason to thank these officers for the really good work they have done with the means at their disposal. At the Inventions Exhibition there was an exhibit of balloons in the War Department. Perhaps the more important feature of that exhibit was a balloon made of gold-beater-skin, such as was used in the war in Egypt. Gold-beater-skin is an admirable substance for forming balloons, on account of its lightness and capacity of holding gas.

The free balloon has its use in war as well as the captive one.

[1] A Lecture delivered by Mr. Eric S. Bruce, M.A. Oxon., at the London Institution, on December 28, 1886.

At the siege of Paris this use of balloons was demonstrated most efficiently. At the time when the Parisians found themselves cut off from all means of communication there were but a few balloons in Paris, but the successful escape of some aëronauts in these few was considered encouraging enough to establish an aërial highway involving a more wholesale manufacture of balloons than has ever been undertaken, the disused railway-stations being converted into balloon manufactories and training-schools for aëronauts. During four months 66 balloons left Paris—54 being specially made for the administration of Posts and Telegraphs—160 persons were carried over the Prussian lines, 3,000,000 letters reached their destination, 360 pigeons were taken up, of which, however, only 57 came back, but these latter brought 100,000 messages. These facts show that free balloons are useful in war. The utility of a free balloon would be largely increased if it could be steered against a considerable wind. Attempts have been made to navigate balloons on two principles: (1) by using the various currents of the air; (2) by some kind of mechanical propulsion. I will say just a word or two on each of these heads.

(1) As regards mechanical propulsion. There are some persons who, when they hear any suggestion regarding a steerable balloon, denounce the idea as impossible ever to be accomplished. I think it a wiser course to reserve a definite opinion as to whether such a thing is possible in the future, as the experiments worth anything which have been made in this direction have been few and far between, and it is unwise to draw conclusions on a basis of inadequate facts. I will, however, say this much, that those who have the task in hand have a difficult problem before them, and that the engineer who first steers a balloon against a strong wind by mechanical propulsion will deserve a high place amongst the heroes of science. I will enumerate some of the difficulties in the way of steering a balloon against the wind by mechanical propulsion, and then proceed to give you a short description of some of the latest experiments that have been made.

There is an essential difference of condition between navigating the water and navigating the air. In the former we have a body moving within the limits of two media, air and water. These two media have different densities and elasticities, consequently resistances. In air-navigation the body moves in one medium only, which renders the motion of a paddle-wheel entirely useless in that one medium—a paddle-wheel moving in the air would effect nothing—therefore, the only available means of propulsion in air-navigation is the screw: this cuts into the medium. Now it stands to reason that this medium must be in a state of comparative rest, or else the work of the screw will be overpowered. A moderate wind is sufficient to overpower a strong screw, hence the obstacle to air-navigation by mechanical propulsion. Capt. Renard has recently sent in to the French Academy an account of his experiments with his so-called navigable balloon *La France*, at Meudon. His experiments were decidedly interesting—in fact, they were in advance of anything yet accomplished in balloon guidance, but there has, I think, been a tendency to exaggerate the results obtained. I think anyone who reads carefully the accounts of those experiments which appeared in *La Nature* will see that the old difficulty with the screw still remains. The experiments to which I refer took place in comparatively calm weather. It is said that out of seven performances the balloon returned five times to the place whence it started. This is certainly more than most balloons do. To accomplish this, much care and ingenuity must have been exercised; but on reading the accounts, we find that great care was taken for the selection of that kind of weather that would not make the work of the screw *nil*. A whole month, in fact, had to elapse between the first ascent mentioned and the second, owing to unfitness of weather. On the day of the second experiment the wind blew from the north-north-west from Paris at a velocity of from 3 to 3·50 metres per second, starting from Meudon. The balloon was directed towards Paris at 4.25 p.m. It crossed the railway-line at 4.55, reached the Seine at 5 o'clock; at 5.12 the balloon entered the *enceinte* by Bastion 65. Then the aëronauts decided to go home. The balloon was easily turned, and, aided now by the aërial current, reached the exact spot whence it had started. The journey going had taken 47 minutes, the journey back took 11 minutes. Such experiments as these, to my mind, deserve praise, because they were conducted in a scientific manner, and because some results were attained; although the result of navigating a balloon against a wind of *considerable* power certainly did not come to pass. One must, it seems, still be content with mere bread-crumbs of aërial navigation.

(2) As regards the second means of navigating the air, by a fit selection of those varying currents that are frequently overlying one another blowing in different directions over the same spot. I think a closer and more methodical study of those currents might lead to satisfactory results. Up to the present time but little has been ascertained concerning them. Unfortunately for aëronautical science its Glaishers have been few, its mountebanks numerous. It is true there has always been a difficulty in the way of studying the aërial currents from a balloon, namely, the difficulty of keeping the balloon at a certain elevation. After expending ballast to make the balloon rise to a certain elevation for the sake of reaching a particular current, some change of temperature produced by the sun or clouds will often affect the delicately-balanced machine, and alter its altitude. If it has risen higher, gas must be sacrificed to reach the lower level; if it has descended, more ballast must be expended. In this way gas and ballast, which a celebrated aëronaut has called the "life-blood of the balloon," is quickly exhausted. It is these facts that make the successful experiment carried out by M. Lhoste last August so worthy of note. In his voyage across the Channel he made use of an apparatus which he called a "*flotteur frein*." This acted as a kind of floating anchor or brake. It was a cylindrical iron vessel with a conical air-chamber at the top, 1 metre 60 centimetres in length, 22 centimetres in width, weighing 10 kilogrammes when empty, and 60 kilogrammes when filled with salt water. The *flotteur* was attached to a bar underneath the balloon, on which a small sail was hoisted. The important function of this *flotteur* is, that by its means the same altitude of the balloon can be maintained when the favourable current is once found. By means of this *flotteur* the water itself can be drawn up into a reservoir in the balloon and utilised as ballast, after sunrise, when the expansion of the gas by the heat of the sun's rays would otherwise cause the balloon to shoot upwards. By this method of adjusting the altitude of the balloon, several important observations of the various currents of air about which we know so little might be taken, and it would, I think, be well if Governments organised experiments with these various currents, as well as with elaborate screws worked with power inadequate for the purpose of propelling a balloon against a powerful wind. Perhaps the aërial machine of the future may be directed by utilising in a thoroughly scientific manner these varying currents. In such a system of aërial locomotion perhaps the screw may be used as a kind of makeshift in a dead calm, when a change of level is not desirable, like the oars when there is no wind to fill the sails.

One of the most practical uses of balloons in war is for signalling. The utility of balloon-signalling consists in the elevation obtainable. Any accepted method of signalling may be used in the car of an ordinary captive balloon, *e.g.* flag-signalling or lantern-signalling. But signalling from the car of a balloon necessitates the use of a balloon of considerable size to secure the required lifting-power. This limits the practicability of such a method. About a year and a half ago it occurred to me to so apply electricity to a captive balloon that a method of flashing signals from a balloon is practicable while the operator remains on the ground. Thus the weight of the operator is obviated, and consequently the balloon can be of such a size as to be extremely portable. It is my wish to thoroughly explain to you this method. In the interior of a balloon which is made of a material that is perfectly translucent and filled with hydrogen or coal-gas are placed several incandescent electric lamps. The lamps are in metallic circuit with a source of electricity on the ground. In the circuit on the ground is an apparatus for making and breaking contact rapidly. By varying the duration of the flashes of light in the balloon, it is possible to signal according to the Morse or any other code. To thus place a source of light in the midst of the gas inside a balloon would not have been possible until the development of the electric light. Many persons even now seem to think the proceeding of showing a light inside a balloon a dangerous one. Therefore, before I describe my invention in detail, I will show you a few experiments, after which I think you will realise that the placing of the incandescent lamp inside a balloon is not attended with danger. [Experiment shown.] If I take a jar of hydrogen in my hands, and insert a taper at the mouth, the gas catches fire, but the taper goes out when I thrust it upwards in the jar. You see, hydrogen gas takes fire under certain conditions, but is incapable of itself of supporting combustion. The flame you have seen burning at the mouth of the jar is the effect of the great affinity which exists between the atoms of hydrogen and the atoms of oxygen which, in the atmosphere of the room, borders upon the hydrogen of the jar. Further up in the jar the hydrogen atoms have no oxygen atoms wherewith to combine. Now, it may seem a surprising assertion to make, but it is nevertheless true that one could place a red-hot poker in the body of gas in a balloon without setting fire to it. If I were to ask anyone here so to do, I am sure he would decline, and say the gas would catch fire as he placed the poker in the mouth. That is quite true; and, to perform the experiment successfully, he would have to avoid the borderland altogether. Here is a puzzle to put to your friends:—How to put a red-hot poker into the body of a gas-balloon without setting fire to the gas. Now, I will show you how to do this. [Experiment shown.] Here is a glass globe, through which a continuous stream of coal-gas is passing. You see this must be so, for I have ignited the gas jet at the top of the globe. Now I have stretched a little piece of platinum wire across the terminals of an electric battery, and placed these terminals inside the globe. Now I will cause the electric current to pass through the piece of wire, and it becomes white-hot, and we have this condition of things: a piece of white-hot metal unprotected inside a globe filled with gas. Now, if we were to substitute a balloon for the globe, and have a battery of exceeding power, and if we were to place a poker between the terminals of the battery, the red-hot poker in a balloon would be a *fait accompli*. The incandescent lamps which we place inside the balloon consist of a thin filament of carbon inclosed in a glass globe exhausted to a high degree of air. This filament of carbon is raised to a white heat by the electric current. [Experiment shown.] I have thrown the image of a filament of carbon upon the screen, rendered thus incandescent. On my table I have another globe filled with gas inside, which is our incandescent lamp. This is the condition of things we have in the balloon. [Experiment shown.] Now, some person may say: "Suppose by accident you get an explosive mixture of oxygen and hydrogen inside the balloon, and that this fragile little bulb breaks." Well, if it does break, one lamp will be lost; that will be all the damage done, for the oxygen present will at once destroy the carbon filament. [Experiment shown.] I will show you this experiment by breaking an incandescent lamp in the midst of this inflammable piece of tow; you see, as I break the lamp, the light instantaneously goes out, as the action of the oxygen is to destroy that delicate carbon bridge which you have seen depicted on the screen. Now, one more of this series of experiments. [Experiment shown.] Here is another globe filled with gas; in this I discharge a naked electric spark between two platinum points. I perform this experiment to show you that, even if there were a bad connection in the electric arrangements inside the balloon, there would be no danger of firing the gas. However, in the special form I provide, I obviate all chance of any sparking, so that, in case of the contingency of there being an explosive mixture of oxygen and hydrogen inside the balloon, there would be nothing to determine it. That an electric spark can fire a mixture of hydrogen and oxygen in certain proportions I can show you by producing this respectable electric spark by means of this induction-machine, and then bringing near it a jet of coal-gas. [Experiment shown.]

A convenient size for one of these signalling-balloons is a gas capacity of some 4000 cubic feet, or, if required, they can be made smaller than this. Varnished cambric is a suitable material. I have two separate arrangements for suspending the lamps inside the balloon; the first consists of a holder made like a ladder, the lamps being placed one above the other in multiple arc. Here is this arrangement before you, with the lamps lit up. This arrangement is convenient because of the small breadth of the ladder, which is easily admitted into the neck of the balloon. The ladder arrangement casts a small shadow on the balloon. In my opinion this shadow is of no consequence whatever; but I have an alternative method which obviates the appearance of any shadow altogether. It consists of a ball, from which project lamps at various angles; the arrangement is protected from risk of breakage by a wire framework. [Experiment shown.]

The form of contact-breaker which produces the intermittent flashes of light is in form somewhat like a Morse key. In reality it is essentially different. An ordinary Morse key, such as is used in telegraphy, would not withstand the large currents used to light the lamps. In my latest form of contact-breaker I use carbon-contacts. These can be easily renewed at trifling cost when worn away. [Experiment shown.] I have also on my lecture-table another form of contact-breaker [experiment shown], in which there is a rubbing contact faced with platinum. The leads which convey the electric current to light the lamps must be as light as possible, consistent with the current they have to carry, and [experiment shown] here is a special type of cable I have had manufactured for the purpose. By means of the model balloon before you, I will now show you the action of the key. We will flash the words "A Merry Christmas and Happy New Year to you all." [Experiment shown.] On the switch-board which contains the key I have an arrangement to switch on the lights in the balloon continuously, in this manner, because these portable balloons thus illuminated would be useful for other purposes than for flashing signals, viz. for a preconcerted signal, or as a "point-light" to guide advances or retreat.

The source of electrical power for working the lamps inside the balloon may be varied according to circumstances. It may be: (1) a small dynamo; (2) a storage battery; (3) a primary battery. Each of these three forms of power can be supplied in portable and convenient form. In some cases, where there is a stationary dynamo-machine in close proximity, storage-cells may be conveniently used, as they can be charged from this stationary dynamo, and brought into the field as required. I used storage-cells just now to light up that ladder of lamps and for working the lights in my model balloon. These storage-cells are, you see, arranged at the foot of my lecture-table. A portable way of obtaining power would be, I think, to use a little gas-engine with dynamo combined, such as, by the courtesy of Messrs. Crossley Brothers, I am enabled to show you this afternoon at work. [Experiment shown.] This might be fixed on the waggon, with all the other apparatus connected with the balloon. The engine would be worked by the gas, which is always a necessary adjunct to the balloon. The gas-supply might be a portable apparatus for generating the gas, or else the method of storing gas in steel bottles could be adopted. This has been done successfully by our own Government. At the Inventions Exhibition a bottle of compressed gas was exhibited in the War Department. I now wish to show you how easily gas may be compressed, stored up, and used when wanted. Here is a small bottle of compressed hydrogen, and I will soon transfer the gas from that to this goldbeater-skin balloon, which now rises to the ceiling. [Experiment shown.] There is another method of lighting these balloons—by using a primary battery. There is a very excellent primary battery now in the market, invented by M. Schanschieff. A good primary battery has long been a great desideratum. For some time I have searched to find one that was anything near the mark for electric lighting purposes. This battery which is before you is the best I have had in my hands, and I am applying it to several of my patent arrangements. I am glad to be able to show you one of these batteries in working order. [Experiment shown.] In this comparatively small compass we have 32 cells. The size of each cell is 3½ inches by 2 inches. In the cells we have a single fluid solution—sulphate of mercury acidulated. There is a sample of the sulphur in this bottle. Now, with most single-fluid batteries we have what is technically called polarisation, which means diminution of electric power. Mr. Schanschieff has overcome this polarisation, and in overcoming it he has done a great deal towards the development of electrical appliances. There is one piece of apparatus connected with the balloon worth mentioning. This is the reel for winding the cable. [Experiment shown.] The electric connection is made, you see, as the cable unwinds.

The advantages which I claim for this method of signalling are, briefly: It facilitates night-signalling; it facilitates signalling to long distances; and in places where the ordinary methods would fail to be of any use, such places as hilly and wooded districts, the apparatus is portable and simple; the balloon shows a large body of light. In order that you may realise the use of a balloon in time of war in a place where ordinary signalling would be of no use whatever, I have prepared the illustrations which my assistants will now throw upon the screen. Here we have a mountainous region. There are supposed to be two friendly armies separated by chains of mountains, and wishing to communicate. Now these two armies might be possessed of every other modern appliance for signalling from the ground without being able to make a signal seen by either side. Therefore, in the scene before you, the signallers of one army are depicted as filling the portable signalling-balloon with gas preparatory to the ascent for purposes of signalling. The army on the other side of the mountains has already sent up a similar balloon. The next scene shows a nearer balloon ascended to a certain height. Now the two balloons are about to communicate. You see the flashes of light from the balloon.

Although this invention is not two years old, it has already a short history. It was exhibited in model in the War Department of the Inventions Exhibition, and while on exhibition there the method was referred for Government trial under a Committee of the Royal Engineers at Chatham. During the time the model was being exhibited at South Kensington, some experiments were tried with a balloon of 4000 cubic feet capacity at the Albert Palace. In this balloon were placed six lamps worked to 16 or 20 candle-power. The six lamps took a current of some 9 amperes, and the electromotive force was 24 volts. The source of electric power then used was 25 cells of the Electrical Power Storage Company. During this Exhibition the value of the method for long-distance signalling was well tested, the flashes of light from the balloon being observed as far as Uxbridge, a distance of sixteen miles. This was effected by less than 100 candle-power. I used the same apparatus for the Government trial at Chatham, after which trial I received an order from the War Office to supply some of my apparatus to the Royal Engineers. The system was again tried at Aldershot under the Signalling Department. On the day fixed for the trial there was a snowstorm and a fog, two very unfavourable conditions in a system of signalling, but signals were read and answered from my balloon, in spite of snow and fog, by the signallers stationed some few miles off. As I mentioned the other day at a meeting of the Aëronautical Society, I wish, as the inventor of this system, to see it tried to its utmost capacity, and I purpose to put the system myself shortly to the most rigorous of tests. One of those tests will be, I hope, to signal over the Channel, *i.e.* to send up the balloon on some site on the English coast, probably Dover, and observe whether the balloon can be seen on the French coast. The Channel is by no means the most favourable expanse for signalling, for there are frequent fogs in it to obscure the view. The Channel, however, is a time-honoured and popular measure of distance, and I must repeat here the wish I expressed lately at the meeting of the Aëronautical Society, that, if the flashes of light can be observed over that expanse, I hope the public will look upon the accomplishment, not as a sensational feat, but as showing the practical value of balloon-signalling. Up till lately I have only considered my system as being useful to the army. I think, however, it would be also useful to the navy. I have schemed a method of employing these balloons on board ship. Their greatest use in the navy would be, I think, for coast-signalling—signalling round corners; I have been asked to submit this scheme to the Admiralty, and am preparing to do so. The picture now before you represents its use in the navy on board a ship stationed in a bay, which vessel wishes to communicate with another at the other side of the cliffs which form the bay. It is, as you see, night-time. The ship that is not visible to you sends up the balloon, and now the two balloons commence signalling to each other. [Experiment shown.]

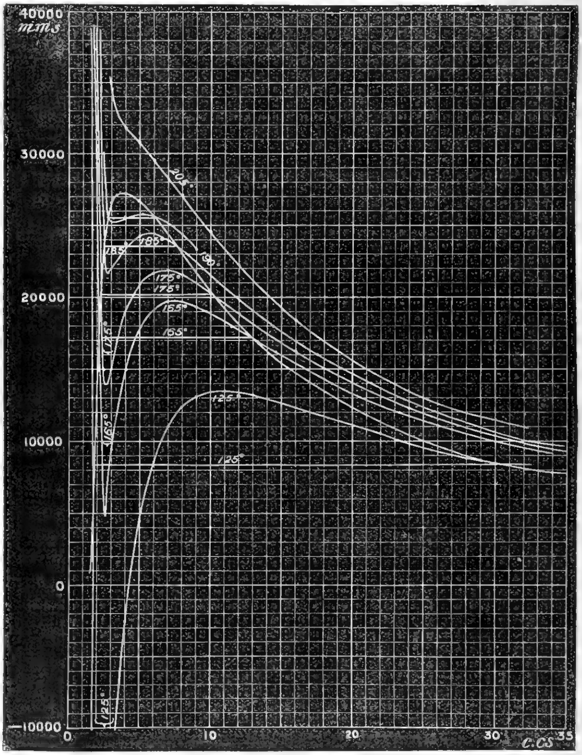
You may perhaps be inclined to think that I ought to mention some one particular occasion in history when this balloon would have been useful. I do not think we need look far back to find one example. But a short while ago there was a brave general shut up in a besieged city with a few followers. Near at hand there were friends ready to help, but ignorant of the immediate necessity of that help. Need I name that general and that city? Now, if from Khartoum there could have arisen such an electric signalling-balloon as I have described to-day, its flashes of light in the skies would have told the tale of the events below—a tale that would have been eagerly read—and perhaps that brave general would then have left Khartoum, a conqueror, and with his life spared for the future service of his country.

SOCIETIES AND ACADEMIES

London

Royal Society, January 6.—"Preliminary Note on the Continuity of the Liquid and Gaseous States of Matter." By William Ramsay, Ph.D., and Sydney Young, D.Sc.

For several years past we have been engaged in an examination of the behaviour of liquids and gases through wide ranges of temperature and pressure. The results of our experiments with ethyl alcohol have recently been published in the *Philosophical*



Transactions; those with acetic acid in the *Transactions* of the Chemical Society; and the Royal Society have in their hands a similar investigation on ether. We have also finished a study of the thermal properties of methyl alcohol.

In consequence of a recent publication by Wroblewski, of which we have seen only the abstract (*Berichte*, 1886, p. 728, abstracts), we deem it advisable to communicate a short notice of an examination in which we are at present engaged.

We find that with the above-mentioned substances, acetic acid excepted, whether they are in the liquid or gaseous state, provided volume be kept constant, a simple relation holds between pressure and temperature. It is $p = bT - a$. This is evidently a simple modification of Boyle's and Gay-Lussac's laws; for at low pressures, where volume is large, the term a approaches and finally equals zero, while b diminishes and finally becomes equal to the value of c, calculated from the ordinary equation,

$$p = \frac{cT}{v}.$$

We have as yet only had time to apply this formula with ethyl ether to the liquid state; and as we are not yet quite certain whether the relation holds for volumes between 4 and 20 c.c. of 1 gramme of ether, we are at present engaged in measurements of volumes and pressures at temperatures between 220° and 280°. Assuming the above relation to be true (and it is at all events a close approximation to truth), it is possible to calculate those portions of isothermals included within the liquid-gas area, and represented in Andrew's diagram by horizontal straight lines. We have calculated a few of these isothermals for ether, and find that the areas above and below the horizontal lines (see woodcut) are equal, when measured by a planimeter.

Reserving a full discussion of the subject until the completion of our experiments, we would here point out the similarity between the equation $p = bt - a$ and those proposed by Clausius and by van der Waals to represent these relations. Clausius's formula is

$$p = \frac{RT}{v - \alpha} - \frac{c}{T(v + \beta)^2},$$

and van der Waals'

$$p = \frac{RT}{v - b} - \frac{a}{v^2}.$$

In these formulæ Clausius's α and c are equivalent to van der Waals' b and a respectively, but R has a different signification.

We find that a somewhat similar formula agrees better with experiment than either of the above; it is

$$p = \frac{RT}{v - b} - \frac{a}{Tv^n},$$

where R, b, and a have the same meaning as in van der Waals' formula. This formula expresses the results of experiments with great accuracy, where the volume of 1 gramme of ether occupies not less than 25 c.c.; but at smaller volumes it ceases to represent the facts.

It is to be noticed that both Clausius's equation and ours introduce T into the denominator of the second term; they evidently differ from our first equation $p = bt - a$, in which a is independent of temperature.

We shall soon be in a position to communicate the results of this investigation, giving full data.

PARIS

Academy of Sciences, January 3.—M. Gosselin, in the chair.—A new method of determining the constant of aberration, by M. Loewy. M. Nyren having shown that none of the methods hitherto adopted are free from systematic error, the author here proposes a process by which all instrumental errors may be avoided. It also eliminates the effects of precession and nutation, and enables the observer to take accurate account of the proper movements of the stars without depending on their approximate values drawn from the catalogues. Lastly, it neutralises the parallactic effect of the stars, dispensing with the numerous experiments needed to determine the instrumental constants. In a word, it calculates directly the phenomenon of aberration itself, without employing any physical constant.—On the relations of the lactiferous vessels with the fibro-vascular system, and on M. J. Vesque's aquiferous apparatus of Calophyllum, by M. A. Trécul. Further researches are described confirming the conclusion already announced by the author regarding the numerous points of contact between the milk-yielding vessels and the various elements of the fibro-vascular system in a large number of plants. It is further shown that the anatomical results described by him in the year 1865 are amply confirmed by M. Vesque's recent note on the aquiferous apparatus of *Calophyllum Calaba*.—Actinometric observations made during the year 1886 at the Montpellier Observatory, by M. A. Crova. The comparative study of these observations (made by M. Houdaille with the author's actinometer) with those of the three previous years confirms the conclusions already arrived at regarding the annual variations of calorific intensity in the solar rays.—Note on the diurnal nutation of the terrestrial globe, by M. Folie. The important consequences of the existence of this phenomenon for geology, astronomy, and geodetics are pointed out, and it is shown that it places beyond doubt the fluid state of the interior of the globe surrounded by a relatively thin outer crust.—Note on the Maclaurin series in the case of a real variable, by M. O. Callandreau.—On a class of differential equations, by M. Emile Picard.—Observations relative to M. P. Serret's recent note on a geometrical theorem, by M. L. Lindelöff. A slight error is pointed out in M. Serret's calculation establishing the correspondence between the lines of curvature in two surfaces with reciprocal vector rays.—Note on the problem of electric distribution, by M. H. Poincaré. The author points out the defective character of the method proposed by MM. Neumann, Schwarz, and Harnack for solving this difficult problem.—Remarks respecting M. Hirn's observations on the flow of gases, by M. Hugoniot. The author returns with regret to this subject, and makes some final remarks on M. Hirn's paradoxical inferences, calling upon him to present a complete statement of his experiments, and of the causes of the errors he professes to have detected in the calculations of the upholders of the kinetic theory.—Note on the specific heats of a perfect gas, by M. Félix Lucas. On theoretic grounds it is argued that the two specific heats of a perfect gas become increasing functions of the temperature.—On the nature of the electric actions in an insulating medium (second communication) by M. A. Vaschy. These problems of electro-statics are brought into general relation with those dealing with the equilibrium of the ether regarded as an elastic body. It is hence inferred that the electric perturbations must be propagated with a uniform velocity, just as a mechanical concussion is propagated in an isotropic body, and this velocity must be that of light.—On electric pressure and on electro-capillary phenomena, by M. P. Duhem.—On a phosphate of hydrated silica, by MM. P. Hautefeuille and J. Margottet. From three analyses made with specimens obtained from different preparations it is shown that the formula of this substance is $SiO_2,2PhO_5,4HO$.—Action of sulphur on ammonia and on some metallic bases in the presence of water, by M. J. B. Senderens. These researches have been carried out in continuation of MM. Senderens and Filhol's studies in connection with the action of sulphur on the saline solutions and on those of soda and potassa.—Note on the maxima vapour tensions of acetate of soda, by M. H. Lescœur. M. Berthelot's conclusion that there is no isomery either between the solid salts or between the diluted solutions of the various acetates of soda, are fully confirmed by the results here obtained by a different process.—On the preparation of the isobutylamines, by M. H. Malbot. It is shown that the three isobutylamines are formed in proportions differing little from each other, the operation constituting an effective method of preparing all these amines simultaneously.—Isomery of the camphols and camphors, by M. Alb. Haller. Here the author deals with the camphols of madder, of Borneo (*Dryobalanops camphora*), and of yellow amber.—Heat of formation of some alcoholates of potassa, by M. de Forcrand. Determinations are given for the heat of formation of the propylate and isobutylate of potassa.—On some points relating to the action of saliva on the grain of starch, by M. Em. Bourquelot.—Experimental researches on mercurial intoxication, by M. Maurice Letulle. The paper deals especially with the paralytic accidents and lesions of the surface nerves caused by this intoxication (chronic hydrargyrism).—Studies of the relations existing between the cranial nerves and the cephalic sympathetic nerve in birds, by M. L. Magnein.—Note on the red and white muscles in the rodents, by M. L. Ranvier.—Observations relative to M. Maupas' recent note on the multiplication of *Leucophrys patula*, by M. Balbiani. It is shown that the peculiar process of fissiparity in these organisms is not such a rare phenomenon as is supposed by M. Maupas.—On the line of development followed by the embryo of bony fishes, by M. L. F. Henneguy. The author's researches confirm the conclusions already arrived at by Kupffer and Œllacher.—On the amphipod crustaceans of the west coast of Brittany, by M. Edouard Chevreux.—Observations relative to M. Viguier's note on the so-called ophite rocks of the Corbières, and to M. Depéret's communication on the Devonian system of the Eastern Pyrenees, by M. A. F. Noguès.—Microscopic examination of the ashes ejected by the Krakatão volcano, by M. Stanislas Meunier.—A critical examination of certain rare minerals, by M. A. Lacroix. Descriptions are given of pterolite, villarsite, grängesite, and gamsigradite.—The death was announced of M. Francisque Fontannes, a distinguished geologist, who was awarded the Academy's Grand Prize for the Physical Sciences in 1883.

BERLIN

Physical Society, November 19, 1886.—Prof. du Bois-Reymond in the chair.—Prof. Liebreich reported on phenomena he had observed in the course of experiments respecting slowly-proceeding chemical reactions. If hydrate of chloral were mixed with an alkaline solution, then was chloroform formed in the shape of a white precipitate. This reaction occurred with all alkaline solutions, only the time varied according to the alkali. While, however, chemical reactions usually ensued in the whole mass of the reacting substances, it was here observed that, when the process of mixture was effected in a test-glass, the uppermost layer remained clear, no turbidity and precipitate formation occurring in it. This layer, which the speaker named the "dead space" ("todter Raum"), was bounded on the upper side by the meniscus of the fluid, and on the lower side by a sharp boundary, having, apparently, a curve opposed to the meniscus. In the capillary space between two glass plates, the dead space displayed itself in very beautiful formation. In horizontal capillary tubes the dead space came into shape at both ends, and in very short capillaries the reaction failed entirely. If from the dead space a little clear fluid were withdrawn and warmed, then did the reaction set in. This showed that in the dead space both fluids were contained, and that it was only their chemical action that was prevented. The dead space showed itself in drops at the edge of the curve. In the capillary space between two menisci was found an external ring, and the middle clear, while reaction occurred only in a small ring. If tubes were closed by a membrane above and below, and filled with the mixture of hydrate of chloral and alkali, then did the dead space appear both at the top and the bottom. The same phenomenon presented itself likewise in animal membranes—for example, in a rabbit's bladder or in an intestine. On the other hand, the dead space was observed neither in a gutta-percha alembic nor in a similar shaped glass retort. The speaker also discussed many other sorts of phenomena in respect of the dead space, both with the fluids already named and with other fluids, demonstrating a large part of them by experiments. In conclusion, he set up the hypothesis that, in the experiments referred to, the chemical reaction was hindered by phenomena of surface-tension, a matter which should be further investigated by additional experiments. A lengthy discussion followed this paper.—Dr. Weinstein then reported on a publication of the Normal Standard of Weights and Measures Commission, "Construction and Repeated Trial of the Principal Standards and the Control Standards" ("Die Herstellung und Wiederkehrende Prüfung der Hauptnormalen und der Controllnormalen"). He brought out that in this publication the idea of weight was officially defined by a mass, the unit of which, the kilogramme, was equal to a cubic decimetre of distilled water at 4° C. The trial of the normal metre of platinum resulted in the establishment of its invariability. The kilogramme of platinum was likewise unchanged, while, on the other hand, the control standard-kilogramme showed a slight increase of weight through oxidation. The examination of the dry measures resulted in showing a considerable diminution of volume, a fact which would have to be ascribed to elastic and thermal after-effects in the material that had been employed for the standard dry measures.

Physiological Society, November 26, 1886.—Prof. du Bois-Reymond in the chair.—After the re-election of the President and Council, in accordance with the statutes of the Society, and the disposal of several business motions, Prof. Falk communicated a case taken from his forensic practice, which was not without physiological interest. A boy was run over by a heavy van and in a few minutes died. A *post-mortem* showed a gaping rupture of the thyroid and of the cricoid cartilage, the entrance of blood into the air-passages—causing death by suffocation—and into the digestive organs. It was, now, a remarkable and physiologically interesting fact that the blood had penetrated not only into the stomach, but into the small intestine, and that, as far as the neighbourhood of the cœcum. Seeing that the abdominal organs were perfectly intact, and the intestines even to a high degree anæmic, the blood must have proceeded from the stomach, and that during the brief time of the agony; for peristaltic movements appeared indeed after death, but in no case in the stomach, and the passage of the contents of the stomach into the intestine was never observed after death had set in. The speaker had, on the other hand, observed very violent swallowing movements as well as increased peristaltic movement in the intestine and stomach in men, and especially in his experiments with animals during the agony of suffocation. In the discussion following, Prof. Zuntz corroborated the fact of the appearance of increased peristaltic movements, and of the abnormally far advance into the intestine of the contents of the stomach during death by suffocation, citing, as he did, some earlier experiments he had not yet published. By way of testing the assertion proceeding from the laboratory of Prof. Ludwig, that acid chyme was normally found in the small intestine of animals, he had instituted experiments in which very soon after death he opened the abdomen of animals, and by a ligature isolated the small intestine from the stomach; he then in every case found the contents of the intestine neutral or alkaline. If on the other hand he poisoned the animals, as in the case of Ludwig's experiments, with curare, then were the contents of the intestine acid. The cause of that, however, was that the animals had died from suffocation, and that the asphyctic blood had induced a lively peristaltic movement of the smooth intestinal muscles not paralysed by curare, and so, therefore, an abnormally rapid propulsion of the contents of the stomach into the small intestine.

THE IMPERIAL INSTITUTE

FOR some time before the scheme of the Prince of Wales's Committee was before the public, there was a feeling that it seemed only too probable that the Imperial Institute would be merely a show-place for the amusement of sight-seers and for the benefit of the showmen. Happily this danger has been averted. Prof. Huxley and others have sounded a note which has now brought the real basis of trade and commerce to the front. It is possible that the mere trade-product view will now give way, so that we may hope the scheme in its final form will be hardly less scientific than that sketched by us in the first of our articles on "Science and the Jubilee" (p. 217). If this anticipation is realised, the Institute will be in every sense a worthy memorial of the fiftieth anniversary of the Queen's reign, and will prove to be of enduring benefit to the whole Empire. There cannot be the slightest doubt as to the necessity for a vital change in our national way of regarding scientific as if they were opposed to industrial methods. There was a time when England, with her monopoly of coal and iron, had practically no competitors in the great markets of the world. By the splendid achievements of her inventors, and by the energy and promptitude of her manufacturers and traders, she had got so far—having such a monopoly of raw material—ahead of her rivals that the foremost place in commerce seemed to belong to her by a sort of natural right. Within the lifetime of the present generation all this has been changed. France, Germany, and other nations gradually became aware that they also, if they pleased, might play a prominent part in the industrial movement, and they set to work in the right way to fit themselves for the new conditions of modern life. Recognising that permanent success could be accomplished only by knowledge and organised effort, they provided for the education both of employer and employed by the establishment of schools, and by every means at their disposal encouraged the development of science. The consequence is that England has been driven from some markets in which she was formerly supreme, and that in others she finds it hard to maintain her ancient predominance. There is not the faintest chance that she will recover the ground she has lost unless she chooses to adapt herself to the altered circumstances by which she is surrounded. In commerce, as in all other relations, it is the fittest that survives; and if raw material fails, then greater knowledge alone can triumph; and the fittest commercial nation is the nation which equips its workers with the most exact knowledge, the most alert intelligence, and the most thorough technical skill. If the Imperial Institute is founded and carried on in accordance with the best and most characteristic ideas of our time, it may make Greater Britain greater yet, if it helps to bring British industry under the dominion of the scientific spirit; and to secure for it this magnificent position ought unquestionably to be the aim of all who undertake to press its claims on the attention of the public.

This aspect of the subject was kept prominently in view by all the principal speakers at the meetings in St. James's Palace and the Mansion House last week. The Prince of Wales laid the strongest emphasis on the fact that, in all parts of the civilised world, commerce and manufactures have been profoundly affected by the progress of science. "I have, on more than one occasion," he said, "expressed my own views, founded upon those so often enunciated by my lamented father, that it is of the greatest importance to do everything within our power to advance the knowledge, as well as the practical skill, of the productive classes of the Empire. I therefore commend to you, as the leading idea I entertain, that the Institute should be regarded as a centre for extending knowledge in relation to the industrial resources and commerce of the Queen's dominions. With this view it should be in constant touch, not only with the chief manufacturing districts of this country, but also with all the colonies and India. Such objects are large in their scope, and must necessarily be so, if this Institute is worthily to represent the unity of the Empire."

Prof. Huxley spoke at the Mansion House and, of all the speeches delivered there, his was the most striking. As the present needs of the nation, and how an Imperial Institute might be made to help us, are never likely to be more lucidly or more impressively stated, it seems to us that we shall do our readers good service by printing the speech in full. Seconding the resolution proposed by Lord Rothschild, "That this meeting pledges itself to take all practicable steps to assist in the formation of the Imperial Institute, and to support it when brought into existence," Prof. Huxley said:—

"He wished to state, very briefly, his opinion of the value of the proposed Institute from the point of view of a man of science. The epoch coincident with Her Majesty's reign was remarkable above all corresponding periods of human history that he knew anything about for two peculiarities. One was the enormous development of industry, and the other was the no less remarkable and prodigious development of physical science, which two developments, indeed, had gone hand in hand. The opinion which he was now expressing was not one formed *ad hoc* for the purpose of this meeting. It was one which he expressed two or three years ago when taking leave of the Royal Society. It was a matter which was perfectly obvious to any person who had paid attention either to the history of science or to the history of industry, that there had been nothing, not only in any period of fifty years, but in any century, in the slightest degree comparable with the magnitude and the importance of the growth of those two branches of human activity which had taken place since 1837. His memory went back far enough to call to mind with great vividness a period when industry, or, at least, the chiefs and the leaders of industry, looked very much askance at science. The practical man then prided himself on caring nothing for it, and made it a point to disbelieve that any advantage to industry could be gained by the growth of what he was pleased to call abstract and theoretic knowledge. But within the last thirty years more particularly that state of things had entirely changed. There began in the first place a slight flirtation between science and industry, and that flirtation had grown into an intimacy, he might almost say courtship, until those who watched the signs of the times saw that it was high time that the young people married and set up an establishment for themselves. This great scheme, from his point of view, was the public and ceremonial marriage of science and industry. It was the recognition on the part of those persons who were best able to judge of what were the wants of the industry of the time, that, if they were to be developed in a way proportionate to their importance, they must be developed by scientific methods and by the help of a thoroughly scientific organisation. A great distinction was commonly drawn by some philosophic friends of his between what they called militarism and what they called industrialism, very much to the advantage of the latter. He by no means disputed that position; but he would ask any one who was cognisant of the facts of the case, who had paid attention to what was meant by modern industry pursued by the methods now followed, whether, after all, it was not war under the forms of peace? It was perfectly true that the industrial warfare was followed by results far more refined in their character than those which followed in the track of military warfare. It did not break heads and shed blood, but it starved. The man who succeeded in the war of competition and the nation which succeeded in the war of competition beat their opponents by his starvation. It was a hard thing to say, but the plain simple fact of the case was that industrial competition among the peoples of the world at the present time was warfare which must be carried on by the means of warfare. In what respect did modern warfare differ from ancient warfare? It differed because it had allied itself with science, because it trusted in knowledge, organisation, and discipline, and not in mere physical strength and numbers, because it took advantage of every scientific discovery by which the weapons of offence and defence could be perfected, and because it required the highest possible information on the part of those who were engaged in that warfare; and if the peaceful warfare of industrialism was to succeed it must follow the same methods. The operations of the leaders of industry must be organised; they must call to their aid, as military leaders were doing, every possible help which was to be gathered from science. They all knew what help science was already giving to industry; it would not do to remain contented with this accidental aid, but those who conducted industrial operations should be trained and disciplined in those different branches of human knowledge which dealt with the needs and wants of nations and with the distribution of commodities. This country had dropped astern in the race for want of that education which was obtained elsewhere in the highest branches of industry and commerce. It had dropped astern in the race for want of instruction in technical education which was given elsewhere to the artisan; and if they desired to keep up that industrial predominance which was the foundation of the Empire, and which, if it failed, would cause the whole fabric of the State to crumble—if they desired to see want and pauperism less common than unhappily they were at present, they must remember that one of the chief means of diminishing those evils was the organisation of industry in the manner in which they understood organisation in science, that they must strain every nerve to train the intelligence that served industry to its highest point, and to keep the industrial products of England at the head of the markets of the world. He looked, therefore, on the Institute as the first formal recognition of this great fact—that our people were becoming alive to the necessity of organisation of industry and the improvement of industrial knowledge. It was on that ground that he supported the proposition. It appeared to him that it would be a worthy and fitting memorial of Her Majesty's reign, if they created an institution which permanently represented that which was the great and characteristic feature of the period, that which would mark the Victorian epoch in history as the epochs of Augustus and Pericles had been marked. An Institute having such objects and purposes as had been described appeared to him to be a monument not only more lasting than brass but one which for centuries to come would hold before the people an image of the objects after which they had to strive, if they desired to organise their activities in such a manner as would lead to their perennial welfare."

This admirable statement by Prof. Huxley it is to be hoped will be read by everybody interested in the welfare of Greater Britain. It will not be enough, however, to see that the army of peace is alone organised within one Institute only, however Imperial it may be.

Our chief want now is knowledge in high places. We do not forget that in our present Prime Minister we have a patient student of science, and one who knows the need of it for the country. But there are a thousand ways in which the ignorance, or rather let us say the want of scientific instruction and of appreciation of the fact that a modern State can only be great on account of its commerce and of its superiority in all international relations, and that greatness in these directions depends upon *knowledge*, is doing this country great harm.

We are not without signs that this also is being recognised. The *Times*, in a remarkable leading article the other day, pointing out the importance of meteorology—and the moral it draws would have been equally true of any other branch of knowledge—writes as follows:—

"Meteorology is a science of great practical importance and of great speculative interest, which is pursued in this country under considerable disadvantages. The Atlantic starves it on one side, and the Treasury on the other. It exists within an area of permanent depression. The Government does dole out something for its support, but it takes a large part of it back in the shape of telegrams. While the Atlantic curtails our horizontal information of the condition of the atmosphere, Nature has given us mountains which offer valuable opportunities for vertical investigation. A few earnest men of science and public-spirited citizens have set up an observatory on Ben Nevis at a cost of more than five thousand pounds, and, beyond allowing twopence in the shilling upon telegrams despatched from the top, the Government, we believe, does nothing for its support. It even charges a heavy rent for the telegraph-wire. This nation thinks nothing of wasting, by improvident method, in the building of a single ironclad as much money as would maintain all our scientific establishments for a decade. But while there is the most indefensible squandering of public money at the War Office and the Admiralty, there is the meanest parsimony towards science and scientific education—the only things that, as Prof. Huxley pointed out the other day, can save us from being crushed in the fierce competition of peace, which kills as surely as that of war. The Treasury knows in a vague sort of way what an ironclad is, but we doubt whether there are three men in the department who could give an intelligent definition of physics."

Assuming that the *Times*' estimate of the knowledge available at the Treasury is exact, our point is that it is the system and not the individuals who should bear the blame. Nor is the Treasury the only department in which a knowledge of science is imperative, or in which successive Ministries have taken no action to provide it.

It is well that all these questions should now be raised, and the more questions of this order are raised by the Institute movement the better for us will it be.

THE BLASTOIDEA

Catalogue of the Blastoidea in the Geological Department of the British Museum (Natural History); with an Account of the Morphology and Systematic Position of the Group, and a Revision of the Genera and Species. By Robert Etheridge, Jun., and P. Herbert Carpenter, D.Sc., F.R.S. Illustrated by 20 Lithographic Plates, &c. (London: Printed by Order of the Trustees, 1886.)

THIS important memoir is in all but in name a monograph of the interesting group of extinct Echinoderms first called Blastoidea by Thomas Say in 1825. It originated, the authors tell us, some seven years ago, in a desire to investigate the structure and relationships of this group by the light of the recent advances made in our knowledge of their living representatives.

Echinoderm structure owes much to the genius and labours of Johannes Müller, and a knowledge of the results of his inquiries largely influenced Prof. F. Roemer in preparing his classical work on the Blastoidea. Recent investigations have added enormously to our knowledge of the structure of the Stalked Echinoderms, so that a renewed morphological examination of their extinct allies was in every way desirable, and this we have now before us. The authors were indebted for much kindly aid in the examination of specimens to a whole host of friends, among whom it seems desirable to mention more especially Mr. Wachsmuth, who sent from America a selected series of forms from his fine collection of American Blastoidea, thus enabling the authors to form their own views on many points of structure. He also supplied them with recent information as to the progress of his own investigations among the American species.

The memoir begins with a chapter on the bibliographical history of the group, commencing with the paper by Say in the Journal of the Philadelphia Academy of Natural Science for 1885. Roemer's monograph appeared in 1852. Billings, in 1869, published a series of important memoirs, in which he suggested that the remarkable lamellar tubes beneath and between the ambulacra appeared to have served the function of respiration, and designated them as "hydrospires;" the summit openings in connection with them were called "spiracles." Wachsmuth's valuable contributions commenced in 1877, while in 1882 the present authors began a series of memoirs, which have now culminated in the present work. A second chapter treats of the Stem and Calyx. The stem of the Blastoidea would appear to be but little known, since individuals in which the stem remains attached to the calyx are rarely found. Mr. Wachsmuth has a slab of Pentremites, in which three specimens have stems of between 5 and 8 inches in length, and the best preserved stem examined by the authors is figured as occurring beneath the calyx of *Granatocrinus norwoodi*, where it is seen to consist of some small thin discoidal joints, which are so little characteristic, that if found isolated it could not be certainly said whether they belonged to a Blastoid or a Crinoid. Though all the Blastoids may have had stems in their early stages, some appear to have had no stem in their adult state. It will be remembered that the adult Comatula shows no trace whatever of having at one time been a stalked form. The calyx is described at great length and with great clearness, and the views of Wachsmuth and others are criticised. Chapter III. is devoted to the study of the Ambulacra, and the fourth chapter to the Summit Plates. These latter were first discovered by Owen and Shumard (1850) forming a conical covering of small plates over the oral and ovarial apertures on a specimen of *Pentremites godoni*. With the exception of Hambach, no recent palæontologist disputes that these plates are an integral part of the organisation of a Blastoid. The chapter on the Hydrospires and Spiracles is full of interest. The former can in no way be regarded as a respiratory portion of the ambulacral system, while the analogy of recent Crinoids goes to show that the ambulacral groove of the Blastoids was a ciliated food-groove, and that it was not occupied by any portion of the generative system; but the authors adopt Ludwig's comparison of the marsupial pouches (genital bursæ) of Ophiurids with the Blastoid hydrospires. The zoological position of the Blastoids is still regarded as a subject of discussion, though it would seem that Say's opinion is correct, and that the Blastoidea may be regarded as a group intermediate between the Crinoidea and Echinoidea. As to the distribution in time, there is no certain evidence of the existence of true Blastoidea anterior to the Upper Silurian period, and it is curious that all the known species of this period are confined to North American strata. The Devonian rocks of the British Islands have yielded but imperfect traces of them. The Lower Devonian rocks in France and in Belgium have each yielded a single Blastoid, but the great centre of their development in Europe during this geological period was in the north of Spain. In North America they were, on the contrary, largely represented, both in generic and specific forms. Regarding the Blastoids of the Devonian system from a general point of view, the number of genera was largely increased at the close of the Silurian period, and all the families are to be found represented in the Devonian period. Pentremites, which is the type form of the class, did not make its appearance until the Devonian. The Carboniferous rocks of the British Islands are rich in Blastoid forms, which are also to be found in Belgium, and were well developed in the sub-Carboniferous rocks of North America. No Blastoid is common to America and Europe, and in Europe the range of specific forms is very limited, though one species is found common to the Devonian of Spain and Germany, and one to the Carboniferous rocks of Britain and Belgium.

A most useful stratigraphical list of all known species, arranged geographically, is given, and then follows the descriptions of the species, to which it is not needful to allude further than to state that the greatest care has been taken, not only with the diagnoses, but with the synonyms and the distribution. A copious index and twenty beautifully executed plates complete the volume. Some sixteen of the plates were drawn on stone by the aid of a grant from the Government Grant Fund of the Royal Society, and, with the approval of the Council, and certainly to the advancement of science, were transferred to the Trustees of the British Museum, by whose order this "Catalogue" has been published.

TEA-PLANTING IN CEYLON

The Tea-Planter's Manual. By T. C. Owen. Pp. 162, with Coloured Lithographed Plates of an Iron and a Wood and Stone Tea Factory drawn to scale. (Colombo, Ceylon: A. M. and J. Ferguson, 1886)

EIGHT years ago, on account of the depression in the coffee industry of Ceylon, the prospects of the colony were of a sufficiently gloomy character. A great improvement has, however, been effected by the partial substitution of tea and cinchona for coffee, and by the general attention given to cacao, cardamoms, and other subsidiary subjects. Ceylon has also been fortunate in possessing a practical scientific institution in the Botanical Gardens of the colony; and its local press is enterprising and well-informed.

It is well to mention here that the excellent growth made by tea plants at the Perideniya and Hakgala Gardens fully justified the advocacy of tea-planting in Ceylon by the late Dr. Thwaites in his Annual Reports, while it is also due to the Colonial Office to state that through Lord Blachford it warmly supported the introduction of Assam tea plants into Ceylon in 1867. In 1877 Ceylon tea in commercial samples was submitted, through the Royal Gardens, Kew, to the Indian Committee of the Society of Arts, and the Report of this Committee clearly foreshadowed the high place which Ceylon tea has since taken in the London market.

The present manual is one of a series issued by the *Ceylon Observer* press, and is intended to be a complete hand-book to all the multifarious duties of a successful tea-planter. Colonel Money's "Essay," and the "Tea-Planter's Vade Mecum," both publications having special reference to the circumstances of Indian gardens, have hitherto been the only books on the subject.

As stated in the preface, Mr. Owen's manual "is more a compilation of the opinions of others and the results they have arrived at than an original work." The very valuable notes of one of the earliest and most successful of Ceylon tea-planters, Mr. Armstrong, of Rookwood, form an important portion of the book. The compiler wisely avoids an extended disquisition on the original home of the tea plant and on the question whether the "Assam tea tree" and the "China bush" are specifically distinct. In the latest works on the subject they are both included under *Camellia theifera*, Griff. There is no doubt that the Assam tea tree—for in a wild state it often reaches 40 to 50 feet in height—is indigenous to the mountainous district lying between South-Western China and the River Brahmaputra. It is probable also, although not clearly proved, that the China tea plant—of a somewhat shrubby habit—is derived from the same stock; although, as we now know, it was greatly altered by persistent cultivation for several centuries in a soil and climate different from those of its original home. The China tea plant has been found wild in no part of China. Under cultivation in Ceylon the Assam variety is suited to the plains, a hybrid form is sought for mid-elevations, while the China variety is useful only for the highest elevations up to 6000 and 7000 feet. Mr. Owen recommends that for all new plantations the best "jat" of Assam or hybrid plants should be obtained, as "no amount of care or skill will make up for a bad class of plant put into the garden at the outset." To a beginner in Ceylon, or to a planter in any other country, unacquainted with the particular methods pursued on Ceylon estates, the book would prove at first somewhat perplexing. Too much knowledge is assumed on the part of the reader as regards the important questions involved in the selection of land, while as regards the details of cultivation the particular "fads" and "fancies" of individual planters are too largely dwelt upon. It would have been more to the purpose to present a clear and simple statement of the first principles upon which the growth and culture of the tea plant, as a plant, should be based, in order to produce the best results. As regards the details of the manufacture of tea, quoting authorities is no doubt the best course, for the process of manufacture consists of a series of purely empirical operations, and a statement of principles alone would not meet the case. After discussing selection of land (Chap. I.), varieties of the tea plant (Chap. II.), seed and nurseries (Chap. III.), lining, holing, and planting (Chap. IV.), field cultivation (Chap. V.), topping and pruning (Chap. VI.), plucking (Chap. VII.), and manufacture (Chap. VIII.), the writer devotes the remainder of the book to buildings and machinery (with plans), and to statistical returns connected with yield and cost of production.

The rapid progress made by the tea industry in Ceylon is exemplified by the fact that, while in 1878 only 282 pounds of tea were exported. during the past year (1886) the exports reached over 7,000,000 pounds. The probable exports in 1887 are placed at 12,000,000 pounds, while in 1888 they are expected to reach 30,000,000 pounds. So far, the price of Ceylon tea has maintained a slight advantage over Indian teas—the average price during 1885 being 1*s.* $3\frac{1}{4}$*d.* per pound for Ceylon tea, as against 1*s.* $1\frac{1}{4}$*d.* for Indian teas. The combined effect of large shipments of Indian and Ceylon teas will no doubt lead in time to a displacement of much that now comes from China. And while the general character of tea obtainable in European markets will improve, there obviously must come a fall in prices for which both Indian and Ceylon tea-planters must be fully prepared. At the Colonial and Indian Exhibition, thanks to the energy of Mr. J. L. Shand, Ceylon tea was admirably brought before the English public. Tea from Natal, Fiji, and a small sample from Jamaica were also shown; but the tea from Fiji possessed such special qualities that we shall probably hear more of this promising article.

To return to the subject of this notice, the "Tea-Planter's Manual" is a useful summary of the knowledge gained respecting tea-planting in Ceylon, and it embodies much valuable information for the use of practical planters. What fault there is to be found is not with the book itself, but with the system of cultivation it inculcates —a system which unfortunately appears to be adopted in the treatment of most tropical economic plants by European planters. These plants are treated too purely as so many "rupee-making" machines. Too little attention is given to the characteristics and habits of the plants as living subjects, and too much to the details of an unsympathetic and essentially artificial system, already proved in Ceylon to be unsuited to the coffee plant, but into which there is now a strong tendency to force the tea plant. As there are diversities of soils and climates, so there are also diversities of industrial plants exactly suited to them. Where all such considerations are ignored, there is danger both to the plants and the planter; and this danger ought in the present case to be avoided. D. M.

GEOMETRY

The Elements of Euclid. Books I.–VI. and part of Books XI. and XII. By H. Deighton. (Cambridge: Deighton, Bell, and Co., 1886.)

Euclid Revised. Book I. with Additional Propositions and Exercises. Edited by R. C. J. Nixon. (Oxford: Clarendon Press, 1886.)

Euclid Revised. Books I. and II. (Same Editor and Publishers.)

First Lessons in Geometry, for the Use of Technical, Middle, and High Schools. By B. Hanumanta Rau. (Madras: Addison and Co., 1885.)

The Origins of Geometry. By Horace Lamb, F.R.S. (Manchester: Cornish, 1886.)

THE author of the first of these books attempts to "give a translation of the Greek text of a somewhat more modern form than the mere verbal ones [what does he mean?] in general use; and, whilst strictly adhering to Euclid's methods, to render his reasoning as clearly and concisely as possible." Hence our presentment of the title-page is supplemented in the original work by the words "newly translated from the Greek text with supplementary propositions, chapters on modern geometry, and numerous exercises." It will be evident that this is Euclid pure and, as far as the author is able to render it, unadulterated; there is no *revision* here such as Mr. Nixon provides for the reader. Mr. Deighton has, however, studied the "Syllabus" (of the A.I.G.T.) and has here and there introduced, with fitting acknowledgment, extracts from it. Further, the author is evidently actuated by the same motives as those which lead the Association to attach so much weight to the solution of geometrical problems as evidence of a student's grasp of the text. A strong feature is the large number of exercises (1419 in all, besides worked out examples), especially of an elementary character, in close proximity to the propositions upon which their solution depends. At the end of the first book are given the enunciations of several propositions which certainly should be mastered by anyone who wishes to gain a sound acquaintance with elementary geometry. Following, it may be, the example of other recent text-books, an excellent collection of the most important propositions on the radical axis, poles and polars, harmonic proportion and centres of similitude are given; there is also a chapter on transversals. The selection of exercises is not confined to Cambridge papers, but levies have been made on the well-known works of Catalán, Rouché, de Comberousse, and Spieker. There are also remarks on plane loci and on the solution of geometrical questions. The letterpress is clear, and the figures are in the main distinctly and carefully drawn, but several monstrosities appear in the third book, as of old, and the drawings on pp. 115, 153, 186 are incorrect as to relative measurements. Perhaps when Mr. Nixon has examined the present book he will modify a statement in his preface (p. vii., we refer to the work reviewed in these columns, vol. xxxiv. p. 50, by R. B. H.) to the effect that "there does not exist a modern edition which gives *Euclid pure and simple*."

The second and third books are the corresponding portions of the larger work referred to above, reprinted page for page, with the addition of an appendix, in which are given proofs of omitted propositions, and also of i. 5 and of i. 8 as a deduction from i. 7. "This addition is made at the request of several teachers. It is of course a concession to the omnipotent examiner; and, as such, is made with much reluctance." One can only regret that a writer who has taken up so advanced a position should have yielded on this point.

The fourth book is interesting as giving evidence of how a modern movement has taken hold of able mathematical teachers of the mild Hindoo. Mr. Rau candidly repudiates all claim to originality for his matter, as in its compilation he has consulted the best English and French text-books both for pure as well as for practical geometry. "If 'Euclid's Elements' is unsuited for beginners who study it in their own native tongue, how much more so should it be in this country, where it is taught in classes consisting generally of lads between ten and twelve, before they have had time to master the difficulties of a foreign language, and before too, I may add, they can benefit by its rigorous logic. The result, as may be anticipated, has been highly prejudicial to the study of geometry and of mathematics in general. With a view, if possible, to remedy the evil, of which I had become painfully conscious in the course of my several years' experience as a mathematical teacher in schools and colleges, I had long been anxious to attempt a departure from the established route." The work consists of the notes he drew up for the pupil-teachers and students under his charge. "My success in the experiment is my justification for publishing this little volume." The figures are roughly drawn, and the cover is a paper one, but the contents are carefully arranged, and furnish a very fair amount of geometrical information for the class aimed at all the propositions being looked at with an eye to their practical utility. Such a class should know how to hold an object "in an oblique position, not permitting it to retrograde to the perpendicular."

"The Origins of Geometry" is an address delivered at the opening of the Owens College session, October 5, 1886. The Professor of Mathematics casts "a rapid glance over the early history of our science, more especially of that branch of it which was first cultivated with success, geometry." Taking Hankel as his guide, he glances rapidly at matters of which Dr. Allman has treated in much fuller detail; he then treats of what has proved "the most formidable obstacle to the further progress of Greek mathematics, the divorce between geometry on the one hand, and arithmetic and algebra on the other. This had its origin in the discovery of incommensurable magnitudes by Pythagoras and his successors." He, by the way, notes that "the greatest advances in mathematics have been made by men whose interest in the subject was of a speculative kind." The address winds up with the question, "What is likely to be the relation of mathematics to the science of the future?" Prof. Lamb answers this question only as regards physical science, and his answer is "contained in that to another question, What is the object of the physical sciences?" The whole concludes with words of the late Prof. H. Smith on the function of mathematics in education.

ACOUSTICS

Hand-book of Acoustics. By T. E. Harris, B.Sc., Lecturer on Acoustics at the Tonic Sol-fa College. (London: J. Curwen and Sons.)

A FEW years ago some wiseacre had the temerity to propound the idea that the scientific and historical data on which music is founded have no bearing on music itself, and need form no part of the knowledge to be acquired by a musician. It is quite true that a man may get through life very comfortably as a singer, a fiddler, or a pianoforte-player, without ever having heard of sound-waves or of the Greek modes; but as regards a knowledge of music in a higher sense the idea is absurdly untrue. The moment we approach the *theory* of music we find the scientific and historical elements confront us at every step, and all attempts to form an intelligible explanation of musical structure without reference to them have been, and must be, failures. In fact, no rational theory of music can exist unless founded on such a basis. This fact is now pretty generally acknowledged by those who have to do with musical education. All examining bodies of any weight require an acquaintance with the data referred to, and all well-constituted courses of teaching include them.

The book now before us is a remarkable instance of this. The Tonic Sol-fa movement is what we may call ultra-practical: its supporters aim at teaching music to the great masses of the people, and their system is purposely contrived to facilitate its practical acquirement, and to bring it down to the proverbial "meanest capacity." Yet the Tonic Sol-fa authorities think it right to have a Lecturer on Acoustics, and to publish a hand-book of the science for the use of their millions of pupils. This is certainly about the severest reproof that could be given to the foolish "practical" notion that would exclude intellectual topics from musical study.

There is not much to say about the book itself. It is an unpretending compilation of the most important facts of the science, gathered from various authentic sources, intelligently stated, and without any crotchetiness or affectation of originality. The peculiar feature, of course, is that the musical illustrations are, wherever possible, given in the Tonic Sol-fa notation. Perhaps, in the 286 closely-printed pages, there is more elaboration of detail than the students may care for; but this is to a certain extent counterbalanced by a condensed summary being added at the end of each chapter.

It would have been an advantage if more copious and complete references had been given to other and more original works, from which the matter has been taken. It is, or should be, one of the most important objects of a "hand"-book to enable students, if they desire it, to put more complete treatises on their study-table. There is no date either on the title or in the preface—a very bad habit of music publishers.

OUR BOOK SHELF

Old or New Chemistry: Which is Fittest for Survival? By Samuel Phillips, F.C.S. (London: Wertheimer, Lea, & Co., 1886.)

THIS small book is a collection of essays more or less bearing on the subject indicated by the title, and may perhaps be also described as a sort of protest against a grievance. The elevating and spurring effect of the possession of a grievance is well known, and it must be admitted that in this case it has, apparently at least, contributed to the production of a very entertaining little book, which will no doubt, as it is intended, "wake up" chemists generally to a clear perception of their absurd and useless theories of chemical constitution.

It is, however, doubtful whether the book will really do anything to forward the science of which the author professes to be such an ardent lover. As to Avogadro's law and the laws known as Dulong and Pettit's, however scanty a basis they may have in experimental facts, they have been useful, and will be until they are supplanted by wider-reaching theories. It is exactly here that the author seems to be too conservative. We not only want more facts—as many facts as we can get—but we want theories as well, if they will only again lead to new facts. And, moreover, what is wanted in this country is for chemists to *work*. There is no lack of problems waiting to be solved.

What we do not want is any further multiplication of "fads." Nothing is gained by writing "Ph" for C_6H_5, and the "equivalent symbol" for "etholo-aceto-acetic acid," viz.,

$$\left.\begin{matrix}432\\432\\45\end{matrix}\right\} 1294, \text{O.HO},$$

at page 19, is no advance but retrogression.

Lectures and Essays. By the late W. K. Clifford, F.R.S. Edited by Leslie Stephen and Frederick Pollock. With an Introduction by F. Pollock. Second Edition. (London: Macmillan and Co., 1886.)

THIS collection of lectures and essays is already so well known that it is now necessary only to note the fact that a second edition has appeared. Two essays have been omitted as being rather mathematical than philosophical, namely, those on "Types of Compound Statement" and on "Instruments used in Measurement." They have found a more fitting place in the volume of "Mathematical Papers" published in 1882. The admirable biographical Introduction by Mr. Pollock has been revised, and some additions and omissions have been made in the extracts there given.

Lives of the Electricians. By William T. Jeans. (London: Whitaker and Co., 1886.)

AN extremely well-compiled and interesting book; but why did the author commence with the life of a living professor, who is not an electrician? Faraday, as the brightest electrical light of this or any other age, should have headed the series. The author has a rich store of names to draw upon—Gilbert, Coulomb, Arago, Snow Harris, Franklin, Cavendish, Galvani, Volta, Henry Davy, Ronalds, Oersted, Ampère, De la Rive, Ohm, Schilling, Gauss, Weber, Daniell, Crosse, Steinheil—without trenching on living celebrities. The work is very impartially written. The life of Morse might have been written by an enthusiastic American, while Wheatstone's friends cannot complain of the eulogy of their hero.

Some statements want revision. The inauguration of the cable system can scarcely be fairly narrated without mention of Messrs. Crampton and Wollaston. Varley's long artificial cable and great experiment shown at the Royal Institution are accredited to Prof. Tyndall (p. 95). The statement attributed to Sir Robert Inglis (p. 285) that in 1847 England was behind America must surely be wrong. The Electric Telegraph Company in England was then in full swing.

As this is the jubilee year of the telegraph in England, it is well to be reminded that Cooke and Wheatstone made their first practical and successful trial on July 25, 1837, between Euston and Camden, while Morse did not file his *caveat* (*i.e.* did not apply for his patent) until October 5 of the same year.

We wish the book every success, and shall be glad to see further instalments.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Normal School of Science and Royal School of Mines

I AM directed to request that you will be so good as to allow me to state, through the medium of your columns, that the number of applications for admission to the Normal School of Science and Royal School of Mines at South Kensington, at the commencement of the present session, having been considerably in excess of the accommodation which the School can afford, it has become necessary to adopt some process of selection for the future. Hereafter, applications for admission should be sent to the Registrar of the School before the end of May, accompanied by a statement of the studies which the applicant has already pursued, the examinations he has passed, and the name of a teacher (or teachers) to whom reference may be made. Such applications will be considered by the Dean and Council of the School, who will decide on them according to their merits. A knowledge of elementary mathematics, such as is required of all Royal Exhibitioners and national scholars, will be held to be of the first importance for those who desire admission to the course for the Associateship of the School; while for occasional students, who propose only to take up certain specific branches of science, some preliminary knowledge of them will have weight. The Cambridge Cholera Fungus

THE letter published by Dr. Klein in your issue of December 23 (p. 171) having incidentally referred to my views as to the nature of the fungus present in choleraic tissue, I should be glad to be allowed to make some further remarks upon the subject.

At an early stage of his investigation Prof. Roy brought for my inspection one of his preparations of intestinal mucous membrane, which clearly demonstrated the presence of certain foreign organisms, and especially drew my attention to a form which he took to be the more usual and typical one. Such a structure might perhaps best be described as consisting of a thin and somewhat moniliform filament which at one end exhibited a distinct nodular swelling. Being struck with a certain (and, as I now fear, a somewhat superficial) morphological resemblance to a group of the Chytridiaceæ, I suggested that the organism might possibly be a Chytridium, and this view was perhaps too confidently adopted by Messrs. Roy and Sherrington in their paper. The appearance of Dr. Klein's letter has naturally led me to carefully reconsider the whole question, and on further consideration I entirely abandon the idea of the organism being a Chytridium. I believe, on the contrary, that it is a Bacterium, and that the structure described by Prof. Roy and seen by myself is that particular phase in the life-history of the Bacterium which is known as an involution form. Such forms are described, for instance, in Zopf's article "Die Spaltpilze," in Schenk's "Encyclopædie der Naturwissenschaften," as *Bacterium aceti* and *Bacterium cyanogenum*. Indeed, the involution form assumed by the latter Bacterium recalls very vividly to my mind the structure shown to me by Prof. Roy.

In conclusion, I may assure Dr. Klein that the fungus is certainly neither a Penicillum nor of the nature of a mould, and that I do not believe it is in any way associated with *post-mortem* change. WALTER GARDINER

Royal Gardens, Kew, January 11

Snowstorm of January 7, 1887

A MOST extraordinary snowstorm occurred here to-day (January 7). In fifty years' experience I have seen nothing like it, nor has anyone else in this neighbourhood seen any similar phenomenon. It would be impossible to realise the gigantic size of the snowflakes without seeing them. I can only compare them to a fall of oranges, though the diameter of an orange would be small in comparison with thousands of these snowflakes; in this immediate neighbourhood (*i.e.* within sight of the place of observation) at 50 yards off it produced a dense snow-wall. The wind was south, and almost calm, and the largest snow came down nearly perpendicularly. The temperature was 32°·6, and the air completely saturated with moisture. Before the storm the temperature was 34°·1. Snow had been falling with a slight thaw from 10 a.m., the snowflakes being small. Suddenly, at 12h. 12m. p.m. they became $2\frac{1}{2}$ inches in length;[1] at 12h. 14m. they had increased to $2\frac{3}{4}$ inches; and one flake that was caught measured $2\frac{3}{4}$ inches by $2\frac{1}{2}$ inches, and was $\frac{3}{10}$ of an inch thick. At 12h. 16m. the flakes had increased in size to $3\frac{1}{2}$ inches (and several measured were 4 inches across, and there were several larger ones not near enough to be caught); at 12h. 19m. they were somewhat less, and at 12h. 20m. though large, were not gigantic. Fortunately I was measuring and weighing snow at the time, with two assistants, and had a number of flat circular glasses kept cold ready for the purpose of catching crystals, and for measuring the snow that fell upon these glasses. As is usual when very large flakes are falling, there were many of smaller size, though when the flakes were from $2\frac{1}{2}$ to $3\frac{1}{2}$ inches, the majority of the next size were about 2 inches, and the very large flakes would be within 12 inches of each other. A dozen of these large flakes were caught, each on a separate piece of glass, measured and removed under cover, my two assistants giving valuable aid. Of three of these flakes one yielded 14 drops of water, a second 15, and a third 16 drops; and these were not the largest flakes seen.[2] The water from seven flakes weighed a quarter of an ounce within 2 or 3 grains. The weight of ten varied from 13 to 16 grains each; most of the flakes were about a third longer than broad, one flake that was $3\frac{1}{2}$ inches long by $2\frac{1}{2}$ broad was estimated (before it touched the glass) to be $1\frac{1}{2}$ inch thick, when flattened by the force of its descent it was $\frac{1}{4}$ of an inch thick.

The flakes were not a mass of broken pieces, but were composed mainly of perfect crystals, and there must have been hundreds of these crystals in each flake; they were clinging together at every conceivable angle, though a much larger percentage were more horizontal than vertical. A terrestrial radiation thermometer, buried a fifth of an inch within this snow, marked a temperature of 32°·4.

The snow which fell during the last six minutes of this great storm was just under one-fifth of an inch in depth, and yielded ·030 of an inch of water, falling at the rate of 1 inch of water in three hours and twenty minutes (yielding 1 inch of water from 6 inches of snow).

There was a great snowstorm here on December 27, 1886, which varied considerably in places near to each other, *i.e.*—

	Amount of rain and snow	Depth of snow Inches	Melted snow alone
Shirenewton Hall	1·55	7	0·97
Dennil Hill	1·07	5	0·71
Wirewoods Green	0·86	3	0·42
Piercefield Park	0·96	4	—
Chepstow (The Mount)	0·70	—	—

The drifts above here are very great, and a large number of men are still engaged in cutting through them.

The following measurements will show the number of inches

[1] The breadth was less than the length, and the thickness less than th breadth; more or less flattened, and curled over on the edges

[2] Besides these drops, the wetted glass shall count f r two more drops.

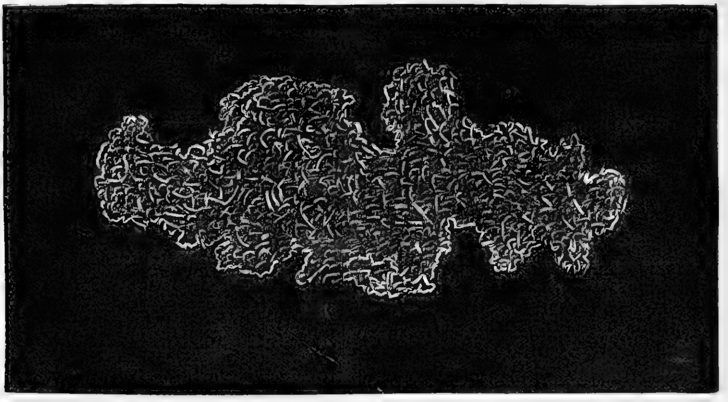
of snow required to yield an inch of water from observations taken here:—

1886, January 23, snow 2 inches, melted ·063 (*i.e.* 33 inches for 1 inch of water); March 1, snow 7 inches, melted ·800 (*i.e.* 9 inches for 1 inch of water); December 26, snow 7 inches, melted ·967 (*i.e.* 7 inches for 1 inch of water). 1887, January 4, snow $3\frac{1}{4}$ inches, melted ·379 (*i.e.* $8\frac{1}{2}$ inches for 1 inch of water); January 7, $\frac{1}{5}$ inch, melted ·030 (*i.e.* 6 inches for 1 inch of water).

The damage done on December 26 was unusually great, the snow being very heavy, as much as 5 lbs. weight on a square foot of a cedar-branch; this, when moved by the wind, caused much breakage.

January 8.—Since sending my note yesterday I find that at Chepstow and at Itton the snowflakes were larger than anyone had before seen, so that probably the storm had an extended area; at all events it was 5 miles broad.

The present storm is a very similar one to that recorded by myself in January 1838, except that the largest flakes in 1838 did not exceed 2 inches. In that storm the largest flakes fell more rapidly and more perpendicularly. I then pointed out that large snowflakes were produced by two upper currents driving the flakes together; and afterwards, by the largest falling with increased velocity and more perpendicularly: they were thus able still more to augment their dimensions by adding smaller ones to their bulk. This was well seen on January 7, when an estimate was made as to the velocity and angle of their descent. Not only were a number seen to be added as they fell upon them, but it was thought that small flakes when near to the large ones were attracted to them. The flakes were, however, large whilst at a considerable distance from the ground.



Shape and size of snowflake. (There were more of a somewhat similar form to this than the more circular ones, though there were very many more circular and less indented.)

Several flakes were sketched before they began to melt, and one of the sketches is sent as an illustration. The glasses were at a temperature of freezing, and therefore it was some time before the snow melted, and not thoroughly so until they had been 5 minutes in a hot-house.

January 13.—The snowflakes folded over on the edges, boat-like, and this curling over caused the thick look observed. There was a slight zigzag in their downward course of some 2° or 3°. This storm passed over Chepstow, Itton, and Monmouth in this county; Wirewoods Green, Tidenham, and Dennil Hill, all in Gloucestershire, and Bath: in all of these places the flakes are spoken of as the largest ever seen. One correspondent at Chepstow reports them as larger than the hailstones in the storm of May 1848, which were larger than hens' eggs, and broke the shop windows, and destroyed the glass of hot-houses near Chepstow.

Shirenewton Hall, near Chepstow

Auroras

THE account, in NATURE for December 16 (p. 159), of a bright cloud "emitting brilliant rays of light," that suddenly appeared at Hamar, in Norway, on the night of November 3, recalls the fact that on November 2 there was at Lyons, New York, an aurora which at one time during the evening consisted entirely of detached luminous clouds, as was noted in NATURE for November 18 (p. 54). It is stated that on November 4 one of the finest auroras of the year was visible at Throndhjem, Norway.

M. A. VEEDER

Lyons, N.Y., January 3

A Solar Halo

IN the weather report issued on Friday evening, the 14th inst., a solar halo is recorded as "observed in Jersey during the day." Between noon and 12.30 I observed a very complete and well-defined halo, of radius about $\pi/8$, in this neighbourhood. It was not perceptibly tinted, but the duskiness of the interior, as compared with the clear sky exterior to the luminous ring, was more pronounced than I ever remember to have noticed it on other occasions—so much as to suggest comparison with the "curtain" of the aurora: "Solem quis dicere falsum audeat!"

J. J. WALKER

Hampstead, N.W., January 15

THE NATIONAL SCIENCE COLLECTIONS[1]

II.

25. REVERTING to this country, the "Patent Museum," now under the charge of the Science and Art Department, is a collection of a peculiar nature; and in order to explain its origin, and the objects it was intended to serve, we may make some extracts from the Report of a Select Committee of the House of Commons, appointed in 1864, to inquire as to the most suitable arrangements to be made respecting the Patent Office, Library, and Museum. The Committee said:—

The second point to which your Committee directed their attention was that of the Patent Museum, having regard especially to its formation, its present state, its relation to the Patent Office and Library, and the nature of its contents, so as to render it practically useful.

Your Committee found that the Patent Museum was formed by Mr. Woodcroft, the Superintendent of Specifications, by the request of the Commissioners of Patents, and that it consists of models and machines belonging partly to the Commissioners of Patents, partly to the Commissioners of the Exhibition of 1851, and partly to Mr. Woodcroft himself, and various private persons.

[1] Continued from p. 254.

This collection has been exhibited since 1857 in the iron building at South Kensington.

Your Committee are of opinion that the term Patent Museum (which is generally applied to this collection) tends to give an erroneous impression as to its character and object.

Various suggestions have been made by witnesses respecting the nature of a Museum connected with the mechanical arts, which may be summed up as follows:—

(*a*) That it should illustrate the history of those arts by a collection of original machines from an early period to the present time.

(*b*) That it should exhibit all known inventions respecting machinery and manufactures.

(*c*) That it should show the present state of all machinery and manufactures.

(*d*) Some of the witnesses suggested that the collection should be restricted to the machinery and manufactures of the United Kingdom; whilst others proposed that it should be extended to those of foreign countries.

(*e*) Some, again, proposed that the collection should contain all the objects of each class, whilst others proposed that a selection only of the most important objects should be exhibited.

(*f*) There was no less diversity of opinion respecting the primary purpose for which any collection or exhibition should be made; some of the witnesses considered that it should be for the purpose of conveying instruction in the mechanical arts, either in a cursory way to people who might visit the Museum, or to students in mechanics, or to persons desirous of applying themselves to the discovery of improvements in machinery and manufactures.

(*g*) Other witnesses deemed the Museum chiefly desirable for the information of persons intending to take out or purchase patents, in aid of the information afforded by books and specifications, to assist them in ascertaining whether the contemplated patent would be valid as a new invention.

(*h*) On the other hand, two witnesses, Mr. Carpmael and Mr. Johnson, gave it as their opinion that for all purposes of the patent law a museum of models would be practically valueless.

Your Committee are of opinion that any special collection of patented inventions made for the purpose of evidence, illustration, or record of patent rights is not so connected with a general museum of mechanical inventions as to render the neighbourhood of such a museum to a patent office and library, or law courts, necessary.

It appears to your Committee that the chief purpose of a general museum is to illustrate and explain the commencement, progress, and present position of the most important branches of mechanical invention; to show the chief steps by which the most remarkable machines have reached their present degree of excellence; to convey interesting and useful information, and to stimulate invention.

In forming an illustrative collection of inventions it would be necessary to adopt the principle of selection. This, however, does not appear to your Committee to be an insuperable objection, especially as no one proposed to substitute models for specifications, which for all the purposes of administering the patent law would still have to be consulted, and bear the stamp of authority.

Such a collection should contain a selection of models of moderate size, which should illustrate different departments of inventions, and also a selection of models of current patented inventions.

The Patent Collection, although it was placed in premises belonging to the South Kensington Museum, remained in the hands of the Commissioners of Patents until January 1, 1884, when, by the "Patents, Designs, and Trade Marks Act, 1883," 46 and 47 Vict. c. 57, it was transferred to the Science and Art Department.

The title "Patent Museum" was never accurate; the collection might with greater propriety have been called the "Woodcroft Museum," from the name of the gentleman, formerly Clerk to the Commissioners of Patents, who originated the formation of it. It contains objects illustrating steps in the history of mechanical inventions, and contrivances of importance and interest, without regard to whether they have been patented or not. Among these, for example, are the earliest locomotive and stationary steam-engines; the first engine used in steam navigation; the first reaping-machine; Arkwright's original spinning-machinery; all Sir Charles Wheatstone's original apparatus, showing a complete history of the various steps by which he perfected electric telegraphy; many of Edison's original electrical inventions; some old clocks dating from 1325; and other objects of similar interest.

Inventions embodied in future patents may be added to this Museum, pursuant to Sections 41 and 42 of the Patent Act above mentioned. These sections enact as follows:—

(41) The control and management of the existing Patent Museum and its contents shall, from and after the commencement of this Act, be transferred to, and vested in, the Department of Science and Art, subject to such directions as Her Majesty in Council may see fit to give.

(42) The Department of Science and Art may at any time require a patentee to furnish them with a model of his invention, on payment to the patentee of the cost of the manufacture of the model; the amount to be settled in case of dispute by the Board of Trade.

We do not consider it to be feasible to combine a complete museum of patented inventions with a methodical collection of objects illustrating practical science, and we infer from the language of Parliament in the provisions just quoted that this is the view taken in the recent Patent Act, which enables, but does not oblige, the Department of Science and Art to acquire specimens of patented inventions.

26. We conceive that it will be useful for the curators of all the collections to bear in mind that their primary and indispensable scope is to provide apparatus and specimens for the instruction given in the Normal College of Science, and for the teaching of science generally throughout the United Kingdom.

Cases may doubtless arise where the acquisition or reception of other objects may be expedient, in the interest of science or of the arts; but in these cases, in order to prevent the unnecessary occupation of space, we recommend that due regard be had to existing public collections elsewhere, so as not unnecessarily to duplicate the provision for illustrating science.

27. Referring now to the space required, we adopt the following figures given by the Reports of the different Committees, adding some estimates for the future where they have not been stated:—

	Space now required	Estimated increase of space required in ten years	Space required at the end of ten years
	Sq. ft.	Sq. ft.	Sq. ft.
Various science collections	37,000	3,000	40,000
Naval models	10,500	10,000	20,500
Building construction	15,000	10,000	25,000
Fish culture	5,000	1,000	6,000
Educational collection and library	7,500	1,000	8,500
Mechanical collections...	45,000	15,000	60,000
	120,000	40,000	160,000

In framing their estimates, the Committees generally took, as the basis of their computation, top-lighted galleries 30 feet wide, which afford a large amount of well-lighted wall-space in proportion to floor-area. But with galleries side-lighted, in which some part of the collections must necessarily be housed, an increase of floor-area will be required.

28. In adopting these estimates, we think an indefinite series of demands for accommodation, involving an indefinite extension of space, ought not to be contemplated. The pleas commonly put forward for such extension at the close of every Exhibition are the number of articles which are either offered as gifts or are said to merit acquisition. We think that merit alone should be the ground of admission, and that even this ground must be subject, in the first place, to the consideration of space, and next, to that of scientific arrangement. If space is to be in any degree limited, and scientific arrangement to be maintained, it is evident that exclusion and depletion, as well as completion, must be kept in view; and that while the Department of Science and Art is left all possible freedom in determining what the contents of its collections shall be, it should be strictly confined to the area which is represented to be sufficient for the future.

In the due appropriation of this area we do not consider that, as a rule, and except in cases of historic interest, engines and machines of the original size should be acquired, or even accepted on terms implying that they will continue to be exhibited otherwise than in models.

29. Comparing now the estimates of space required with the area at present available, we find as follows:—

The total available floor-space in the present buildings, assuming the Western Gallery, D, to be given up, and the building E to be abolished, is 51,500 square feet.

This is 17,480 feet less than the collections at present occupy, and less than half what the Committees estimate for them when fairly completed.

It is clear, therefore, that new buildings are absolutely required.

Provisions for Housing the Collections

30. The second duty confided to us is:—

To suggest plans for housing the collections in the existing galleries to the south of the Horticultural Gardens, or in new galleries to be built upon their site, and the adjacent ground now the property of the Government.

31. In considering this matter, we have had the valuable assistance of Mr. Taylor, the Surveyor to Her Majesty's Office of Works, who has, in accordance with our suggestions, carefully examined the existing buildings, and prepared sketch-plans and estimates to meet the circumstances of the case.

32. We have already referred to the land available. It is shown on the Drawing No. I., marked G, and coloured red, and it consists of a plot of ground to the south of the South Galleries A, B, C, containing 4 acres and 23 square yards.

This land, as well as the site and ground of the Natural History Museum to the south of it, was purchased by the Government, in 1864, from the Commissioners of the Exhibition of 1851, and the particulars of the transaction are fully set forth in the Fifth Report of the Commissioners, dated August 15, 1867.

33. In this Report (p. 31) the Commissioners say:—

"We have set forth in detail all the circumstances connected with the sale by us to Her Majesty's Government of the site of the Exhibition of 1862, with the sanction of Parliament, and under the special condition that the site in question shall be permanently devoted to purposes connected with Science or the Arts."

This condition is fully and strongly carried into effect in the deed of conveyance, which is published as an Appendix to the same Report; so that the appropriation of this land for the erection of a Science Museum is in strict compliance with the conditions of its acquisition.

34. The buildings forming the southern range A′, A, C, B, B′, although not of first-rate character, will yet last in good order for many years to come, as will also the Western Gallery D.

We are, however, of opinion that a plan should be prepared to include the eventual reconstruction of the whole southern range.

But it should be a plan capable of being carried out by degrees, as and when necessity demands.

35. Drawing No. II. shows a ground plan of a design which fulfils these conditions.

It provides for two three-storied buildings of ornamental elevation, forming frontages (with returns) to Exhibition Road on the east, and to Queen's Gate on the west; and for plain two-storied buildings adjacent to these east and west frontages. These buildings, together with the existing southern buildings (A, B, C) will afford the required space until the latter become unserviceable, and permanent structures have to be erected on their site.

These buildings would give room for the collections, with the necessary offices, for the Portrait Gallery, and, if desirable, for examination-rooms.

Measures Recommended

36. The measures we recommend are as follows:—

Section I.—*Alteration of Arrangements in the existing Galleries*

(*a*) Remove the collection from the upper floor of the Western Gallery, D, and place it temporarily on the lower floor of the same building, and in A, B, or C.

(*b*) Remove the Portrait Gallery into the upper floor of the Western Gallery, D; this floor has been used during former Exhibitions as a Picture Gallery, and has given great satisfaction to the artists. This gallery, as it exists, is more secure against accidents by fire than the building in which the pictures are now placed, and can be rendered, at a moderate outlay, practically incombustible.

(*c*) Clear out the ground floor of the Western Gallery, D.

(*d*) Then use this ground floor for examination-rooms. When this is done, the entire Western Gallery, D, will be occupied, and none of it will be further available for the collections.

(*e*) Make an opening through the wall which now shuts off the centre building, C, so as to give an approach from Exhibition Road to the western parts of the galleries, and thus do away with the unsightly gallery K.

(*f*) Proceed to arrange the rooms as they are set free.

(*g*) In addition to the access from Queen's Gate to the portrait gallery in D, afford access to it from Exhibition Road through the Science collections.

Section II.—*New Works to be undertaken*

37. The proposed new building is so designed that it may be carried out in separate portions progressively.

The portion to be first undertaken should be on the parts marked L and L¹, with the temporary entrances, all coloured yellow on the drawing No. II. These buildings may be completed in about eighteen months, and are estimated to cost about 43,520*l.*, which may be distributed over the financial years 1886-87, and 1887-88.

Before the end of 1887, also, the option must be exercised of purchasing the central building, C.

When the above-mentioned first portions of the new building are completed, they will add an available area of 28,700 square feet, which, with the areas already existing in the southern galleries, will make a total of 80,200 square feet.

This will provide, for the Science collections, about 11,000 feet more than they at present occupy, and it will admit of the Patent Museum being removed to the western side of Exhibition Road, and of the building E being abandoned. At the same time the temporary appropriation of the Western Gallery, D, to the Portrait Gallery and the examination-rooms, will give them an advantageous increase of accommodation. Hence, by this first instalment of the new works, a considerable improvement on the present state of things will be effected; but the space will still be much below what has been estimated as necessary by the Committees who have investigated the matter.

38. The next portion to be undertaken may be the building with façades at the eastern end, marked M[1] on the drawing, and coloured red. This is estimated to cost 54,183*l.*, and it will furnish 33,750 square feet of additional floor-space.

When this is built there will be, in all, 113,750 square feet available, *i.e.* enough not only to accommodate the present collections, with some increase, but also to receive the Portrait Gallery, and to provide examination-rooms, if required.

At this time, therefore, there will no longer be any need to hire from the Commissioners of 1851 the Western Gallery, D, and thus an expenditure of 2000*l.* per annum will be saved.

39. The accommodation can afterwards be extended from time to time, as and when means may be voted for the purpose, by the erection of the other portions shown on Drawing No. II., as follows:—

	Additional space obtained Square feet	Estimated cost £
Interior building at the east end, marked N[1], and coloured brown	28,350	32,930
Building with façades at the western end, marked M, and coloured red	37,950	59,240
Interior building at the west end, marked N, and coloured brown	28,350	32,930

40. The entire floor-space gained by the new buildings, when completed according to Drawing No. II., will be 157,100 square feet. To this must be added the space in the existing southern galleries, which will be assumed still to remain available. They contain, at present (as we have already stated), 51,500 square feet; but, in the process of building the new erections, a portion of the old ones will have become absorbed therein, and the space will be reduced to 41,818 square feet. The total available space will therefore amount to 198,918 square feet.

The total estimated cost of the new work shown on Drawing No. II. is 222,803*l.*

41. In submitting this Report to the Treasury, we desire to state to their Lordships that one of the principal considerations guiding us has been to prepare a plan which admitted of being executed in parts, but which, when completed, should suffice for as long a period as we think it necessary to foresee. We have taken as our starting-point the demand of 160,000 square feet of area, and we have shown how it may be provided without more than a strictly temporary use of the Western Gallery, which does not belong to the Government.

42. We have been invited to express an opinion as to whether there would be space, in the completed plans, to provide for the collections now housed in the Museum in Jermyn Street, and the instruction now given there. We believe that there would be space for the purpose.

We have the honour to be, Sir,

Your obedient Servants,

FREDERICK BRAMWELL
LINGEN
J. F. D. DONNELLY

WILLIAM POLE,
Secretary,

Westminster, July 27, 1885

P.S.—Mr. Mitford dissents, for the reasons appearing in a separate Report handed in by him on the 4th ultimo, which, with other documents relative to it, is inclosed in the letter covering our Report.—F. B.; L.; J. F. D. D.

TRANSMISSION OF POWER BY COMPRESSED AIR

A MOST interesting experiment is about to be tried in Birmingham. A Company, whose engineer is Mr. J. Sturgeon, has obtained Parliamentary powers to supply power from a central station by compressed air through pipes laid in the streets. The application to Parliament was supported by the Birmingham Corporation, and the powers extend over an area of between four and five square miles. It is at first intended to restrict operations to about one square mile and a half. This area will include twenty-three miles of main pipes. The central works are designed for the production of 15,000 horse-power, of which the engines laid down at first will supply 6000 horse-power. The authorised capital expenditure for the whole is 276,800*l.*, of which 150,000*l.* will be spent at once for the initial 6000 horse-power. In this journal we have nothing to do with the financial aspects of the project, but we mention these figures to show that within a short time the system may be expected to be in operation on such a scale as will very fairly test its mechanical efficiency. At a recent meeting of the directors it was determined to start clearing the ground and commencing the foundations for the central station at once, so that by next summer we may see considerable advance made towards the realisation of the project.

This is the first time that an experiment of this kind has been tried in Britain. Power is distributed from a central station at Hull by the hydraulic system, but transmission by air has hitherto only been tried in small installations at mines, quarries, in sinking piers, as at the Forth Bridge, and in tunnel-boring. In mines and tunnels it has very evident advantages, in that it keeps up a continual supply of fresh, cold air where ventilation is very much needed; and therefore its undoubted success at the St. Gothard works does not demonstrate its certainty of success for the distribution of power on a large scale to the workshops of a town where the atmosphere is bearably pure. Moreover, the pipe systems of these small installations have not been sufficiently long and complicated to test in any severe sense the liability to loss by friction, leakage, and variation of temperature.

The results of the present experiment will therefore be of the utmost scientific value to engineers, and will be watched with corresponding interest. No fairer field for such an experiment could be found than in Birmingham, which is marked out from all other towns by the enormous number of its small workshops requiring minute amounts of driving-power, and the total turn-over of each of which is too small to enable the owner to afford skilled tendance to his boiler and engine. In these small shops the power is required only intermittently throughout the day. At times the engine may actually stand altogether for an hour or two, while it is only rarely that it is called to exert more than a comparatively small fraction of its full power. Meanwhile the large loss due to furnace and boiler inefficiency—that is, to waste of heat by radiation and by hot gases passing up the chimney—goes on steadily at a pretty uniform rate. Under such circumstances, the advantages of generating the power at a great central station are so evident as not to require demonstration. The question of chief technical interest is really as to whether the best means of distribution is by air, by water, by electricity, or by cheap gas to be used in gas-engines. That question can only be finally settled by expensive experiment. In passing, the writer may indicate his own opinion that there lies in the future a magnificent field for enterprise on the part of the gas companies of large towns in supplying cheap gas for heating and the production of mechanical power, and it is most decidedly their interest to improve the efficiency and lower the prime cost of gas-engines.

The site of the central works is a triangular plot of ground adjoining Garrison Lane, at the intersection of the

London and North-Western and the Midland Railways. The Birmingham and Warwick Canal forms one boundary of this plot. The fuel to be used under the boilers is gas obtained from Wilson's eight-hundredweight producers. Eighteen of Lane's water-tube boilers will supply six engines to produce the 6000 horse-power aimed at at first Air is admitted to the furnaces through gridiron sliding shutters, by means of which the supply is hand-regulated. It mixes with the gas in a mixing-chamber immediately below the front end of the furnace. The roof of this mixing-chamber is an arch of perforated bricks, and these bricks becoming highly heated the mixed air and gas is raised to a high temperature before being ignited. No special means have so far been considered necessary to prevent risk of lighting back into the mixing-chamber. The production of gas in the producers is controlled by the steam jet blown in at the foot of each. The steam for these jets is supplied from a special donkey boiler. The whole of the steam jets are throttled down by the action of a governor that runs, so to speak, in equilibrium with the air-pressure in the mains. The engine drives a small air-pump, which forces air into one end of a small cylinder, to the other end of which the air from the mains is admitted. If the pressure rises in the mains above standard, the piston of this cylinder is moved, and this movement is communicated by suitable gearing to the throttle-valve regulating the steam jet to the producers. The production of gas, and therefore the production of heat by its combustion under the boilers, are thus automatically regulated in accordance with the requirements, so that the air-pressure in the mains is prevented from varying outside certain narrow limits. In connection with this part of the scheme we may point out that it seems to be a mistake not to throttle the entrance-areas for the air to the furnaces automatically and simultaneously with the regulation of the gas supply. The chief advantage in using gas instead of solid fuel lies certainly in the power of obtaining perfect combustion by thorough admixture and careful proportioning of air to fuel. This advantage is sacrificed if the air supply is not diminished and increased simultaneously with, and in the same proportion as, that of gas. We suspect also that it will be found desirable not to rely solely on the throttling of the steam blast as at present intended ; the more direct and rapid action of a throttle-valve between the producer and the boiler-furnace will be highly advantageous, if not necessary. By means of simple mechanical relays, actuated either by the steam or by the compressed air, there can be no difficulty in controlling these three sets of throttle-valves by the action of a single governor.

The steam-pressure is to be 160 pounds per square inch. Each set of three boilers supplies an engine of 1000 horse-power. The engine is of the triple-expansion type ; the high-, intermediate-, and low-pressure cylinders having the diameters 20, 30, and 49 inches, and a common stroke of 48 inches. The areas of the three pistons are thus in the ratios 1, $2\frac{1}{4}$, and 6. The cranks are at 120° to each other. The high-pressure and intermediate cylinders are steam-jacketed at the sides. The low-pressure cylinder is not jacketed, but a novel arrangement of steam-jacketing its piston is adopted. The piston is hollow, and steam is led into its interior by a tube which is parallel to the piston-rod, and moves to and fro through a stuffing gland in the cylinder cover, projecting into a larger tube screwed on the gland and supplied with steam direct from the boiler. The argument in favour of this arrangement is that side-jacketing of the low-pressure cylinder involves a large absolute waste of heat that goes towards heating the exhaust-steam as it leaves the cylinder on its way to the condenser ; this loss of heat by the jacket steam being noxious, not only because it is pure waste, but also because it raises the back pressure against the piston. The fresh steam in the hollow piston sweeps over the inside surface of the cylinder just in front of the incoming working steam, and thus heats the metal and prevents undue condensation of the working steam, while it is comparatively inactive in heating the back-pressure steam. In criticism of this argument, it may be remarked that towards the end of the stroke (during the last quarter of the stroke) this piston-jacket surface giving heat to the exhaust-steam is greater than a side-jacket would offer. For three-quarters of the stroke, however, it is less.

Each cylinder is connected with the fly-wheel shaft by a cross-beam. Over each end of each beam stands a single-acting, air-compressing cylinder of 26 inches diameter and 48-inch stroke. Each engine thus drives six of these air-pumps ; and, since the speed is ninety double strokes per minute, the volumetric capacity of the compressors of each engine is close on 8000 cubic feet per minute.

The pressure in the mains is to be 45 pounds per square inch above the atmosphere, and the delivery-valves are expected to lift a little before three-quarters of the compressor piston-stroke is finished. Thus the volume of air compressed to the above pressure delivered per minute by each engine is taken as about 2000 cubic feet.

The ratio of pressures is $\frac{59{\cdot}7}{14{\cdot}7} = 4{\cdot}06$. Thus, if the compression curve were isothermal, the valves would lift, as above assumed, at ·75 of the stroke. If it were adiabatic, this pressure ratio would correspond to a ratio of final to initial volume of ·367, and the valves would lift at ·63 of the stroke. If the curve lay exactly mid-way between these two, or were according to the law $p \propto v^{-1{\cdot}2}$, the ratio of final to initial volume would be ·31, and the valves would lift at ·69 of the stroke. In the latter case the volume delivered would be $\cdot 31 \times 8000 = 2480$ cubic feet per minute. Calculating simply from the product of this volume by 45 pounds per square inch pressure (*i.e.* from the work the air could do in an air-engine without clearance, without expansion, and without more than atmospheric back pressure), this would give about 487 horse-power delivered in the consumer's engines for each engine developing 1000 horse-power at the central station. Two indicator-cards taken from two air-compressing cylinders at Frood Colliery, near Wrexham, give very different results, possibly because one compressor was near the steam-engine cylinder, and was heated by it, while the other was not. The compression-curve from the one cylinder corresponds with the relation $p \propto v^{-1{\cdot}237}$, while that from the other corresponds to $p \propto v^{-1{\cdot}06}$. The latter curve is thus much steeper even than the adiabatic, and would indicate that the air was actually heated by conduction or radiation during its compression. Such heating could hardly have taken place to such an extent as to account for the above very high index, and the more probable explanation is that the air was steam-laden as it was taken in, and that the extra rise of pressure is really due to that of the steam in the mixture consequent on the rise of the temperature.

It is desirable to keep down the compression-curve as nearly as possible to the isothermal line, because by doing so the area of the compressor indicator-card, and therefore the work to be done by the engines, is kept down to its minimum ; whereas no advantage can be derived from the increase of temperature obtained by adiabatic compression, because this is rapidly lost by cooling in the pipes long before the air is utilised in the air-engine it drives. It is worth noticing that, because of the air being discharged from the compressors through valves which *automatically* lift when a certain designed pressure is reached, this loss of power due to cooling in the pipes is effected rather by a contraction of *volume* than by a diminution of *pressure*. The decreasing-pressure gradient along the pipes is very small, and is due solely to frictional and viscous resistance to the flow, and to variation of velocity consequent on variation of section.

In order to approximate to isothermal compression, Mr. Sturgeon has adopted very special cooling arrangements for his compressors. Firstly, the air used is all taken through the roof of the engine-house, and thus heating by contact with the boilers and engines below is avoided. It is filtered of deleterious dirt in entering through the roof. Secondly, the compressor cylinders are surrounded by ample water jackets, through which a continual fresh-water circulation is kept up. Thirdly, the delivery-valve—it is a single large disk of slightly greater diameter than the cylinder—is made hollow, and through it a cold-water circulation is kept up, the water being spread out in a thin radial stream across the valve face over which the air flows as it leaves the cylinder. This cooling-water is supplied to the hollow valve through a tube sliding in a stuffing-box in the cylinder cover. A further development of this system would be a supply of cooling water to the face of the piston after the manner that the steam is supplied to the piston-jacket of the low-pressure engine cylinder; but this refinement has not been deemed necessary in the design as at present adopted.

The compressor piston-face travels a little beyond the position assumed by the flat face of this delivery-valve when the latter is closed. During the momentary pause at the end of the stroke, the valve therefore falls into actual contact with the piston-face, and the two descend together until the valve is landed on its seat. Thus the clearance space is reduced absolutely to zero.

The suction-valves are somewhat similarly arranged so as to reduce the clearance at the other end of the stroke to a very small amount. The cooling-water is circulated by gravity from a tank giving a head of 20 feet. The water is pumped into this tank from the canal, and the power spent in pumping this water is a partial set-off

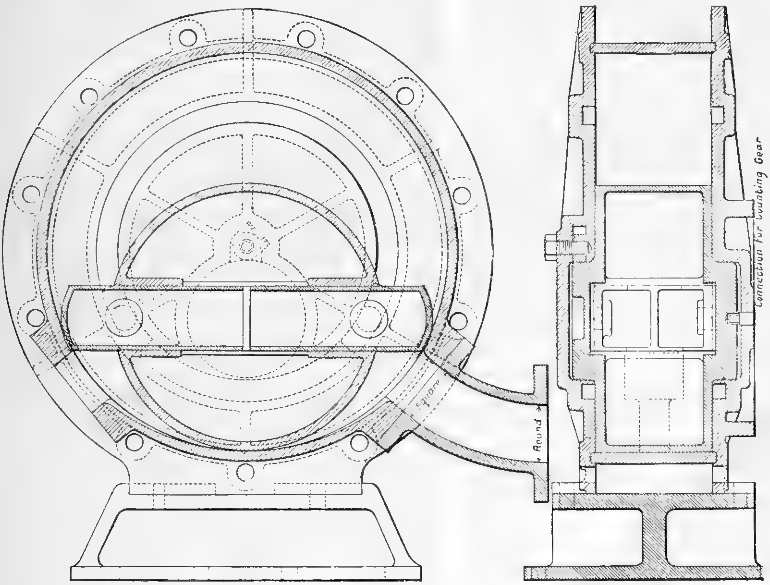

Fig. 1.

against the economy resulting from the approximation to isothermal compression; but the power thus gained greatly outweighs the work spent in this pumping.

As at present designed, the air-pipes are of wrought-iron plate, riveted, but a new design for plate-steel tubes is being considered. The pipes are to be laid in concrete tunnels, which free them from all pressure of superincumbent soil or paving, and will always be very accessible for examination and repair. They are of 24 inches diameter near the central station, and diminish to 7 inches in the smallest branches. The joints are given a small degree of flexibility. In one design they are formed by two angle-irons riveted to the outside ends of the two pipes, a hard rubber ring of circular section being placed between the flanges thus formed, and the flanges being drawn together by bolts. In another design a sort of double-socket coupling-piece covers the ends of both pipes for a few inches; the end of each pipe has formed on it two slightly projecting rings, and between these is poured, in the molten state, through a hole in the socket-coupling, a soft metal that expands during solidification. We rather doubt whether this last design will give sufficient tensive strength to the joint. Tensive strength is required simply because there are necessarily bends in the pipe here and there.

The air is supplied to the consumer through a registering meter. This meter is similar in construction to Beale's gas exhauster. It consists of two cylinders, one inside the other. Both are 4 inches long; the outer one has a diameter of 14 and the inner a diameter of $9\frac{3}{8}$ inches. The outer one is fixed, and is furnished with an inlet and an outlet opening. The inner cylinder revolves freely on a fixed axis, distant $\frac{1}{2}(14-9\frac{3}{8}) = 2\frac{5}{16}$ inches away from the centre of the outer case, so that the two cylinders always touch along a fixed line. Two sliding shutters project from a slot through the centre of the revolving cylinder. By means of a pin and a pair of sliding blocks running in circular grooves cut on the inner surface of, and concentric with, the fixed cylinder, these shutters are drawn out and in from the revolving cylinder so as always to keep in contact with the fixed one. During one revolution these shutters sweep through the meter a volume of air about ·17 cubic feet.

This rotation is reduced three times by worm-gearing in being transmitted to the counter-box, so that a single dial with two concentric circular scales, which are read by two fingers like the hour- and minute-hands of a common clock, is sufficient to register up to a million cubic feet. Fig. 1 shows this meter. It is driven by a small difference of air-pressure between the inlet and outlet.

The Company intend to charge at the rate of 5*d.* per 1000 cubic feet at standard pressure of 45 pounds per square inch. If the air were used in an engine without expansion, without clearance space, and without back pressure above the atmosphere, this would correspond to a cost per hour per indicated horse-power of

$$\frac{60 \times 33000 \times 5}{144 \times 45 \times 1000} = 1·53 \text{ pence.}$$

Under the conditions of actual practice the writer calculates that at the above rate of 5*d.* per 1000 cubic feet, assuming intelligent and economical management, each

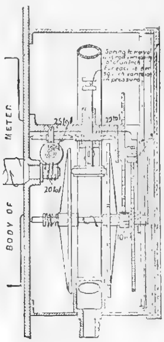

FIG. 2.

indicated horse-power will cost per hour from 2*d.* down to as low as $1\frac{1}{3}$*d.*, excluding cost of engine attendance and depreciation, and interest on first cost of engine.

The standard pressure at which the air is sold at the above price being 45 pounds per square inch, a reduction of price per cubic foot has to be made if the pressure of the supply be less than this pressure. This is effected by introducing a variable velocity-gear between the volume-meter and the dial-counter. This arrangement is shown in Fig. 2.

The rotation is transmitted to a small roller on a spindle capable of sliding in its bearings parallelly to its own axis. It drives a disk on the counter-arbour by rolling contact. The end of the roller-spindle is linked to the end of the tube of a Bourdon pressure-gauge. As the pressure rises, the roller is thus pushed nearer the centre of the disk, and gives this disk, therefore, an increasing fraction of a revolution per revolution of the roller. The roller really lies between two disks, but the one is "idle" and serves simply to support the roller in pressing against the driven disk.

This integrator is wholly wrong in principle, and it is badly designed in detail. The roller has a rubber tyre round it, and therefore touches the disk at different radii, and thus must rapidly wear away, owing to the want of pure rolling action at one or other side of its tread. The wearing might not be of much consequence in itself, except that it gradually vitiates the accuracy of the indication; and besides, the velocity ratio is uncertain because of the contact taking place over a perceptible range of radius. There ought to be an idle roller between the disks opposite the driving roller, and both disks ought to be pressed inwards by springs, instead of one only. But the chief defect is in the principle of the construction, which does not make the dial-indication proportional to PV as it ought to do. If R_0 be the disk radius at which the roller would stand when zero pressure existed in the Bourdon tube, and if C be the inward movement per pound per square inch rise of pressure, and if r be the radius of the roller, then at pressure P the contact radius on the disk will be $R_0 - CP$, and the fractional revolution of the disk per revolution of the roller is $\frac{r}{R_0 - CP}$. This is not proportional to P as it ought to be. Its differential coefficient with respect to P should be constant, whereas it is really $-\frac{Cr}{(R_0 - CP)^2}$. The converse gearing ought to be substituted; that is, the volume-meter should be geared positively with the disk, and the disk should drive

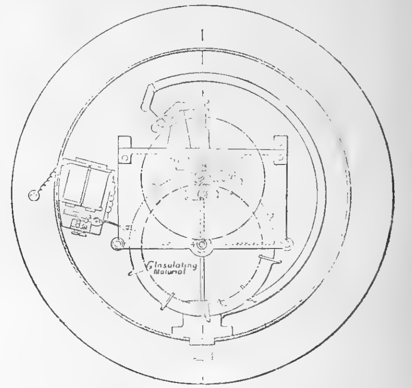

FIG. 3.

the roller, the point of contact for zero pressure coinciding with the centre of the disk. It also seems a pity, when a Bourdon tube that measures the pressure exists in any case in the meter, that its measurement of the pressure should not be made visible by the simple addition of a pointer and graduated dial.

The registrations of all the meters in the whole district are telegraphed to the central station and added up on one large central counter, so that the engineers in charge may have means of continually comparing the actual consumption with the duty of the engines, known from ordinary engine continuous counters, and of detecting any serious leakage that might occur in consequence of breakage of a main or branch pipe. The telegraphing apparatus is shown in Fig. 3. The counting disk is divided into ten equal divisions, each representing 1000 cubic feet, by small metal projections. As these come successively underneath a contact-maker, they allow the passage of a current, which moves the finger of the central counter through a corresponding division. One main wire, with branches to the separate meters, is sufficient for the whole district, the earth return being used. As the counter-disk moves slowly, special means must be taken to break the contact instantaneously after it is made; otherwise all but one of the indications of several meters, whose times of contact with the tooth on the disk overlapped, would fail to be registered at the central station, and should the stoppage of any one engine in the district happen to occur while this tooth of its meter was in contact the whole registering apparatus would cease to act for an indefinite time.

The contact-breaker is shown in Fig. 3, at the left-hand side. The momentary current caused on making contact magnetises an electro-magnet, which, by attracting its armature, draws the contact-maker (which is mounted on a piece of watch-spring) past the tooth into such a position that it catches behind a small plate of insulating material at the back of the tooth, which prevents it springing again into contact with the latter when the armature of the magnet is released.

Fig. 4 explains the calculation of the thermodynamic efficiency of this mode of transmission of power. It is drawn for unit volume of atmospheric air drawn into the air-pumps. The pressures are reckoned in atmospheres. A B C D E is the indicator-diagram showing the work done by the compressor-pump. The compression-curve C D is taken according to the law $p \propto v^{-1.2}$ because it seems probable that this index may be reached with the efficient water-cooling system adopted. The suction-line A B is taken $\frac{1}{25}$ atmosphere below atmospheric pressure. The point F is taken on the same isothermal as C; thus D F is the loss of volume consequent on the air cooling in the pipes down to atmospheric temperature. The diagram E F G H is the indicator-diagram for an engine driven by the air without loss of initial pressure below the compressor pressure, without clearance, without expansion, and with a back pressure $\frac{1}{10}$ atmosphere above atmospheric pressure. The same back pressure is used for all the other engine diagrams. The diagrams E F I K H, E F L M H, and E F N H are diagrams for engines with similar conditions, and with ratios of expansion $1\frac{1}{3}$, 2, and $2\frac{1}{2}$; that is, with cuts off $\frac{3}{4}$, $\frac{1}{2}$, and ^{2}, the last being that that brings the final pressure down to $1\frac{1}{10}$ atmosphere. The expansion-curve F I L N is taken as adiabatic. If $\frac{1}{5}$ atmosphere be lost in frictional and viscous resistance to flow through the pipes, by obstructions at bends, passage through meter, &c., or by sudden change of section of pipe, then the admission line is lowered to P Q. The effect of clearance is to cut off a part of the diagram by a vertical line at the left-hand end. This vertical line is not drawn in the diagram, because its position varies with the grade of expansion employed In calculating the following results the clearance has in each case been taken as $\frac{1}{20}$ the volume of the cylinder. The area of the compressor-diagram is 1·6, and the efficiency is in each case obtained

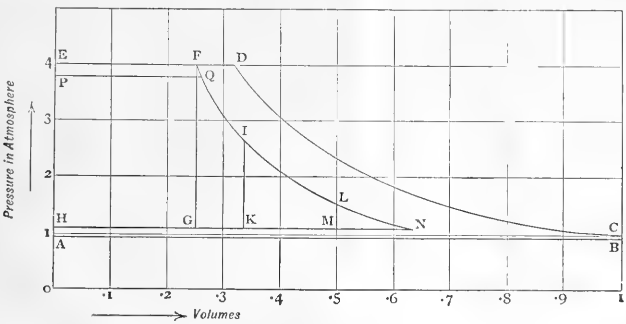

FIG. 4.

by dividing the engine-diagram area by 1·6, and multiplying this quotient by $\frac{9}{10}$. This $\frac{9}{10}$ is the ratio between the compressor-diagram and that of the central station engine which drives it, the mechanical inefficiency of this central plant being taken as $\frac{1}{10}$. The results are most clearly shown in tabular form.

Table of Efficiencies of Transmission of Power by Air compressed to 45 *pounds per square inch*

	Efficiency			
Ratio of expansion =	1	$1\frac{1}{3}$	2	$2\frac{1}{2}$
No loss of initial pressure; No clearance; Back pressure 1·1 atmos.	·45 ...	·58 ...	·67 ...	·72
Initial pressure 3·8 atmos.; No clearance; Back pressure 1·1 atmos.	·42 ...	·54 ...	·64 ...	·69
No loss of initial pressure; Clearance $\frac{1}{20}$ vol. of cyl.; Back pressure 1·1 atmos.	·39 ...	·50 ...	·57 ...	·60
Initial pressure 3·8 atmos; Clearance $\frac{1}{20}$ vol. of cyl.; Back pressure 1·1 atmos.	·36 ...	·47 ...	·54 ...	·57

The last two sections of this table comprise the limits of practicable results. The highest efficiency shown is 60 per cent. This could only be obtained by avoiding absolutely all loss of pressure between compressors and air-engine. This can hardly be accomplished even if the engine be situated close to the central works. It need hardly be pointed out that the expansion will not usually be carried so far as to bring the working pressure to near equality with the back pressure; in fact, to do so is decidedly very bad practice, and does not lead to economy in the brake-power, especially when depreciation and interest on first cost of the engine is taken into account. With good management, from 30 to 50 per cent. efficiency may be expected.

In a paper read by Mr. Sturgeon before the British Association last summer, he gives a table of calculated efficiencies ranging from ·32 to ·84. These calculations include allowances of 2 per cent. for valve-resistance and leakage past compressor-piston; 13 per cent. for leakage, friction, and wire-drawing in the pipes; and 8 per cent. for clearance and back pressure in the consumer's engine. Except the last, these allowances are much more liberal than those that have been made in calculating the above table. On the same basis as ours have been made, Mr. Sturgeon's calculations would have given considerably higher figures than the above ·32 to ·84. But the higher figures in Mr. Sturgeon's table are obtained by supposing that the consumer heats the air by a gas-stove, before passing it into his engine, up to temperatures from 212° F. to 320° F. How the resulting figures can be in any sense called "efficiencies" it is difficult to understand. The consumer is supposed to supply a large extra amount of power at his own cost by burning gas to heat the air, and it seems an extremely evident misuse of the word "efficiency" to apply it to the ratio of the diagram so got to the diagram of the central station engine. By a little more liberal burning of gas, the efficiency obtained by this method could quite easily be made higher than unity. On the same principle we might calculate the efficiency of a steam-engine by taking the ratio of the indicator-card from the steam cylinder to that taken from the feed-pump that supplies water to the boiler, and thus obtain an efficiency of, let us say, 50,000 per cent. This is a *reductio ad absurdum* of the method of calculation which is perfectly legitimate and logical. R. H. S.

THE CLASSIFICATION OF THE CÆCILIANS

IN a paper on the structure and affinities of the Amphiumidæ, published in the newly-issued part of the Proceedings of the American Philosophical Society (vol. xxiii. No. 123), Prof. Cope has put forward some views as to the position of the Cæcilians or Apodous Batrachians in the Systema Naturæ, which are worthy of careful consideration. The Cæcilians, Prof. Cope observes, are generally regarded as representing a distinct order of the Batrachian class, which bears the name "Apoda," or "Gymnophiona." The definition of this order given by Mr. Boulenger in his recently published Catalogue of the specimens of these animals in the British Museum is: "No limbs; tail rudimentary; males with an intromittent copulatory organ; adapted for burrowing." Of these definitions Prof. Cope maintains that not one is of ordinal value. "The tail in some Cæcilians is distinct. The intromittent copulatory organ in such species as *Dermophis mexicanus*, *Gymnophis proximus*, and *Herpete ochrocephala* is not a special organ, but merely the everted cloaca. The hard papillæ observed by Günther in *Ichthyophis glutinosus* are wanting in the above-mentioned species, and the protrusion of the cloaca is performed by two special muscles."

As regards the absence of limbs in the Cæcilians, Prof. Cope points out that the extremely rudimentary character of these organs in *Amphiuma* is well known, and that their non-existence has no greater claim to be considered as of ordinal value in the Batrachians than in the adjoining class of Reptiles, where it is in some cases not even a "family" character. Looking to these facts, Prof. Cope proposes to unite the Cæcilians with the Urodele Batrachians, and to class them only as a family, "Cæciliidæ," connected with the more typical forms of the group through the Amphiumidæ.

Messrs. Sarasin, who have recently published a most interesting account of their observations on the development of a species of Cæcilian in Ceylon,[1] seem to have come to nearly the same conclusions as to the correct systematic position of this group of Batrachians.

NOTES

THE Prince of Wales has requested the President of the Royal Society to join the Committee appointed to advise on the organisation of the proposed Imperial Institute.

WE have referred elsewhere to some of the possible results of the meetings held last week in favour of the Imperial Institute. Some very striking features which have been developed in connection with this movement during the last week are, first of all, the considerable desire which has been evinced to enrich various localities with some Jubilee memorial, and, again, the wisdom generally displayed in selecting worthy local objects, such as museums, improved science schools, and the like. All this of course is admirable and entirely to be applauded, but believing as we do that there is a possibility of the Imperial Institute, if properly conducted, doing more good for the future development of science and commerce in Greater Britain than any other single organisation can possibly effect, we hope that it will not be starved in favour of merely local objects. We hear that the women of England have already subscribed a noble sum. This no doubt Her Majesty will hand over to the Institute, if it is organised so as to command the confidence and respect of the various leaders of opinion in this country and in the colonies.

MANY of our readers will attach much importance to Colonel Donnelly's letter, which appears in another column. A large increase in the number of students anxious to enter the Normal School of Science and Royal School of Mines was of course to be expected, and we are glad that this influx has induced the department to take steps to increase the accommodation, and at the same time to insist upon one of the best possible forms of entrance examination; a strict inquiry, namely, into the educational history of each candidate for admission.

THE Norwegian Government has presented a Bill to the Storthing for fixing a standard time for the whole of Norway. The standard time proposed is Greenwich time *plus* one hour.

MR. W. BALDWIN SPENCER, Fellow of Lincoln College, Oxford, has been appointed to the Chair of Biology in the University of Melbourne, and will leave England in about three weeks. Mr. Spencer distinguished himself lately by his important memoir on the pineal eye in lizards.

A NUMBER of eminent men of science have addressed a memorial to the President, Vice-Presidents, and Council of the Royal College of Surgeons of England, suggesting that the legacy bequeathed to the College by the late Sir Erasmus Wilson might with advantage be devoted to the establishment of an institution having for its object "physiological and pathological research." It is pointed out that the want of such an institution in England has long been felt, and more especially of late, when we have had to look to Berlin for information respecting tubercle, and to Paris for experiments on the prevention of hydrophobia. That the Government will do anything in the matter no one is so sanguine as to believe; and it is hardly more probable that the want will ever be supplied by public subscription. There is, therefore, much to be said for the present proposal, and the authorities of the College of Surgeons will, no doubt, give it due attention. It seems strange that in London there should be nothing like the splendid laboratories which exist not only in the capital cities of Europe, but in comparatively small German towns, such as Bonn, Strasburg, and Leipzig.

UNIVERSITY COLLEGE, Liverpool, has reason to congratulate itself on having some remarkably generous and enlightened friends. On Tuesday last it was announced at a meeting of the College Council that Mr. Thomas Harrison, shipowner, of Liverpool, had endowed the Chair of Engineering with 10,000*l*. Only a few weeks ago Sir Andrew Walker, also a citizen of Liverpool, gave 15,000*l*. to build Engineering Laboratories.

ON Thursday last the honorary freedom of the City of London was conferred upon Mr. H. M. Stanley, in recognition of his services as a traveller and explorer in Africa. The presentation was made at a special meeting of the Court of Common Council in the new council chamber at the Guildhall. The City Chamberlain, in making the presentation, referred to "the remarkable development of journalistic enterprise during the Victorian era," observing that Mr. Stanley was the first member of "the

[1] "Ueber die Entwicklungsgeschichte von *Epicrium glutinosum*," Arb. Zool. Inst. Würzburg, vii. p. 292 (1885).

class of special travelling and war correspondents" whom the City had enrolled among its freemen. Mr. Stanley was evidently much pleased by the honour done to him, and declared that it would stimulate him to further exertions. After luncheon at the Mansion House, he spoke of the various routes which have been proposed for the expedition for the relief of Emin Pasha.

MR. ALFRED RUSSEL WALLACE lately delivered, at Boston, U.S.A., a course of "Lowell Lectures." He proposes to make a Western tour, in the course of which he will lecture on, among other subjects, "The Darwinian Theory: What it is, and How it is Demonstrated," "The Origin and Use of the Colours of Plants," "The Permanence of Oceans, and the Relations of Islands and Continents," and "The Biological History of Continental Islands, Recent and Ancient." Mr. Wallace is thought by the Americans to be a more effective speaker than most of the eminent Englishmen who have lectured in the United States.

THE Indian Survey Staff seems to be considerably undermanned. The Government of the Straits Settlements recently applied to the Government of India for an experienced officer to advise them on the way of placing the system of survey in the colony on a satisfactory footing. As no qualified officer on the former establishment was available, Mr. J. B. N. Hennessey, now on the retired list, was offered the duty, but as he declined it the Straits Settlements Government had to be told that the Government of India could render no assistance on a work so necessary to the development of the colonial resources, and likely to be of so much service to science.

A MOVEMENT is on foot at Gothenburg for the founding of a free University in that city. A large sum of money has already been subscribed.

THE results of the new censuses of France and Germany show a marked falling-off in the rate of increase. In the case of France the rate of increase was low enough before; now it threatens to stop altogether, and in many departments there has been a considerable decrease. The addition to the population in five years has only been 213,857, bringing the total up to 37,885,905. This is equal to an annual rate of only ·1 per cent. per annum. Germany is not quite so bad, but the rate of increase between 1870 and 1880 was abnormally high. The population by the latest returns is 46,844,926 as compared with 45,234,061 five years before; giving an annual rate of increase of ·71 per cent. per annum in 1880-85, as compared with 1·14 per cent. per annum in the previous five years.

THE Lieutenant-Governor of the Punjab has proposed to the Government of India the establishment of a University at Allahabad, and has furnished a scheme for such an institution in the capital of his province.

AT the afternoon sitting of the Association for the Improvement of Geometrical Teaching, held at University College, on the 14th inst., the President (R. B. Hayward, F.R.S.) in the chair, the Rev. G. Richardson, of Winchester College, read a paper on the teaching of modern geometry, in which he indicated the lines which, in his opinion, a Syllabus on the subject should follow. The draft, which covered an extent of ground too great, we think, for ordinary school-teaching, did not consist of a bare enumeration of the subjects of sections and chapters, but was rendered very interesting by the quaint humour which lightened up and pervaded the whole. The Rev. J. J. Milne read a short note on a part of the above subject, which had been omitted by the previous speaker, viz. the modern treatment of maxima and minima; his strong point was the light to be derived from symmetry in the search for cases of maximum and minimum. Mr. G. A. Storey, A.R.A., read a paper on "Geometry from the Artist's Point of View." In this the writer introduced Euclid and Apelles in converse, and showed the agreement which exists between the purely geometrical method and perspective. The paper was illustrated by numerous drawings of triangles, squares, and cubes. A brief discussion of the several papers followed, and then Mr. E. M. Langley communicated a very simple proof of Feuerbach's theorem (that the nine-point circle touches the in- and ex-circles of the triangle). We may return to the consideration of one or more of the above papers when they have been printed in the Association's Report. Upwards of twenty new members were elected.

WE have received a hand-book entitled "Through the British Empire in Ten Minutes with C. E. Howard Vincent, Esq., C.B., M.P." It is intended to accompany a wall-map on which Mr. Vincent has brought together a large amount of useful information about the British Possessions. In his hand-book he glances at the leading characteristics of each of the great groups into which the Empire beyond the seas is divided.

A STATE weather-service for Pennyslvania is to be formed at Philadelphia by the Franklin Institute. The State Legislature will be petitioned for an appropriation of 3000 dollars for instruments and publications, and it seems to be assumed that so reasonable a request will be readily granted.

THE Americans also have a Society for Psychical Research. The Society proposes to issue the next number of its Proceedings as soon as sufficient material can be collected. Apparently it is not quite so easy to get startling evidence of the "psychical" kind in the New World as in the Old.

DESCRIBING in an American medical journal the influence of the recent earthquake shocks in Charleston upon the health of the inhabitants, Dr. F. Peyre Porcher, of that city, says that many persons experienced decidedly electrical disturbances, which were repeated upon the successive recurrence of the shocks. These disturbances were generally accompanied by tingling, pricking sensations, like "needles and pins," affecting the lower extremities. One gentleman was completely relieved of his rheumatism; another, who for months was nervous, depressed, and entirely unable to attend to business, regained his former activity and energy.

AN interesting sketch of the great Serpent Mound in Ohio is given in *Science* by Mr. W. H. Holmes. It is in the northern part of Adams County, somewhat remote from frequented routes of travel. The entire body of the serpent and the peculiar features of the enlarged portion are all distinctly traceable, and leave no doubt in the mind, Mr. Holmes thinks, as to their artificial character. He is decidedly of opinion that the work should be classed among the products of the religion of the aboriginal races.

MR. J. H. STEWART LOCKHART, of Hong Kong, has addressed, on behalf of the Folk-Lore Society of England, an appeal in the English and Chinese languages, through the press, to students throughout China to co-operate in investigating the folk-lore of that country. He points out that no attempt has been made to deal with this subject as a whole, the work done so far being for the most part of a local character. He now proposes to obtain collections of the lore peculiar to different parts of the empire and its dependencies. Each collection, he goes on, while in itself highly instructive, will be chiefly important as forming a link in the chain of facts from which a general account of the folk-lore of China may be deduced. The Chinese version of the appeal is intended for circulation amongst natives, who, "experience shows, evince a great interest in the subject when once they comprehend its aims and objects." Competent scholars are scattered over the greater part of China, and, as

Mr. Lockhart says: "If willing helpers can be found to assist in the work of collection, the success of the scheme is assured. Failure can only result from want of co-operation and support."

IN a paper entitled "Thirty-six Hours' Hunting among the Lepidoptera and Hymenoptera of Middlesex," reprinted from the *Journal of Microscopy and Natural Science*, Mr. Sydney T. Klein has some interesting notes on the best methods of capturing Lepidoptera. He has found it very useful to take advantage of "the attractiveness of the ladies among the Lepidoptera gentry." To those who have not had experience, or have not persevered in, this art, he says, the result is truly marvellous, and will sound very much like a fairy tale. The good taste possessed by the males of Lepidoptera is shown to the greatest perfection among the Bombycidæ. On several occasions, when on botanical excursions in Hertfordshire, Mr. Klein has taken with him a female of *Bombyx quercus*, or other Bombycidæ, fresh from the pupa; and, in a wooded country, provided the sun was hot and a gentle breeze blowing, he was certain of having, within ten minutes, a dozen of the opposite sex flying round him, and from time to time even settling on his shoulders or hands. On one occasion, after remaining, as an experiment, for some time on the same spot, he counted over forty of these large moths within fifty yards.

NEGOTIATIONS are being carried on in Denmark for the holding of a Fisheries Exhibition in Copenhagen next year.

AN enthusiastic fish-culturist is trying to introduce scaleless fishes into English fresh waters. In a lecture on Fish, lately delivered at Worcester, and now published, Dr. Francis Day, C.I.E., expresses his belief that they will prove worthless for sport, almost, if not entirely, useless as food, and dangerous to handle on account of the spines with which they are protected. These fishes delight to eat other forms of fish-life. "I obtained," says Dr. Day, "a specimen of a common Indian catfish at Madras, which I placed in an aquarium that contained some carp. It rushed at one of my poor little fishes, and, before I could interfere, seized it by the middle of its back and shook it until it was dead, as a dog kills a rat."

AT the monthly meeting of the Council of the Sanitary Assurance Association on January 10, the Sanitary Registration of Buildings Bill was re-considered. A report on the draft Bill was submitted, with several clauses re-drawn. The Bill was further amended, and ordered to be printed for final consideration at the next meeting of the Council. It is proposed that the new Bill shall be compulsory with regard to schools, hotels, asylums, hospitals, and lodging-houses, and Clause 6 has been made much more stringent in the matter of qualification of persons entitled to give sanitary certificates.

BARON VON MUELLER, who retains the office of Government Botanist to the colony of Victoria, is about to issue a series of plates with descriptions of the acacias (wattles) of Australia. The work will be similar to the "Eucalyptographia," probably the best and most useful of his publications. For diagnostic purposes he makes use of two characters hitherto overlooked, viz. the number of divisions in the pollen-mass and the position of the seed. The retirement of Baron von Mueller from the direction of the Botanic Garden, some few years since, has enabled him to devote more attention to scientific botany and its applications to practical purposes.

DR. GILES, who was attached as scientific member to the Chitral-Kafirstan Mission, is now stated to be in Calcutta, engaged in writing a report on the geology of that region.

CAPT. PEACOCKE, R.E., is said to be preparing a report, with sketches, of his experiences with the Afghan Boundary Commission.

ON Thursday evening last the Society of Telegraph-Engineers and Electricians held the first general meeting of the session of 1887. Sir Charles T. Bright, the new President, delivered an address on the history of the electric telegraph. Speaking of the progress which has been made since the property of the Telegraph Companies was bought by the State, he said that in 1870, when the transfer was completed, there were 48,378 miles of land wires, and 1622 miles of cable wires (irrespective of railway wires), connecting together 2488 telegraph stations. Now the Post Office has 153,153 miles of wire (including submarine wires) in communication with 5097 offices. In addition, the railway companies have 70,000 miles of wire, making a total of 223,153 miles.

THE additions to the Zoological Society's Gardens during the past week include a Red-fronted Lemur (*Lemur rufifrons* ♂) from Madagascar, a Vervet Monkey (*Cercopithecus lalandii* ♂) from West Africa, presented by Mrs. Pawelzig; a Patas Monkey (*Cercopithecus patas* ♀) from West Africa, presented by Mr. George Ellis; a Common Otter (*Lutra vulgaris*), British, purchased.

OUR ASTRONOMICAL COLUMN

NEW VARIABLES IN CYGNUS.—A new variable of the Algol type (D.M. + 34°, No. 4181, R.A., 1887·0, 20h. 47m. 32·5s., Decl. 34° 13′ 59″·5 N.), has been discovered by Dr. Gould. Its period is about three days in length, and it varies from 7·1 mag. to 7·9 mag. A minimum occurred at about 10h. 19m. G.M.T. on January 17. This discovery raises the number of stars of the type to eight, the other seven being Algol, period 2·49d.; λ Tauri, 3·95d.; S Cancri, 9·48d.; δ Libræ, 2·32d.; U Coronæ, 3·45d.; U Cephei (D.M. 81°, No. 25), 2·49d.; and U Ophiuchi (DM + 1°, No. 3408), 0·839d.

Mr. S. C. Chandler, Jun., in a note in Gould's *Astronomical Journal*, No. 148, calls attention to a new short-period variable very close to the above. This star (Lalande 40083, R.A., 1875·0, 20h. 38m. 30·2s.; Decl. 35° 8′ 24″·6 N.) varies from 6·3 m. to 7·6 m. in a little over fourteen days, the increase occupying about four days, the decrease ten days, with a halt in the latter about midway of its course. Mr. Chandler gives for first elements of the star, 1886 October 3·60 G.M.T. + $14^{d}·04$ E.

NEW MINOR PLANET.—Prof. C. H. F. Peters, at Clinton, discovered a new minor planet on December 22. This will be No. 264, and the forty-sixth discovered by Prof. Peters.

A NEW METHOD FOR THE DETERMINATION OF THE CONSTANT OF ABERRATION.—In the *Comptes rendus*, tome civ. No. 1, M. Loewy explains how the principle of his method of determining the amount of astronomical refraction (NATURE, vol. xxxiii. p. 303) can be applied to the determination of aberration also. By means of the two reflecting surfaces forming the double mirror placed in front of the object-glass of an equatorial, the images of two stars situated in different parts of the sky appear, in the field of view, side by side; their angular distance is then to be measured in a known direction. To obtain the amount of aberration it is, of course, necessary to measure a properly chosen pair of stars at successive epochs. The first observation is to be made when the stars are at the same height above the horizon, and the second, after a certain interval, under similar conditions. The comparison of the two measures will give a multiple value of the aberration which is independent of instrumental errors. By a proper choice of the angle of the double mirror employed, of pairs of stars selected for measurement, and of the circumstances of observation, M. Lœwy contends that, by attention to the details which he specifies, a more accurate value of the constant of aberration can be obtained by his method in an interval of three months than could be deduced by the methods hitherto in vogue, liable as these are to systematic error.

THE MADRAS OBSERVATORY.—In his Report for the year 1885, Mr. Pogson states that the volume of telegraphic longitude determinations in India, and the two volumes of hourly magnetical observations made at Singapore between 1841 and 1845, and at Madras between 1851 and 1855, which were mentioned as ready for issue in the last Report, were distributed in 1885. Mr. Pogson's attention was chiefly directed, during the year, to the necessary preliminary investigations for the publication of the meridian-circle observations from 1862 to the present time. The formation of the star ledgers and the deduced catalogues of mean positions for each year were completed for the years 1862, 1863, and partly for 1864, which will form the first of the eight volumes about to be published. The star ledgers for the next three years—1865-67—are also in progress, for the second volume of the series. Except for time observations and determinations of positions of a few comparison stars for equatorial observations, the meridian-circle will be little used until the publication of its past results is accomplished. Only 352 complete positions of stars were determined in 1885, making 52,074 during the past twenty-four years. A few observations of minor planets were made with the equatorials during the year. We are glad to find that there is at length a prospect of the publication of the Madras meridian observations, the long delay in which has been a serious blot on the fair fame of the Observatory.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *JANUARY* 23-29

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 23

Sun rises, 7h. 54m.; souths, 12h. 12m. 4·4s.; sets, 16h. 30m.; decl. on meridian, 19° 27′ S.: Sidereal Time at Sunset, 0h. 41m.

Moon (New, January 24) rises, 7h. 14m.; souths, 11h. 40m.; sets, 16h. 9m.; decl. on meridian, 18° 13′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	7 38	11 34	15 30	23 0 S.
Venus	8 34	13 4	17 34	17 34 S.
Mars	8 49	13 36	18 23	14 36 S.
Jupiter	1 0	6 2	11 4	11 54 S.
Saturn	14 59	23 6	7 13*	22 6 N.

* Indicates that the setting is that of the following morning.

Occultations of Stars by the Moon (visible at Greenwich)

Jan.	Star	Mag.	Disap. h. m.	Reap. h. m.	Corresponding angles from vertex to right for inverted image ° °
28	4 Ceti	6	19 16	20 13	179 296
28	5 Ceti	6	19 42	20 26	196 281

Variable Stars

Star	R.A. h. m.	Decl. ° ′		h. m.	
U Cephei	0 52·3	81 16 N.	Jan. 26,	22 21	*m*
λ Tauri	3 54·4	12 10 N.	,, 24,	20 33	*m*
			,, 28,	19 25	*m*

S Cancri	8 37·5	19 26 N.	,, 24,	0 55	*m*
R Virginis	12 32·8	7 37 N.	,, 26,		*M*
V Virginis	13 22·0	2 35 S.	,, 23,		*M*
δ Libræ	14 54·9	8 4 S.	,, 24,	18 23	*m*
			,, 27,	2 15	*m*
U Coronæ	15 13·6	32 4 N.	,, 27,	19 21	*m*
U Ophiuchi	17 10·8	1 20 N.	,, 25,	3 30	*m*
		and at intervals of		20 8	
R Scuti	18 41·4	5 50 S.	Jan. 27,		*m*
β Lyræ	18 45·9	33 14 N.	,, 26,	3 0	*M*
δ Cephei	22 25·0	57 50 N.	,, 28,	1 0	*m*

M signifies maximum; *m* minimum.

Meteor-Showers

On January 28 a radiant near δ Coronæ Borealis is in evidence. The meteors from this radiant are very swift, R.A. 236°, Decl. 25° N. Another radiant giving very swift meteors lies near σ Leonis, R.A. 168°, Decl. 7° N.

GEOGRAPHICAL NOTES

It is all but certain that Mr. Stanley will lead the Emin Pasha Relief Exploration by the Congo route. He will certainly go to Zanzibar, prepared to follow whatever route circumstances may indicate as likely to prove the most successful. At Port Said he will meet with Dr. Junker, who may give him information of critical importance. At all events, Mr. Stanley and his staff and the whole of the baggage will proceed, in the first instance, to Zanzibar. If a steamer is handy, the Expedition, after recruiting a caravan and laying in a store of suitable goods for trade by the way, will sail round the Cape to the Congo; that at least is Mr. Stanley's present intention. All the available steamers belonging to the King of the Belgians will be placed at his disposal, and probably by the beginning of May he will be at the limit of navigation and ready for his land journey eastwards to Lake Albert Nyanza; if, indeed, he does not give the lake a wide berth westwards and go direct to Wadelai. A camp as a base of operations will be established, as far as safe from the Congo, and left in charge of a trustworthy member of the staff. About fifty donkeys will be taken to carry the heavy baggage, and the caravan will consist of about 100 men, with a few Egyptian soldiers to maintain discipline. The staff consists of half-a-dozen carefully selected men, among whom are two able engineer officers, under whose care the interests of science will be attended to. Four or five carefully rated chronometers and other instruments are being taken, so that we may expect some good results. It is probable that Mr. Stanley will endeavour to solve the Albert Nyanza and the Wellé-Mobangi problem, as well as other obscure points in African hydrography, on his return journey. It is to be hoped that Emin Pasha will not think of coming away, as Dr. Junker states he wishes to do; but if he does, then no doubt Mr. Stanley will be able to make arrangements to carry on the work which Emin has begun so well. Mr. Stanley leaves England to-morrow, and the good wishes of all will go with him. He is confident of being able to reach Emin Pasha by July 1, and possibly may be back in Europe about Christmas; in that case, we fear, he could not do much exploring work.

Dr. Lenz has at last arrived at Zanzibar, having taken less than eighteen months to cross the African continent from the mouth of the Congo. A fortnight ago we gave some account of his journey up the Congo from Stanley Falls to Nyangwe and Kasonge; it will be interesting to know what route he followed after leaving the Upper Congo. It will be remembered that Dr. Lenz went out eighteen months ago for the purpose, if possible, of reaching Emin Pasha and Dr. Junker. From Zanzibar the late Dr. Fischer started through Masai Land on a similar errand. In both cases the object has not been accomplished, and no wonder, now that we know the real facts. Much good work, however, has been done by both men. Dr. Lenz is a man of scientific training and experience in African travelling, and there can be no doubt that the results of his just completed journey will be a gain to science. It is possible that Mr. Stanley may meet with Dr. Lenz on his way to Zanzibar; and if so may obtain some information that will be of service on his great expedition.

The Rev. Thomas Brydges, a missionary in Tierra del Fuego, in the large island of Onisin, among the Ona and the Yagbons, mentions a curious circumstance with reference to the people, illustrating the influence of environment on the acquirement of habits. Between men and women there is a fair subdivision of labour. Among other things, the men make and fit up the canoes, but the women are the rowers. The result is that the women are good swimmers, but the men cannot swim at all. The reason is that often on the coast there is not a single tree to which to fasten the canoes. The women, therefore, after landing their husbands, have to row the canoes to a spot where sea-weed has been massed together, in order to moor the canoes thereon; after which operation they are compelled to swim back. So, also, when the canoe is wanted, the woman has to swim out for it and row back for her husband.

The current number of the *Mittheilungen* of the Geographical Society of Vienna (Band xxix. No. 10) has a large map of the route from Ango-Ango to Leopoldville, made by Herr Baumann, of the Austrian Congo Expedition, with accompanying remarks, and a comparison with other recent maps of the same part of the river. There is an interesting note by Herr Baumann on the numerical systems of the Why or Wai Negroes and of the Mandingoes. The former, although they have a writing of their own—the Mandingoes use Arab letters—have no expression in their language for 100, and use the English, while the Mandingoes, Bantus, and other tribes can count with ease up to 1000. Herr Baumann also writes on the region around Stanley Falls, and its inhabitants. The two remaining papers are mainly geological, one being on the geography of Persia, by Dr. Tietze, the other the conclusion of Dr. Diener's paper on the hypsometry of Central Syria.

EXPERIMENTAL SCIENCE IN SCHOOLS AND UNIVERSITIES

PROF. G. F. FITZGERALD, as Vice-President of the Dublin University Experimental Science Association, delivered an address at the opening meeting, held on November 23 in the Museum Buildings of Trinity College, under the presidency of the Rev. the Provost, on "Experimental Science in Schools and Universities."

Prof. Fitzgerald, at the outset of his address, dealt with the history of Universities, and showed how they gave such preponderance to book as against experimental knowledge. That had led, the Professor continued, to a dual system of education—the professional and the commercial. That gap between the classes was much to be lamented, and necessitated, from a political point of view, the desirability of having all classes educated in the same institutions. The commercial classes would not, however, enter the Universities at present, because they required to be taught useful subjects, and they would not learn the Latin and Greek now required in our Universities. From the political side of the question, he thought, they had got these results—that they must be content to have useful subjects taught in their schools and Universities if the schools and Universities were to be used by the large body in the country who were willing and able to pay for it. What they must have, if possible, was a single school and college system for all classes of the community who were able to spend the first twenty years or so of their life in education, and they ought to have a system that was complete, a training which gave both those who could not afford to go on the whole length up to twenty years, and which ought to be able to train those who desired to go on for the higher culture. Returning to the education side of the question, he insisted that almost the whole importance was as to how the subject was taught. He thought the use of the Latin Grammar had been reduced to a very good system, but he thought it was perfectly evident from the course that things were taking and the reasonableness of things, that they must teach their youth some knowledge of science. People who felt responsibility in the matter were being more and more convinced that it was not right for them to allow their children to grow up ignorant of the laws of the world in which they live. Others made answer to that that they left those laws of the world to the doctors. But how were they to know under what circumstances it was well to consult a specialist? It was very necessary for us to have a knowledge when we required to consult a doctor. Hundreds of people were killed by ignorance of the fact that dirt was the cause of disease. That was a very elementary subject. Nevertheless, people were dying every day from ignorance of that very fact; and, unless they were taught to believe in the fact that there were laws of Nature, they would not believe that dirt was the cause of disease, because they saw some people living in dirt and yet not the victims of disease. He thought that time for teaching science must be found for these two reasons—it was necessary that our youth should learn the laws of the world in which they live, and that they also should learn how to discover those laws. Unless our people were taught the laws under which plants and animals were best grown, the people of other countries would rival them in the manufacture of butter and beef, and the result would be that our people must starve. Another advantage of such training was to prevent superstition such as that of the people of Spain, who preferred the use of charms as a safeguard against cholera to the cleansing of their wells. All the classes of the country required this training—they would die without it, so they must have it.

Having shown that the cultivation of Latin and Greek was originally with the view of acquiring the information contained in the ancient books in those languages, the Professor combated the five reasons formulated by the German professoriate as to why they thought that the cultivation of Latin and Greek was so important, observing, with regard to the fourth reason—that these languages were the best varied exercise in thinking—that if the connection between words and ideas was a thing that must be taught in every system of education, his impression was that that would be a great deal better attained by describing accurately and thinking out the consequences of physical experiment. In choosing the sciences that they should teach, there were three conditions that should be fulfilled. First of all, the sciences chosen ought to be within the grasp of children, because it was highly important that the science begun with childhood should be continued on in the University days; secondly, it ought not to require any expensive apparatus, because schools and people who trained children could not be expected to buy elaborate apparatus, and children could not be expected to work with them satisfactorily; and, thirdly, he thought the sciences should be chosen so as to be concerned with a large number of the laws of the world in which we live. There were two large branches of science which included nearly all the laws of the world, namely, the physical and the biological; and, therefore, he thought it would be desirable to choose two sciences—one on the physical and one on the biological side, so that children might learn something about the laws of living things, and something about the laws of physical things. He therefore suggested chemistry and botany, and he thought the whole weight of their efforts should be devoted to trying to get the children in schools to learn the elements of chemistry and the elements of botany, for there were no other two sciences the elements of which were almost similar, and at the same time there were no other two sciences that led up to a greater number of the laws of life, nor that gave a wider and more extended view of the laws of the world in which we live. The objections to the present system of teaching a knowledge of experimental science was that it almost entirely concentrated the person's attention upon phenomena instead of upon reasoning. Therefore, in choosing their system of teaching, all their weight ought to be thrown into making sure that their plan had the effect of making the child learn to think a good deal. Another thing they had to consider was the enormous time that children were made to remain in school without being engaged in anything except mischief. He thought a child should not spend more than four hours a day at literary work. Well, that occupied but a small part of a child's day; and one of the great advantages of having experimental subjects introduced into school teaching would be that they were subjects at which a child could work without experiencing very much fatigue. He could not help calling attention to the flagrant abuse of the teaching of experimental science in Irish schools. Experimental science in Irish schools was very nearly the same as snakes in Iceland. Having pointed out the fallacy of an examination—as exemplified in the Intermediate Education system—that was satisfied with a reading of the musical signs unwedded to a knowledge of the sounds they represented, the Professor said it would be an enormous advantage if the Intermediate Commissioners could be induced to keep up a peripatetic system of periodical examinations that would insist upon practical knowledge. That, however, should not interfere with the giving of papers also. After observing that it was at the present time impossible to carry out a proper examination in laboratory work, and stating that he considered it would be very desirable that the actual work in the laboratory and analyses in practical subjects should count towards the University prizes, Mr. Fitzgerald said he considered that the present system of analysis was not very satisfactory, and he urged the introduction of a system that would teach chemistry practically. Though that might be harder to teach than Latin and Greek, it would not be so if they had a system worked out and teachers to promote it, and it would have the inestimable advantage that, in addition to training the child to think—which he thought it would do equally well with Latin and Greek—it would teach him the laws of things, and how to see and learn the laws of things. It would also teach the child to use language to express real ideas, and not merely phrases. They would also learn a good deal more of the laws of language from a modern language that they learned with the grain than they would by learning an ancient language against the grain. He thought that literature and history were co-ordinate with science, and they certainly ought to be a large part of education. Literature and history were grievously neglected in the present day—practically they had no place, and that was substantially because Latin and Greek were supposed to be a literary education. One of the reasons was that those subjects were hard to examine in, but there was an easy way out of that difficulty in Universities. They need not examine, but they could require attendance at lectures—attendance on good lecturers; and the student would pick up more culture and would be obtaining a better literary education from hearing a good lecturer and being inspired by his enthusiasm than he would get by learning off one of Shakespeare's plays, and answering it at an examination. Those two aspects of education, the literary and scientific, were often put in opposition, just as the freedom of the individual and the power of the State to control the individual were very often set up in opposition to one another; but he did not think any one would believe that that opposition really arose, for the freest States were those in which the power of the State was the strongest. In conclusion, he would say that we must equip our youth for the battle of life physically and ethically. The present is a great crisis in Irish education. There is danger of science schools starting, and all the evils of dual education. There are a large body who like Latin and Greek, because they exclude literature and history. These are to be fought tooth and nail. There are those who would sacrifice the rising generation on an altar of so-called culture to starve and die, with their only comfort that they can describe their agony in well-expressed phrases. There are those who would grind all soul out of mankind in a mill of manual labour, constructed on scientific principles. All those are to be guarded against. We must have literature and history. We must have knowledge of the laws of the world in which we have to work. We can have both if we will but work out a reasonable system of education, instead of pretending that the lop-sided corpse that occupies our schools and Universities is a well-developed, symmetrical giant.

ABORIGINAL ART IN CALIFORNIA AND QUEEN CHARLOTTE'S ISLAND

IN the fourth volume, recently issued, of the Proceedings of the Davenport Academy of Natural Sciences there is a valuable article by Dr. W. J. Hoffman on "Aboriginal Art in California and Queen Charlotte's Island." In the summer of 1884 Dr. Hoffman visited the Pacific coast for the purpose of continuing his researches on primitive art, and he was fortunate enough to find a number of localities in which there are painted and "etched" records, of considerable interest, made by Indians belonging to tribes now unknown. These records occur in groups. One group, the first described by Dr. Hoffman, is in the neighbourhood of Santa Barbara. The best preserved paintings in this series are in a cavity which measures about twenty feet wide and eight feet high. The rock consists of gray sandstone, but the ceiling and back portion of the cave have a yellowish appearance. The colours employed were red ochre, white, and bluish black. Some of the paintings Dr. Hoffman takes to be representations of gaudily-coloured blankets. In several instances a grotesque human figure is drawn over or in front of what seems to be a blanket, as if the latter were intended as a body blanket or serape. In the Azuza cañon, about thirty miles north-east of Los Angeles, Dr. Hoffman examined a second series of painted records. Rudely sketched human figures are represented as pointing in certain directions, and the intention evidently was that they should serve as guides to travelling parties. For instance, the left arm of a figure on a white granitic boulder points towards the north-east. The precipitous walls of the cañon make egress in that direction impossible, but two hundred yards further on the cañon makes a sharp turn towards the north-east, and in rounding the point of land to the right the traveller comes to another boulder, on which are numerous faint drawings of various kinds. This boulder is on the line of an old trail leading from the country of the Chemehuevi, on the north of the mountains, down to the valley settlements of San Gabriel and Los Angeles. A third series of records was found in the southern part of Owens Valley, California, between the White Mountains on the east and the Benton Range on the west. They are "etched," not painted. The most common characters in this group are circles, either plain, nucleated, bisected, concentric, or spectacle-shaped, by pairs or threes, with various forms of interior ornamentation. This group resembles etchings in the Canary Islands so closely that the illustrations given by Dr. Hoffman serve for both localities. On one of his plates he presents a number of circles with ornamented interiors, from a simple bisection to the stellate and cruciform varieties. Similar circles bearing cross-lines occur at Grevinge, Zeeland; and other forms resembling some at Owens Valley are found at Slieve-na-Calliagh, Grange, and Dowth, in Ireland. The spectacle-shaped variety resembles the mysterious symbol on some Scottish monuments which has given rise to so much vague speculation. The reversed Z, however, is wanting in the Californian examples. Of the various outlines of the human form presented by Mr. Wallace from Brazil, and referred to more recently by Prof. Richard Andree in "Ethnographische Parallelen und Vergleiche," a considerable number are almost identical with etchings in the Owens Valley series. Many of the characters in these three Californian groups are similar to, and some are indistinguishable from, those made by the Moki and other tribes of the Shoshonian linguistic stock. Further research on the same lines may, therefore, enable anthropologists to determine the former geographical area of the Shoshonian family, as has already been done in the case of the Algonkian tribes.

In the neighbourhood of Los Angeles Dr. Hoffman obtained a portion of an old Indian gravestone. On this slab there are incised characters which seem to represent a whale-hunt, and no doubt they were intended to denote the occupation of the person to whose memory the tablet was erected. Honour is done to the dead in a similar manner by the Innuit of Alaska and by the Ojibwa. Among the Innuit, the posts erected for men usually bear rude drawings of weapons and animals; those for women have representations of household utensils and implements. On Ojibwa gravestones, as Mr. Schoolcraft has noted, the totem of the deceased is drawn in an inverted position.

Dr. Hoffman offers some interesting remarks on the subject of tattooing. In former times, in the vicinity of Los Angeles, every chief caused the tattooed marks upon his face to be reproduced upon trees or poles which indicated the boundaries of his land; and as these marks were well known to neighbouring chiefs, they were a sufficient warning that trespassers would be punished. A custom akin to this prevails in Australia, where the tattooed designs upon the face of a native are often engraved upon the bark of trees near his grave. Among many of the tribes west of the Mississippi there are still numbers of persons who bear tattoo marks upon the chin, the cheeks, and even upon other parts of the body, but the marks seldom occur in any forms other than narrow lines, except among the Haida Indians of Queen Charlotte's Island, where the art of tattooing has reached a higher degree of development than on the mainland. The Haidas tattoo upon the back, breast, fore-arms, thighs, and the legs below the knees; and women submit to the operation as well as men. The characters are totemic, and represent either animate or mythologic beings. They are usually drawn in outline, with interior decorative lines, red being sometimes introduced to form what is supposed to be a pleasant contrast. The ceremonies at which the tattooing is done are held in the autumn, and extend over a period of several weeks. Among the figures generally adopted are the thunder-bird, raven, bear, skulpin, and squid. A former Factor of the Hudson's Bay Company told Dr. Hoffman that when he first went to the country occupied by the Haida Indians he saw no tattooing upon the bodies of the older members of the tribe; and he contends that they have learned the art from natives of some of the South Pacific Islands, which they occasionally visit as traders.

The Haidas display considerable skill as carvers in wood and slate. Totem posts are often placed before the council-houses, and more frequently before private dwellings. When the posts are the property of some individual, the personal totemic sign is carved at the top. Other animate and grotesque figures follow in rapid succession down to the base, so that unless one is familiar with the mythology and folk-lore of the tribe the subject would be utterly unintelligible. On one post to which Dr. Hoffman refers there are only seven pronounced carvings, but they relate to three distinct myths. On household vessels, the handles of wooden spoons, and other objects, the Haidas often carve the head of a human being in the act of eating a toad. Sometimes the toad is placed at a short distance below the mouth. The idea is that in the wooded country there is an evil spirit who has great power of committing evil by means of poison extracted from the toad. The Indians are not willing to acknowledge the common belief in this mystic being, even when they are aware that the inquirer is in possession of the main facts.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The long-expected reform of the examination system which makes it unnecessary for men reading mathematics and natural science to pass any examinations of a non-scientific character after coming into residence has at last been accomplished. The arrangement, which comes into force with the beginning of this year, is that candidates for degrees in mathematics and natural science take up responsions (or some equivalent examination at school) like other people, but by passing in one extra subject they are excused the second classical examination, in preparing for which they used to waste a good part of their first year of residence. The extra subjects from which candidates may choose include Greek, Latin, French, and German authors, Bacon's "Novum Organum," and the elements of logic. This alteration will be an undoubted benefit to science men, for, as the new examination involves no preliminary residence and occurs four times a year, they can proceed at once to take up the subject which they have chosen for their final schools.

The following courses of lectures and practical classes are announced for this term :—

Prof. Pritchard is to lecture at the Observatory on "Planetary Theory" and on "Astronomical Instruments and Methods," and offers practical instruction. Prof. Bartholomew Price lectures at the Museum on "Optics."

At the Clarendon Laboratory Prof. Clifton continues his course on "Electricity," and Mr. Walker lectures on "Double Refraction treated Mathematically." The practical work remains in the hands of the Professor, Mr. Walker, and Mr. Selby. Sir John Conroy, who has undertaken Mr. H. B. Dixon's work at Balliol and Trinity, lectures on "Elementary Electricity."

In the Chemical department Prof. Odling will lecture on the "Benzoic Compounds"; Mr. Fischer and Mr. Watts continue their systematic courses on "Inorganic" and "Organic Chemistry" respectively. Mr. C. J. Baker and Mr. Marsh assist in the laboratory teaching. In Mr. Vernon Harcourt's laboratory at Christ Church and in the Balliol Laboratory the usual work is to be carried on.

The arrangements in the department of Morphology have been somewhat disturbed by the appointment of Mr. Baldwin Spencer to the Biology Professorship at Melbourne. Prof. Moseley is to lecture on the "Comparative Anatomy of the Vertebrata," and is to have Mr. G. C. Bourne as Assistant Lecturer and Demonstrator. Mr. Barclay Thompson lectures on the "Osteology and Distribution of the Ichthyopsida."

In the new Physiological Laboratory, Prof. Burdon Sanderson lectures on the "Physiology of the Nervous System," Mr. Dixey on "Histology," and Mr. Buckmaster gives an elementary course of Physiology for the newly-organised preliminary examination. Practical instruction is given in Physiology by Mr. Gotch, in Histology by Mr. Dixey, and in Physiological Chemistry by Mr. Haldane.

Quite a number of men are beginning to read for the new Medical School. The dissecting-room is under the charge of Mr. Arthur Thomson, who lectures on the "Digestive System."

Prof. Prestwich is to lecture chiefly on "Ternary and Quaternary Geology," including the Glacial period and questions relating to the antiquity of man. Prof. Westwood lectures on the "Arthropoda."

At the Botanic Garden, Prof. Bayley Balfour lectures on "Vegetable Morphology and Physiology," and has both elementary and advanced instruction in practical Botany.

The Pitt-Rivers Anthropological Collection is now so far arranged that the formal opening will probably take place this term. All the cases on the ground floor of the new building have been arranged by Mr. Balfour. Dr. Tylor is to lecture on the "Development of Arts" as illustrated by the collection.

Next week the annual examination for a Radcliffe Travelling Fellowship begins.

SCIENTIFIC SERIALS

Bulletins de la Société d'Anthropologie de Paris, tome 9ème, 3ème fascic. 1886.—On the relations between the organs of touch and smell, by Dr. Fauvelle. In this paper the author considers the proposition advanced by M. Pozzi that the attitude of an animal is always in accord with the exercise of its predominant organ of sense. On this assumption the biped station would be the consequence of the predominance of vision over smell, and the attitude of quadrupeds the result of the relatively higher development of their sense of smell. In refutation of this view the writer argues that the relations between the organs of sight and smell in bipeds and quadrupeds are the result, rather than the cause, of their different stations, while he shows that wherever in the animal series the organs of sight would seem to have lost their importance in proportion to the development of the sense of smell the latter is aided by delicate organs of touch situated on those parts of the body which form its anterior side when moving forward. Thus in the vertebrates all the organs of the senses are situated at the cephalic extremity of the body.—On a woman with a tail. The case, reported by M. Melikoff, was observed by Dr. Eliséeff, of St. Petersburg, author of an interesting work on men with tails. According to the statement of the woman, who suffered great pain from her caudal appendage, a similar abnormality had been observed in several female members of her family, in all of whom it had appeared between the ages of 12 and 17 years. Dr. Eliséeff refers this formation to embryogenic causes, such as an arrest of development in the fœtus, and observes that such cases are more frequent in males than in females, the latter, according to him, presenting a much more advanced corporeal development than men.—A case of double uterus, by Dr. Landowski.—On short-tailed dogs, by M. Duval.—Observations on the crania of several insane subjects, by M. Manouvrier.—On the weight of Gambetta's brain, by M. Duval. This paper, and the discussion to which it gave rise, are especially interesting from the new light which they throw on the assumed relations between the large volume of the brain and intellectual capacity, the weight of Gambetta's being only 1160 grammes, or, according to M. Duval, 1246 after making all possible allowance for accidental diminution by faulty methods of preparation, while the mean for persons not gifted with more than ordinary intelligence is 1360 grammes.—On a new variation of the ossa wormiana, by M. Manouvrier.—A case of pilosity in a young Laotian girl, by Dr. Fauvelle.—On acclimatisation in reference to French colonisation, by Dr. Fauvelle.—On the anthropological characteristics of the Indo-Chinese peoples, by Dr. Maurel.—On the origin of the bronze and tin of prehistoric times, by Mme. Clémence Royer. The writer believes that Europe supplied the sources whence bronze implements were fabricated by early man, while M. Mortillet considers that both the material and the production of the weapons, ornaments, and other objects of this kind which belong to prehistoric times must be referred to India and the Far East.—Enumeration of the megalithic remains of Nièvre, by Dr. Jacquinot. The number of such remains in the whole of France, as certified by official inquiry, amounts to 6310, of which thirty-five belong to Nièvre. Among these special interest attaches to the horizontal slabs of Saint Agnan, which Dr. Jacquinot considers to have been altars for human sacrifices.—Summary of the answers given by New Caledonians to the interrogatories of the Society of Sociology and Ethnography, by M. Moncelon. These answers supply interesting materials for the ethnographic study of these races, and show the importance of following a definite plan in pursuing such inquiries.—Anthropological observations of the Khmer tribes of Cambodia, by Dr. Maurel. The writer, who supplies numerous anthropometric measurements, believes that these peoples belong to the Mongolian group.

Rendiconti del Reale Istituto Lombardo, November 11, 1886.—Meteorological observations made at the Brera Observatory, Milan, during the months of August and September.

November 25.—Results of the experiments carried out at the experimental farm of the Royal Milanese School of Agriculture against the mildew of the grape-vine, by Prof. Gaetano Cantoni. Of the various methods of treatment here described, the preparation of a sulphate of copper dissolved in water in the proportion of three per thousand is shown to be the most efficacious. The analysis of the wines obtained from crops so treated shows that they usually contain a scarcely appreciable quantity of the copper.

Bulletin de l'Academie des Sciences de St. Petersbourg, tome xxi. No. 2.—Report on a memoir by M. Harzer on a special case of the problem of the three bodies, by O. Backlund. It is considered a most valuable work, being the first attempt to apply the method of Prof. Gyldén.—New transcription of the Castrén's Koibal dictionary and Koibal poetry, made by M. Katanoff (who is himself of Sagai origin), from the Abakan, with a preface by W. Radloff.—Photometric researches on the diffusion of light, by O. Chwolson, being numerical data of new experiments mathematically treated.—Hydrological researches, xlv. to xlvii., by C. Schmidt.—Chemical analyses of water from lakes in North-west Mongolia and in North Tibet.—On a differential equation, by B. Ichmenetzky.

SOCIETIES AND ACADEMIES

London

Royal Society, November 25, 1886.—"On the Dynamical Theory of the Tides of Long Period." By G. H. Darwin, LL.D., F.R.S., Fellow of Trinity College, and Plumian Professor in the University of Cambridge.

Laplace sought to show that, as regards the oscillations of long period, called by him "of the first species," friction would suffice to make the ocean assume at each instant its form of equilibrium. His conclusion is no doubt true, but the question remains as to what amount of friction is to be regarded as sufficing to produce the result, and whether oceanic tidal friction can be great enough to have the effect which he supposes it to have.

In oscillations of the class under consideration, the water moves for half a period north, and then for half a period south. Now in systems where the resistances are proportional to velocity, it is usual to specify the resistance by a modulus of decay, namely, that period in which a velocity is reduced by friction to $1 \div 2\cdot783$ of its initial value; and the friction contemplated by Laplace is such that the modulus of decay is short compared with the semi-period of oscillation.

The quickest of the tides of long period is the fortnightly tide, hence, for the applicability of Laplace's conclusion, the modulus of decay must be short compared with a week. Now it seems practically certain that the friction of the ocean bed would not much affect the velocity of a slow ocean current in a day or two. Hence we cannot accept Laplace's hypothesis as to the effect of friction.

This paper then gives a solution of the equation of motion when friction is entirely neglected. The method is indicated in a footnote to a paper by Sir William Thomson (*Philosophical Magazine*, 1875, vol. 50, p. 280), but has never been worked out before.

It appears in the result that with an ocean 1200 fathoms deep, covering the whole globe, the fortnightly tide has about 1/7th of its equilibrium value at the pole, and nearly a half at the equator. If the ocean be four times as deep we get analogous results, and it appears that with such oceans as we have to deal with the tide of long period is certainly less than half its equilibrium result.

In Thomson and Tait's "Natural Philosophy" (edition of 1883) a comparison is made of the observed tides of long period with the equilibrium theory.

This investigation was undertaken in the belief of the correctness of Laplace's view as to the tides of long period, and was intended to evaluate the effective rigidity of the earth's mass.

The present result shows that it is not possible to attain any estimate of the earth's rigidity in this way, but as the tides of long period are distinctly sensible, we may accept the investigation in the "Natural Philosophy" as generally confirmatory of Thomson's view as to the great effective rigidity of the whole earth's mass.

There is one tide, however, of long period of which Laplace's argument from friction must hold true. In consequence of the regression of the nodes of the moon's orbit there is a minute tide with a period of nearly nineteen years, and in this case friction must be far more important than inertia. Unfortunately this tide is very minute, and as is shown in a Report for 1886 to the British Association on the tides, it is entirely masked by oscillations of sea-level produced by meteorological or other causes.

Thus it does not seem likely that it will ever be possible to evaluate the effective rigidity of the earth's mass by means of tidal observations.

December 9.—"Note on a New Form of Direct-Vision Spectroscope." By G. D. Liveing, M.A., F.R.S., Professor of Chemistry, and J. Dewar, M.A., F.R.S., University of Cambridge.

December 16, 1886.—"Preliminary Account of the Observations of the Eclipse of the Sun at Grenada in August 1886." By Captain Darwin, R.E. Communicated by Lord Rayleigh, Sec.R.S.

The instruments allotted to me consisted of the coronagraph and the prismatic camera; the two instruments being mounted on the same equatorial stand.

The photograph obtained with the prismatic camera shows several images of the prominences, and it therefore gives every promise of yielding good results when measured and examined.

The five- and ten-second photographs of the corona show signs of a slight vibration, but they will be useful for the inner part of the corona. As my main object was to obtain instantaneous photographs, these long-exposure plates had to be obtained by working the automatic shutter by hand; it was this probably that caused the vibration.

The instantaneous photographs of the corona when developed were complete blanks, proving that the exposure was too short. It should, however, be observed that this does not prove that the light of the corona was insufficient to cause an appreciable effect on the plate if combined with other light. More light energy is necessary to start photographic action than is required to produce a visible difference of shade when once the action is started.

Many of the photographs taken during partial eclipse show what may be described as a false corona, that is, an increase of density near the sun and between the cusps, or *in front of* the moon. In none of them can the moon be seen eclipsing the corona.

The results, therefore, are adverse to the possibility of obtaining photographs of the corona in sunlight; it is, however, I consider, by no means proved that the method is impossible. But at present I am inclined to consider that the result tends to show that a *practical* method of obtaining photographic records of the corona during sunlight is not likely to be obtained. The trial was not conclusive because the conditions were very unfavourable. In order to reduce the air-glare to a minimum, so that the light of the corona shall not be overpowered, the following points must be observed:—

(1) The air should be clear and dry.

(2) The sun should be near the zenith.

(3) The station should be at a considerable elevation above the sea.

(4) The corona, if it does vary in intensity, should be at its maximum brightness.

Now every one of these conditions was unfavourable. The air was saturated with moisture, the sky was of a hazy blue, the sun was low, the station was near the sea-level, and the corona, according to the general impression, was not so bright as on other occasions.

I hope, however, to deal more fully with these considerations on another occasion.

Mathematical Society, January 13.—Sir J. Cockle, F.R.S., President, in the chair.—Prof. G. B. Mathews was elected a Member.—The following communications were made:—Conjugate "Tucker" circles, by R. Tucker.—On the incorrectness of the rules for contracting the processes of finding the square and cube roots of a number, by Prof. M. J. M. Hill.—On the complex angle, by J. J. Walker, F.R.S.—Shorter communications were also made by Messrs. Heppel, Macmahon, and S. Roberts, F.R.S., in the discussion of which several members took part.

Victoria Institute, Jan. 3.—Dr. Wright read a paper describing the Hittite monuments which he had examined in the East, and giving an account of the present position of the question as to the age and extent of the country of the Hittites. Many afterwards joined in the discussion. Thirty members and associates were elected, and it was announced that 100 had joined during the past year, making 1200 members the Institute's strength.

Edinburgh

Mathematical Society, January 14.—Mr. W. J. Macdonald, Vice-President, in the chair.—Prof. Chrystal gave a paper on the generation of any curve as a roulette; and Mr. William Renton contributed some mnemonics for plane and spherical trigonometry.

Paris

Academy of Sciences, January 10.—M. Gosselin in the chair.—Note on the works of the late M. Oppolzer, Corresponding Member of the Section for Astronomy, by M. Tisserand. In this obituary notice reference is made more especially to the eminent astronomer's "Traité des Orbites," his determination of the orbits of the planets and many comets, and his theory of the movement of the moon.—On various phenomena presented by the artesian wells recently sunk in Algeria, by M. de Lesseps. The results are described of unusually successful operations undertaken in 1885 and last year in the region of the Shotts, where one well, yielding as much as 8000 litres per minute of pure water at a temperature of 25° C., has already developed a considerable lake 10 metres deep, by means of which from 500 to 600 hectares of waste land have been reclaimed. Similar results elsewhere give hope that large tracts now uninhabited, but which supported a numerous population in the time of the Romans, will soon be again brought under cultivation.—On the theory of algebraic forms with *p* variables, by M. R. Perrin.—On the action of the chloride of carbon on the anhydrous oxides, by M. Eug. Demarçay. Schützenberger having shown that the tetrachloride of carbon reacts readily on the sulphuric anhydride, forming phosgene and chloride of pyrosulphuryl, the author here describes some experiments he has carried out for the purpose of ascertaining whether the same substance reacts on the oxides, and whether this reaction might not be utilised in the laboratory for facilitating the preparation of the anhydrous chlorides.—On erythrite, by M. Albert Colson. This substance should yield successively by oxidation a monobasic and a bibasic acid, the latter being tartaric acid, according to Henninger's formula. But no monobasic acid derived from erythrite has yet been described, nor has the transformation of this alcohol into tartaric acid ever given satisfactory results. The author here accordingly resumes the study of its oxidation, testing by the thermo-chemical process the formulas hitherto accepted for erythrite and tartaric acid. He also treats erythrite with the perbromide of phosphorus, obtaining a bromhydrine, $C_4H_6Br_4$, fusible at 112° C., and identical with the tetrabromide of crotonylene, described by Henninger.—On the glycerinate of potassa, by M. de Forcrand. Having already determined the heat of formation of the glycerinate of soda, and of its ethylic combination, and the conditions under which these compounds have their origin, the author here subjects the glycerinate of potassa to a similar process with analogous results.—On the substances derived from erythrene, by MM. E. Grimaux and Ch. Cloez. The object of the experiments here described is to ascertain whether erythrene and the carburet of gas oils are really identical, as supposed by Henninger. The result so far shows that the erythrene derived from the oils of compressed gas unites readily with hypochlorous acid, the product of the reaction being soluble in ether, alcohol, and water.—On the artificial production of zincite and willemite, by M. Alex. Gorgeu. The methods by which the author reproduces zincite are based on the decomposition of several salts of zinc by heat alone, or aided by the vapour of water. It is merely an application of the process by which M. Debray has obtained crystals of glucine, magnesia, &c. Willemite, $SiO_2,2ZnO$, he produces by a method based on the action of silica on a mixture of alkaline sulphate and sulphate of zinc.—Observations on fishes inhabiting very deep waters (second communication), by M. Léon Vaillant. The really characteristic types of this class of deep-sea fauna are referred to the sub-order of the Anacanthini, which yields a considerable number of species, living at great depths. There is almost a total absence of Pleuronectes, the solitary exception being *P. megastoma*, Donov., fished up from a depth of 560 metres. A striking feature of this ichthyological fauna is its great uniformity, the same genera and even closely-allied species constantly reappearing and being evidently diffused over the widest ranges.—Researches on the mechanism of respiration in the Myriapods, by M. J. Chalande. Most zoologists suppose that the breathing process is the same in the Myriapods as in insects; but the author's researches show conclusively that this hypothesis is absolutely erroneous. In them respiration is effected by the rhythmical movements of the dorsal vessel, the air also penetrating by diffusion to the most delicate tracheæ.—On the age of the Bauxite formation in the south-east of France, by M. L. Collot. This formation, which in the Ariège district occurs between the Coralline and Urgonian deposits, is referred to the successive geological epochs between the Lower Lias and the Urgonian.—On the partial results of the first two experiments made to determine the direction of the North Atlantic currents, by Prince Albert of Monaco. Of the 169 floats cast overboard 300 miles north-west of the Azores in 1885, fourteen have been recovered, showing a general south-easterly direction and a mean velocity of 3·83 miles per twenty-four hours. Of the 510 floated in 1886 much nearer to the French coast, nine have reappeared, showing nearly the same direction, with velocities of from 5·80 to 6·45 miles.—Coincidence of certain solar phenomena with the perturbations of terrestrial magnetism, by M. E. Marchand. A comparative study of the solar observations made at the Lyons Observatory in 1885-86 with the curves of the Mascart magnetic recorder shows that there exists a direct relation between the terrestrial magnetic disturbances and the displacements of certain solar elements accompanying the spots and the faculæ.—On the actual value of the magnetic elements at the Parc Saint-Maur Observatory, by M. Th. Moureaux.—Note on the recent minimum of the solar spots, by M. A. Riccò. This minimum, which occurred between October and December, 1886, was specially remarkable for its intensity, no spots or pores being at all visible twice for eleven days and once for eight days during that period.—Remarks on the geological chart of Lake Baikal and the surrounding district, by M. Venukoff. A careful study of this map, drawn to a scale of 1 : 420,000, shows that the Baikal basin is not a *crevasse* in the Jurassic beds, as had been supposed, nor a subsidence due to plutonic or volcanic causes, but that its formation dates from pre-Silurian times and is still in progress.

THURSDAY, JANUARY 27, 1887

SCIENTIFIC FEDERATION

IN an article on "Science and the Jubilee" a week or two ago, we referred to the possibility that the Royal Society might feel it desirable to consider whether it was feasible to signalise the present year of Jubilee by any new departure. It so happens that quite independently of the proposed celebration a very appropriate extension of the Society's usefulness to our colonies has been suggested and has already been accepted by one of the Australian colonies. This suggestion, and the action which the Royal Society has already taken upon the question submitted to it, really raises the whole question of the desirability of a scientific confederation of all English-speaking peoples.

The suggestion to which we refer was made in Prof. Huxley's Anniversary Address to the Royal Society little over a year ago, from which we make the following extract:—

"Since this Society was founded, English-speaking communities have been planted, and are increasing and multiplying, in all quarters of the globe,—to use a naturalist's phrase, their geographical distribution is 'worldwide.' Wherever these communities have had time to develop, the instinct which led our forefathers to come together for the promotion of natural knowledge has worked in them and produced most notable results. The quantity and quality of the scientific work now being done in the United States moves us all to hearty admiration; the Dominion of Canada, and our colonies in South Africa, New Zealand, and Australia, show that they do not mean to be left behind in the race; and the scientific activity of our countrymen in India needs no comment.

"Whatever may be the practicability of political federation for more or fewer of the rapidly-growing English-speaking peoples of the globe, some sort of scientific federation should surely be possible. Nothing is baser than scientific Chauvinism, but still blood is thicker than water; and I have often ventured to dream that the Royal Society might associate itself in some special way with all English-speaking men of science, that it might recognise their work in other ways than by the rare opportunities at present offered by election to our foreign Fellowship, or by the award of those medals which are open to everybody; and without imposing upon them the responsibilities of the ordinary Fellowship, while they must needs be deprived of a large part of its privileges. How far this aspiration of mine may be reciprocated by our scientific brethren in the United States and in our colonies I do not know. I make it public, on my own responsibility, for your and their consideration."

It would appear that the matter was at once considered by the Council of the Royal Society, because the next year (1886) Prof. Stokes, the present President, referred to the subject in the following words:—

"In his Presidential Address last year, Prof. Huxley suggested the idea, I may say expressed the hope, that the Royal Society might associate itself in some special way with all English-speaking men of science; that it might recognise their work in other ways than those afforded by the rare opportunities of election to our foreign membership, or the award of those medals which are open to persons of all nationalities alike. This suggestion has been taken up by one of our colonies. We have received a letter from the Royal Society of Victoria, referring to this passage in the address, and expressing a hope that, in some way, means might be found for establishing some kind of connection between our own oldest scientific Society and those of the colonies. The Council have appointed a Committee to take this letter into consideration, and try if they could devise some suitable plan for carrying out the object sought. The Committee endeavoured at first to frame a scheme which should not be confined to the colonies and dependencies of the British Empire, but should embrace all English-speaking communities. But, closely connected as we are with the United States by blood and language, they are of course, politically, a foreign nation, and this fact threw difficulties in the way of framing at once a more extended scheme, so that the Committee confined themselves to the colonies and dependencies of our own country, leaving the wider object for some future endeavour, should the country concerned seem to desire it. The scheme suggested was laid before the members of the present Council, but there was not an adequate opportunity of discussing it, and it will of course come before the next Council. Should they approve of some such measures as those recommended by the Committee, they will doubtless assure themselves, in some way or other, that those measures are in accordance with the wishes of the Fellows at large before they are incorporated into the statutes."

What the Council of the Society has already done in the matter is of course unknown to us, as it has not yet been made public; but it is unnecessary to point out the extreme fitness of some such action as this being taken this year, if it is to be taken at all.

Undoubtedly the scheme foreshadowed by Prof. Huxley, if carried out in a proper way, may lead to a great many advantages. It is not unimportant that all the scientific organisations of Greater Britain should be welded into a homogeneous whole, so that, if at any time a common action should be necessary on any subject, the work could be done promptly and with the least strain. If any scientific organisation in a colony were affiliated with the Royal Society at home, there can be no doubt that it would be in a stronger position; that its standard of scientific work would be raised; that other kindred institutions would be more likely to be formed, on which a similar status might at some future time be conferred also. Such an organisation, too, would have a *cachet* conferred upon it, so that colonists would consider it a greater honour to belong to it, and would have a greater inducement to work for it, and to aid in all its efforts.

We can imagine some possible criticisms of Prof. Huxley's suggestions. For instance, it may be asked, Why should not Scotch and English and Irish organisations be treated in the same way? We think there is a very good answer to this objection. Any member of any of the British Societies, by taking a little trouble, may obtain any of the privileges which the Royal Society might confer upon colonists. To a great many British

Societies the publications of the Royal Society are sent gratuitously; there is no difficulty in obtaining access either to the libraries or to the reading-rooms when the members are in London, for the reason that all necessary knowledge as to how these privileges are to be obtained is of course possessed by those at home, whereas the member of a colonial Society who finds himself in England is in a very different position. He may know nobody, he may not know even of the existence of the facilities afforded, and he may leave England without having been present at any meetings of the Society, and without the knowledge that almost anyone who chooses can attend them. We are glad then on these and on other grounds that the question has been raised, and we believe that great good may be accomplished by acting on Prof. Huxley's suggestion.

SUPERNORMAL PSYCHOLOGY

Phantasms of the Living. By Edmund Gurney, Frederic W. H. Myers, and Frank Podmore. (London: Trübner and Co., 1886.)

UNDER the title "Phantasms of the Living," three of the leading members of the Society for Psychical Research have presented to the world at large, in two bulky volumes running to upwards of 1400 pages, the evidence they have collected in support of the hypothesis of telergy and telepathy, or the influence of one mind on another, near or at a distance, without the intervention of the ordinary channels of sense. The division of labour, for such we may truly term it, seems to have been as follows: Mr. F. W. H. Myers writes an introduction and a concluding chapter on "A Suggested Mode of Psychical Interaction"; Mr. Edmund Gurney is responsible for the compilation of the body of the work, the presentation and criticism of the evidence; while in the collection of evidence and examination of witnesses Mr. Podmore "has borne so large a share, that his name could not possibly have been omitted from the title-page."

It is a matter of peculiar difficulty to do justice, in the space that NATURE can place at my disposal, to a work of such portentous bulk, one written in such obvious good faith, one on which the authors have bestowed so much time, labour, and thought, and yet one presenting views which no one who has learnt to believe in the parallelism or identity of neuroses and psychoses can accept without abjuring his scientific and philosophic faith. I hold it to be the duty of a reviewer not merely to air his own opinions, but to give his readers a sketch of the contents of the volumes before him. But how can one sketch in two or three columns so vast a mass of evidence, the chief value of which is, we are told, its cumulative nature? And if the reviewer owes it to his readers to present some sort of outline of the picture his author presents, he none the less owes it to himself, his author, and his journal, to endeavour to estimate the value of the original thus roughly outlined. Difficult as the task is, it must be faced.

The evidential part of the work opens with a record of cases which form, it is held, an experimental basis for thought-transference. The following description is given by the Rev. H. M. Creery of experiments with his own daughters:

"Each went out of the room in turn, while I and the others fixed on some object which the absent one was to name on returning to the room. We began by selecting the simplest objects in the room, then chose the names of towns, dates, cards out of a pack, &c. I have seen seventeen cards, chosen by myself, named right in succession, without a mistake."

In similar experiments the investigating committee acted as agents. This excluded, in their opinion, the possibility of trickery. Tabulating the results thus obtained, they submitted them to Mr. F. Y. Edgeworth, who applied to them the calculus of probabilities, obtaining "a row of *thirty-four nines* following a decimal point," or practical certainty in favour of their being due either to collusion or to thought-transference.

Details are given of experiments on the transference of tastes under conditions which, in the opinion of the authors, precluded the possibility of collusion or deception. The following are a few successive results:—

Substances tasted	Answers given
Vinegar	A sharp and nasty taste.
Mustard	Mustard.
Sugar	I still taste the hot taste of the mustard.
Worcestershire sauce	Worcestershire sauce.
Port wine (quality not stated!)	Between eau-de-cologne and beer.
Bitter aloes	Horrible and bitter.

Instances of the localisation of pains are given. "The percipient being seated, blindfolded, and with her back to the rest of the party, all the other persons present inflicted on themselves the same pain in the same part of the body. Those who took part in the collective agency were three or more of the following: Mr. Malcolm Guthrie, Prof. Herdman, Dr. Hicks, Dr. Hyla Greves Mr. R. C. Johnson, F.R.A.S., Mr. Birchall, Miss Redmond, and, on one occasion, another lady. The percipient throughout was Miss Relf. In ten out of twenty cases the percipient localised the pain with great precision; in seven, the localisation was nearly exact; in two, no local impression was perceived; and in one, the last, the answer was wholly wrong."

Facsimiles are given of pictures reproduced by thought-transference. In a continuous series of six—none of which can be said to have been complete failures—two were reproduced by the percipient with great fidelity; even the comparative failures are instructive from their partial success. The position of the agent, we are told, rendered it absolutely impossible that she should obtain a glimpse of the original.

Such is some of the experimental evidence for thought-transference. Readers of NATURE will understand why this section of the authors' work, giving results obtained under conditions within control, is noticed at greater length than can be devoted to other branches of the evidence.

The next chapter deals with cases transitional between experimental thought-transference—in which both agent and percipient are voluntarily taking part with a definite idea of certain results in view—and spontaneous telepathy, where neither has voluntarily or consciously formed an idea of any result whatever. These transitional cases are those in which the agent acts consciously and voluntarily, but the percipient is not consciously or voluntarily a party to the experiment. Of these cases, a single example must suffice. Two fellow-students of naval engineering at Portsmouth had been in the habit of making experiments in mesmerism. One, ere long, acquired mesmeric control over the other, who was able to see, in the mesmeric trance, places in which he was interested, if he resolved to see them before he was hypnotised. One day he expressed a wish to see a young lady living in Wandsworth. He was hypnotised; and when he came round, he said he had seen her in the dining-room. A few days afterwards, the experiment was repeated. He saw, as he lay entranced, the young lady in a room with her little brother; she fell back in her chair in a sort of faint. A letter was subsequently received from the young lady, dated the morning following the last experiment, beginning: "Has anything happened to you?" and stating that "she could have declared she saw him looking at her" on two occasions, on the latter of which she was so frightened that she nearly fainted. "Luckily," she adds, "only my brother was there, or it would have attracted attention." Although there is some discrepancy as to the date of the first appearance, the second (January 18, 1886) is accordant.

After the enumeration of fifteen or sixteen transitional cases, Mr. Gurney devotes a chapter to a general criticism of the evidence (to which is added an appendix on witchcraft), and then gives a chapter of specimens of the various types of spontaneous telepathy. For these types and their various sub-classes, the reader must be referred to the work itself. I must here again content myself with quoting a single case (which is both "reciprocal" and "collective") from among the 700 or so that are given.

"On the evening of, I think, March 23, 1883," writes a Mrs. Bettany, of Dulwich, "I was seized with an unaccountable anxiety about a neighbour. I tried to shake off the feeling, but I could not; and after a sleepless night, in which I constantly thought of her as dying, I decided to send a servant to the house to ask if all were well." (This is confirmed by the servant.) "The answer I received was, 'Mrs. J. died last night.' Her daughter afterwards told me that the mother had startled her by saying, 'Mrs. Bettany knows I shall die.'"

Mrs. Bettany adds:—"My cook, to whom I had not mentioned my presentiment, remarked to me on the same morning: 'I have had such a horrible dream about Mrs. J., I think she must be going to die.' She distinctly remembers that some one (she does not know *who*, and I think never did) told her in her dream that Mrs. J. was dead." (This is also confirmed by the cook.)

Of somewhat analogous cases of phantasms, presentiments, or dreams occurring to one or more percipients at or shortly after the death of the agent, there is a surprising but wearisome abundance.

So much for the evidence. The authors are fully alive to its liability to error. But they note that their "somewhat persistent and probing method of inquiry has usually repelled the sentimental or crazy wonder-mongers who hang about the outskirts of such a subject as this; while it has met with cordial response from an unexpected number of persons who feel with reason that the very mystery which surrounds these incidents makes it additionally important that they should be recounted with sobriety and care."

We turn now to the theory; and though Mr. Gurney tells us that the character of the present work is mainly evidential, there is no lack of theory scattered up and down throughout its multitudinous paragraphs. The authors, it need hardly be said, regard their hypothesis as strictly scientific. "We wish distinctly to say," writes Mr. Myers, "that so far from aiming at any paradoxical reversion of established scientific conclusions, we conceive ourselves to be working (however imperfectly) in the main track of scientific discovery."

We must, however, carefully separate the views of Mr. Myers from those of Mr. Gurney. Both of them, of course, insist on the reality of experimental thought-transference and of spontaneous telepathy—the radical difference between which is well brought out. In the one an object or sensation kept steadily before the mind of the agent or agents is transmitted as such to the mind of the percipient; in the other the case is different: not the death-swoon of the agent, but the image of the agent as dying is transmitted. And here it is that our authors begin to part company. Calling to mind the facts (or supposed facts) (1) that the dying man may have in intervals of consciousness a vivid mental picture of himself and his surroundings; (2) that most of us have in the background of consciousness a tolerably well-developed conception of our own proper selves; (3) that there is some experimental evidence of collective telepathic influence, so that the percipient may be jointly influenced by the dying man as principal agent, and by the bystanders at the death-bed as subsidiary agents—taking these, avowedly or implicitly, into consideration, Mr. Gurney does not feel forced to go beyond the theory of thought-transference. Not so Mr. Myers. He rises boldly into what looks uncommonly like spiritualism, and accepts clairvoyance, where the percipient "seems to visit scenes, or discern objects, without needing that those scenes or objects should form a part of the perception or memory of any known mind." "*Correspondently with clairvoyant perception*," he says (the italics are his own), "*there may be phantasmogenetic efficacy*," which in plain English means that the percipient may visit in spirit scenes he has never visited in the flesh, and that his spirit may be visible as a phantasm to the human occupants of these scenes. And in support of his view he adduces such cases as that of the two students which I have summarised above.

On the question of the physical aspect of the psychical phenomena, again, our authors do not agree. Mr. Gurney holds that "mental facts are indissolubly linked with the very class of material facts that science can least penetrate—with the most complex sort of changes occurring in the most subtly-woven sort of matter—the molecular activities of brain-tissue." And though he subsequently says: "Not only, as with other delicate phenomena of life and thought, is the *subjective* side of the problem the only one that we can yet attempt to analyse: we do not even know where to look for the *objective* side:" he rather advocates the limitation of the question for the present to the psychical aspect, than dismisses the physical as a piece of unwarrantable materialism. But Mr. Myers goes further: "The psychical element, I repeat, must henceforth almost inevitably be conceived as having relations which cannot be expressed in terms of matter." And again: "I claim at least that any presumption which science had established against the possibility of spiritual communion is now rebutted; and that the materialist must admit that it is no longer an unsupported dream, but a serious scientific possibility, that, if any intelligences do in fact exist other than those of living men, influences from those intelligences may be conveyed to our own mind."

And now, in conclusion, what shall we say of these ponderous tomes? Shall we lightly dismiss the whole subject as a "pack of nonsense"? I do not think that this would be a wise or a scientific procedure. Speaking for myself, I must confess that, in my opinion, Mr. Myers's views are not "on the main track" of the science of to-day, whatever relation they may hereafter be shown to bear to the science of the future. Speaking for myself again, I am ready to accept experimental thought-transference as a working hypothesis, that is to say, a guide to future research on the subject. It may be that any physical explanation we can at present offer is no nearer the truth than was the Ptolemaic hypothesis in astronomy, and yet such a working hypothesis may be valuable in the existing state of psychology. With regard to spontaneous telepathy, notwithstanding the large amount of evidence so carefully collected and criticised, notwithstanding that I have first-hand evidence more convincing (to *me*) than anything recorded in these volumes, I prefer to credit the whole to a suspense account. The physical difficulties are enormous. We have to conceive the action of brain on brain across a whole hemisphere. Not that this must be pressed too far. There is much that is provisionally accepted by science (much anent ether, and atoms, and modes of molecular action) that I find it exceedingly hard to conceive. And perhaps the distant action of brain on brain is not harder for us to conceive than would be the transmission of luminiferous waves to beings in whom the visual sense was not as yet recognised, and who, hitherto only acquainted with auditory vibrations transmitted by the air, were called upon to believe that waves could be transmitted by the ether from distant stars, and could pass almost unchecked through thick masses of solid material. Still, though the mass of evidence is considerable, and though the physical difficulties must not be pressed too far, I am not prepared fully to accept the doctrine of spontaneous telepathy. At the same time, I hold that the evidence adduced by earnest workers is not to be met by easy and ignorant ridicule. I do not think that science is best served by those who are ever ready to throw the cold water of impossibility on the light of new ideas struggling into existence.

I am, moreover, strongly of opinion that normal psychology has much to learn from experiments on supernormal and abnormal "subjects." Beneath the threshold of consciousness there is a vast amount of sub-conscious and unconscious mental action. Of the multitudinous simultaneous neuroses only the superficial film (so to speak) emerge into the light of consciousness as psychoses. The study from the psychological standpoint of the underlying *hypopsychoses*, as I have elsewhere suggested that they should be termed, is as important as it is difficult. If the result of such work as Messrs. Gurney, Myers, and Podmore have entered upon aids in throwing light upon these hidden mysteries, which are none the less realities, of the human mind, their labour will, in my opinion, not have been in vain.

C. LLOYD MORGAN

ELEMENTARY RESULTS IN PURE MATHEMATICS

A Synopsis of Elementary Results in Pure Mathematics, &c. By G. S. Carr, M.A. Pp. xxxviii. + 936 + 20 folding Plates of Figures. (London: Francis Hodgson, 1886.)

IN our last notice of this work (vol. xxxi. p. 100) we gave an account of Sections X., XI., and XII. The complete volume contains two additional sections. The first of these treats of plane co-ordinate geometry, under which heading we have systems of co-ordinates, analytical conics in Cartesian and trilinear co-ordinates (we miss the *m* equations for the parabola and the corresponding equations for chords, &c.). In the latter division we have, amongst the particular conics considered, the triplicate-ratio and seven-point circles (or, as they are more usually styled, the Lemoine and Brocard circles). The account is carefully drawn up from original authorities, and will help to bring this latest development of the geometry of the circle and triangle more into notice. At present this and Dr. Casey's books are the only source readily accessible to students. We are promised another presentment of these circles shortly, but of this more anon. The concluding portion of this section is devoted to the theory of plane curves. Here we have, *inter alia*, inverse and pedal curves, roulettes, and the various forms of transcendental curves. Considerable space is taken up with linkages and link-works: here we have accounts of Kempe's five-bar linkage, the six-bar inversor, the eight-bar double inversor, the quadruplane, the isoklinostat, the planimeter, and the pantograph (this Mr. Carr generally calls pentograph—evidently he has not consulted the "English Cyclopædia"—and in one place only, pantograph). The concluding section is mainly taken up with solid co-ordinate geometry, the final articles being devoted to Guldin's rules, moments and products of inertia, perimeters, areas, volumes, &c. Here we have the theorems which go by the names of Fagnani, Lambert, and Griffiths (not Griffith, as the "Contents" and "Index" print the name; the text, § 6096, is right).

We have in our former notices sufficiently indicated our opinion of the utility of such a book as this if thoroughly trustworthy, and have suggested that a student should have this synopsis by his side when he is carefully going through his subject, that so he may be able to spot any slight inaccuracy in the text. We believe the book is singularly free from errors, but it would be absurd to suppose that there are not several which have escaped even the notice of the author, who has imposed upon himself numerous guards for the prevention of such slips. For it must be remembered that this is no hastily-prepared work: it has occupied much of the writer's time since 1866, when the *magnum opus* was commenced. The author is to be heartily congratulated on the successful termination of labours which must have occupied most if not all of his leisure time from other more regular work.

But Mr. Carr has not confined his work to the limits of his previous title-pages: he has "supplemented" it "by an index to the papers on pure mathematics which are to be found in the principal Journals and Transactions of learned Societies, both English and foreign, of the present century." Such indices have, in these busy times, great value for students in all branches of knowledge, and this one is, we think, very accurate for a first edition. There are, however, some defects. On p. 720 occurs an historical note on the cycloid; no reference is made to the exhaustive treatise, on the cycloid and all forms of cycloidal curves, by Mr. Proctor (Longmans, 1878). In the like case of Cartesian ovals there is no account taken of Prof. Williamson's paper on these curves in Hermathena (No. iv. p. 509; subsequently given in the author's "Differential Calculus"). For the length of an arc of an oval expressed by elliptic functions, Mr. Carr (p. 731) cites a paper by Mr. S. Roberts, F.R.S., in the London Mathematical Society's Proceedings (vol. v. p. 6), but does not mention that Mr. Roberts (vol. vi. p. 200) subsequently found that he had been anticipated by Prof. Genocchi (1855, see "Il Cimento," Turin). The name of Desargues, rightly given p. 917, is twice printed Desarques on p. 858. On pp. 913 and 935 we have "polyzonal," "zonal," and "tetrazonal": the author of the paper in question has "m" in place of "n" throughout. "Nicomaque" (p. 853), "implexe" (p. 859), "pseudosfera" (p. 915), are easily traceable; "coplanation" and "complanation" are also to be traced to the titles of the original papers. Cases of wrong spelling occur in the names of Hesse (p. 890), Kronecker (p. 890), Plücker (p. 916), Rodrigues (p. 921), Lissajous (p. 900), and there are various forms of MacCullagh; but "Tetratops" (p. 931) eludes us. These are trifling matters, and in the text in such parts of XIII. and XIV. as we have read we have not observed any errata of consequence.

It would be a boon to students if Mr. Carr would issue this supplement in a separate form, and add to his extensive list of thirty-two periodicals references to the papers on pure mathematics which occur in the *Philosophical Magazine*, *Lady's and Gentleman's Diary*, the *Mathematician*, "Reprint from the *Educational Times*" (a limited selection here of general results and the occasional papers), and *Mathesis*. For instance, on the "15-girl" problem there is a good article in the *Diary*, on the "chessmen" in the *Philosophical Magazine*.

Mr. Carr will understand that our remarks are made in no captious spirit: we are very grateful for the trouble he has taken, and desire only that a second edition may be made even more valuable from its increased accuracy and stores of information than the present one is.

He is to be congratulated on the arrangement of his text, the several different kinds of types which have been put at his disposal by the printers, and the excellent diagrams. It only remains to express the wish that what the author has done for one side of mathematics he may be encouraged to do for the other, *i.e.* for applied mathematics.

COMMERCIAL ORGANIC ANALYSIS

Commercial Organic Analysis. By Alfred H. Allen, F.I.C., F.C.S., &c. Second Edition, Revised and Enlarged. Vol. II. Fixed Oils and Fats, Hydrocarbons, Phenols, &c. (London: J. and A. Churchill, 1886.)

THIS work has been so much enlarged and so thoroughly revised that it has become almost a new book, and certainly its value has been greatly enhanced to all analysts and others interested in the special points discussed. These copious additions have rendered it necessary to divide the present edition into three volumes, the first of which appeared some little while ago, whilst the third (on Aromatic Acids, Tannins, Colouring Matters, Cyanogen Compounds, Organic Bases, Albumenoids, &c.), is now in course of preparation, and is promised shortly. Of the sections treated in the present volume it may be said generally that the author has collected together and systematically digested almost all the available information extant scattered about in text-books and numerous papers read before scientific Societies, and that he has largely contributed personally to the mass of information by means of experimental and observational work carried out in his own laboratory at the cost of much time and labour. Moreover, he has sought and obtained the aid of several well-known chemists possessing special knowledge and skill in certain kinds of work, by whose assistance many of the more important articles have acquired an almost exhaustive character. As a result, the treatise has become a most valuable hand-book and book of reference with respect to the class of matter coming within its scope; and it may now be fairly said to be an essential item in the list of works requisite in the library of an analytical chemist.

Amongst the numerous special points of research to which the author has devoted much personal attention, a notable one is the examination of various of the physical properties of fatty and oily matters with a view to their discrimination and identification, and more especially the methods in use in the determination of their specific gravity. In order to avoid complications arising from differences in physical state—some being solid, others pasty, and others fluid at the ordinary temperature—he recommends, as previously proposed by Estcourt, that comparisons should always be made at the temperature of boiling water, the melted fat or fluid oil being placed in a test-tube heated in a water-bath (of such construction that no steam escapes in the vicinity of the operator), and the indications of a Westphal's hydrostatic balance noted when the plummet is immersed in the hot oil. The figures thus obtained on repetition of experiments show very little divergence; and characteristic values are thus obtainable for certain kinds of fats, *e.g.* butter-fat when genuine. Owing to the fact that the Westphal balance as sold is constructed to give specific gravity indications *at the ordinary temperature* (*i.e.* that the plummet is adjusted so as to lose a particular weight, conveniently 5 or 10 grammes, when immersed in water at, say, 15° C.), it is obvious that the numerical values obtained on immersion in hot material at close upon 100° C. represent neither the true densities at 100° of the substances (weights per cubic centimetre) nor the ratios between these densities and that of water at 100°, *i.e.* their specific gravities at 100°. But for any particular instrument, the different values obtained with different fatty matters exhibit the same differences as those obtained with any other instrument; whilst the indications of any two instruments are obviously comparable, provided that the mode of graduation and the coefficient of expansion of the plummet are the same; which practically is the case if a *glass* plummet be always used, as recommended. In a recent communication to the *Analyst* (January 1887, p. 18), the author suggests that the term "*indicated plummet-gravity*" should be employed to represent the apparent values obtained at such and such a temperature by means of the plummet-balance; which is clearly preferable to the use of either of the terms "specific gravity" or "density" in such cases. It may be noticed in passing that the "indicated plummet-gravities" of fats and oils at 100° or thereabouts by no means necessarily follow the same order as the so-called specific gravities obtained at lower temperatures, not only on account of difference of physical state, but also through the different rates of expansion possessed by the various substances.

Another point on which the author has worked with results of some interest is the determination of the amount of glycerol yielded by fats and oils on saponification. He concludes that there is no experimental basis for the suggestion put forth some time ago by Wanklyn and Fox that *isoglycerides* are present in such substances, these bodies yielding on saponification propionic (or other homologous) acid and water, instead of glycerol. Such a view is opposed not only to the author's laboratory experience, but also to that of manufacturers, who frequently recover 7·5 to 8·0 parts of glycerol per 100 of fatty matter, instead of less than 5 as stated by Wanklyn and Fox. Making allowance therefore for deficient saponification and loss of glycerol by evaporation during recovery, the theoretical amount of glycerol obtainable is satisfactorily accounted for, instead of being largely in excess of that actually produced. It is noticeable that, whilst the author obtained results reasonably concordant with the permanganate process for the determination of the glycerol produced during saponification as compared with the other ordinary methods in many instances, this was not always the case, the former process sometimes yielding figures far in excess, indicating the presence of other substances besides glycerol capable of forming oxalic acid by treatment with permanganate. An extreme case was afforded by linseed oil dried up to elastic skin, which gave 4·9 per cent. of impure glycerol directly isolated, and 15·5 per cent. by the permanganate process.

The author considers that the usually received molecular weight of linoleic acid, generally represented as indicated by the formula $C_{16}H_{28}O_2$, is incorrect, as the mean equivalent of the acids obtainable from linseed oil on saponification has been found by him to be considerably higher than that thus indicated. The formula $C_{18}H_{32}O_2$ agrees better with his results, and moreover is not at all incompatible with the analytical data obtained by previous investigators. The analogous determination of the mean molecular weight of the acids produced on saponification (by means of alcoholic potash and phenolphthalein) of fatty, waxy, and oily matters, and of the fatty and resinous acids contained in soaps, is justly regarded by the author as a valuable criterion in judging of the nature of such substances, especially when taken in conjunction with other data (*e.g.* in the case of butter-fat, the amount of volatile acids capable of being subsequently distilled off along with water, working under particular constant conditions as recommended by Reichert; and the proportion between acids soluble and insoluble in water, &c.); and a large amount of experimental work has been done by him in connection with such valuations. He has also made an excellent digest of recent researches in connection with fats, oils, waxes, soaps, and analogous bodies. In connection with toilet-soaps, he regards the addition of sugar to produce transparency as "simply diluting the true soap-material as so much water would do, without communicating any compensating property of value." This is a very mild way of putting the case, the fact being that soaps containing sugar are liable to produce, in sensitive subjects, a great amount of irritation of the skin (in fact, a mild kind of "grocer's eczema," traceable to the same cause), even though free from causticity and otherwise unobjectionable: and numerous persons are, to the reviewer's knowledge, unable to use certain widely-advertised soaps, in consequence of the large admixture of sugar therein contained, although the composition would otherwise be quite uninjurious.

The sections devoted respectively to hydrocarbons and phenols are equally comprehensive, including descriptions, necessarily in some cases somewhat brief, of the leading points in the petroleum, coal-tar, and shale-oil industries, and of the technical examination of the various products obtained on fractional distillation and subsequent further treatment of these and allied raw materials, *e.g.* wood-tar; and the commercial examination of turpentines and resins, essential oils, camphors, and various miscellaneous substances, such as cantharidin and cholesterin. In these, as in the previous section, the value of the various *précis* given of other observers' work is frequently further enhanced by the comparative experiments and examinations made in connection with different analytical methods, &c., by the author himself. Bone-tar, obtained as a by-product of the animal charcoal manufacture, is not described, probably on account of the limited uses to which, hitherto, it has been put; whilst, for similar reasons, but little is said of blast-furnace and coke-oven tars.

C. R. ALDER WRIGHT

OUR BOOK SHELF

Practical Dynamo-Building for Amateurs. By Fred. W. Walker, M.E. (London: Iliffe and Son, 1886.)

WOULD that all books for amateur guidance were written with as full a knowledge of proper principles as this unassuming little work. We are not saying that the machine which the author recommends amateurs to construct is the equal of the commercial dynamos of the current date. His field magnet cores are of cast iron, and not of the best form; his armature might be improved by getting greater cross-section of iron into it. But there is nothing wrongly done. All instructions about the essential details of proper insulation and testing of the work in progress are accurate and full; and an appendix on alternative constructions of field-magnets supplies in some degree the deficiencies of the earlier text.

Hand-book of Zoology, with Examples from Canadian Species, Recent and Fossil. By Sir J. William Dawson, LL.D., F.R.S., &c. Third Edition, revised and enlarged. (Montreal: Dawson Brothers, 1886.)

IN this little work, the President of the British Association for the Advancement of Science has concentrated into some 300 pages a very fair account of the principal divisions of the animal kingdom. It is specially adapted for Canadian students, inasmuch as the examples of every group are selected, as far as possible, from species found within the limits of the Dominion. The fact of the volume having reached a third edition shows that Sir William Dawson's plan and method have been appreciated. That the arrangement adopted is altogether unexceptionable, and that all the most recent discoveries in zoological science are taken advantage of, we could not fairly say. For example, *Eozoon* is still treated of as if it were without doubt an organic structure; the unquestionable affinity of the larval Ascidian to the Vertebrate embryo is but faintly alluded to; and the much-talked-about *Peripatus*—one of the most singular types of Arthropodal life—seems to have been altogether omitted from the list. Yet there is, in the main, an absence of the serious errors which are too often found in such manuals. The volume is well illustrated and well printed, and will, we have no doubt, be of much service as a text-book in Canadian schools of science.

Theory of Magnetic Measurements. By Francis E. Nipher, A.M., Professor of Physics in Washington University, President of the St. Louis Academy of Science. (New York: D. Van Nostrand; London: Trübner and Co., 1886.)

DURING the last twenty years there has been considerable activity amongst observers on land and at sea in adding to our knowledge of the magnetism of the earth, and it is certainly desirable, if not necessary, that those busy workers, who are only acquainted with the practical use of the instruments employed, should know something of the theory of the magnetic measurements upon which they may be engaged.

To those conducting magnetic surveys under English auspices, the article on Terrestrial Magnetism in the "Admiralty Manual of Scientific Inquiry" has proved a valuable aid in showing both what was required and the practical means of obtaining observations on land and sea, with the methods of calculating the results. The theory of the subject, however, is beyond the intended scope of the Manual.

The magnetic survey of the United States has, during the period under consideration, been continuously carried on under the Government and private enterprise, and Prof. Nipher has been one of the diligent workers, as shown by his survey of Missouri, published in NATURE, (vol. xxiii. p. 583). In the book before us he combines some excellent practical information for those undertaking the observation of the three magnetic elements on land, with the theory of the several magnetic measurements thus made.

A large portion of the book is necessarily occupied by the theory of the horizontal force magnetometer and its several parts. Here the reader will find some differences from the English notation. For instance, H is substituted for X when denoting the horizontal force, and I for K, as the moment of inertia of the deflecting magnet. A more important departure from the usual method of calculation will be noticed in the omission of the coefficient of induction μ, which has been so entirely rejected as not even to be discussed. The retention of this coefficient has already been challenged elsewhere, but the general support of European practice seems to forbid any change until its place in our formulæ has been proved unnecessary. In the concluding pages there is an article on the systems of units adopted in magnetic measurements, and plates of the unifilar magnetometer and dip-circle generally used.

The appendix is devoted to a discussion of the method of least squares in the reduction of observations, an article on graphic methods, with the aid of which so much may be done to shorten the labour of computation, and some tables giving the times of the elongation of Polaris with its corresponding azimuth for the years 1886-95, from which the true meridian may be readily deduced for declination-observations. These tables will probably be found convenient in latitudes between the northern tropic and the Arctic circle.

The large domain of magnetic observations at sea is not touched upon, but intending observers on land should be pleased to possess a book of this kind, which might be included in their travelling equipment without fear of adding much to the weights to be carried.

The Coming Deluge of Russian Petroleum. By C. Marvin. (London: R. Anderson and Co.)

THIS pamphlet does not pretend to add to our limited knowledge of the origin of petroleum or of its connection with the Tertiary deposits and volcanic activity of the Caucasus. It is in reality an appeal to English enterprise to direct its attention to at least the carrying trade of a district so rapidly growing in industrial importance. The enormous figures given (*e.g.* more than a million gallons a day from a single well) are enough, however, to stimulate scientific as well as Stock-Exchange inquiries, and the development of communications between Baku and the West is sure to be, sooner or later, fruitful in geological results. G. C.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Cambridge Cholera Fungus

I HAVE read with great surprise Mr. Gardiner's letter in your issue of January 20 (p. 271). We are there told that on reconsideration Mr. Gardiner has now come to the conclusion that the organism which he saw in Prof. Roy's preparations of the intestinal mucous membrane—which Prof. Roy took to be the more usual and typical form, and which Mr. Gardiner then thought to belong to the Chitridiaceæ—is probably the particular phase in the life-history of Bacterium known as an involution form, *i.e.* "a thin and somewhat moniliform filament which at one end exhibited a distinct nodular swelling." If Mr. Gardiner has studied the filaments of a growth of mould in animal tissues, he must have come across numbers of such forms. But granting for the sake of argument that what Mr. Gardiner saw in Prof. Roy's specimens bears a resemblance to and is in reality an involution form of Bacterium, how about the branched threads figured in the Report by Messrs. Roy, Brown, and Sherrington in No. 247 of the Proceedings of the Royal Society, on p. 179?

Each of these two figures introduced here, no doubt as typical representations of the organisms in the mucous membrane, shows unmistakably BRANCHED mycelial threads of a true fungus. If what Mr. Gardiner has seen in Prof. Roy's preparations is an involution form of some Bacterium, then the branched threads figured in Messrs. Roy, Brown, and Sherrington's Report are something else, unless somebody started the novel and extraordinary view that a Bacterium possesses branched mycelial threads like a true fungus.

I should be glad to hear Mr. Gardiner's opinion as to these branched mycelial threads figured on p. 179 of the Proceedings of the Royal Society, No. 247, in the Report by Messrs. Roy, Brown, and Sherrington. E. KLEIN

The Coal-Dust Theory

THOSE readers of NATURE who have followed the various phases of the coal-dust question will be interested to know that the following resolution was carried at the Conference of Miners, which concluded its sittings in Birmingham yesterday morning :—

"This Conference, believing that recent explosions have demonstrated that coal-dust is sufficient, without the presence of gas, to cause a serious explosion, is of opinion that a clause should be inserted in the new Mines Act, making it illegal to use blasting-powder, or other inflammable substance, in any part of the tram or trolly-way, unless the dust on the top, the bottom, and the sides of such tram or trolly-way has been properly damped or removed, for a distance of fifteen yards on each side of the hole in which the shot is to be fired."

This practical method of dealing with part of the difficulty will doubtless lead to the happiest results, if properly carried out.

The use of *dust-tight* tubs, or mine-waggons, as a means of preventing the deposition of coal-dust in the first place, and thus avoiding the necessity for so many precautions in dealing with it afterwards, suggested itself to me while I was examining the scene of the explosion in the silkstone-pits at Altofts Colliery. In order to fulfil the condition of being dust-tight, the mine-waggons would require to have no crevices of any kind through which dust could be shaken, and they would require to be so filled that no pieces of coal would roll over their sides on to the floor.

This alternative method, which I propose to discuss at greater length elsewhere, showing practical results as far as they extend, might perhaps meet the case of those mines in which the use of water is objectionable, on account of its disintegrating effect upon the roof or floor. W. GALLOWAY

Cardiff, January 15

Barnard's Comet at Perihelion

IN spite of the bad weather and the glare of twilight and moonlight, I have made a good number of observations and drawings of this comet; especially on December 16, 1886, the day of its passage at perihelion, and consequently of its shortest distance from the sun (nearly two-thirds of the distance of the earth from the sun).

The head of the comet was a large, brilliant, star-like nucleus, surrounded with a splendid, globular *chevelure*. From this sprang two tails : the larger, directed towards the North Pole, was straight, or but a little convex to the east (on which side it was also a little thicker), ending in an extremely faint nebulosity nearly 10° from the head. The smaller tail was much shorter, and directed 50° to the west of the other. The colour of the comet was a beautiful light blue.

The spectrum of the comet resulted from the ordinary three bands of the hydrocarbons; the green being the strongest, then the yellow, whilst the blue was the faintest. The bands were crossed by the linear spectrum of the nucleus, continuous, but strongly reinforced on the bands, and extended very little beyond the limits of the bands themselves.

Before the passage at perihelion the comet had the same form, but less developed ; the spectrum also was the same.

On the morning of December 7 I followed the comet with the 10-inch refractor till twenty-five minutes before sunrise : this proves the great brilliancy of the comet. A. RICCÒ

Palermo Observatory, January 9

Magnetic Theory

MAY I trespass upon your space to ask a question which I have never seen proposed, but which is so obvious that it must have occurred to many others interested in magnetic theory?

In a current field—with closed currents—we have the familiar equations—

$$F = \iiint \frac{u\,dx\,dy\,dz}{r},\ G = \&c.,\ H = \&c.,$$

$$\frac{du}{dv} + \frac{dv}{dy} + \frac{dw}{dz} = 0 = \frac{dF}{dx} + \frac{dG}{dy} + \frac{dH}{dz},$$

$$\nabla^2 F + 4\pi u = 0,\ \&c.$$

And if a, b, c are the components of magnetic force—

$$a = \frac{dG}{dz} - \frac{dH}{dy}\ \&c., \qquad 4\pi u = \frac{dc}{dy} - \frac{db}{dz}\ \&c.$$

In a magnetised mass, A, B, C being components of magnetisation, if we take

$$F = \iiint \left\{ B\frac{d}{dz} - C\frac{d}{dy} \right\} \frac{dx\,dy\,dz}{r}, \qquad G = \&c., \quad H = \&c.$$

We have at all *external* points a magnetic force of the components a, b, c, where $a = \frac{dG}{dz} - \frac{dH}{dy}$, &c.

If we introduce the vector whose components per unit volume, u, v, w, are $\frac{dB}{dz} - \frac{dC}{dy}$, &c., where A, B, C are continuous and per unit surface are $nB - mC$ over surfaces where A, B, C pass discontinuously to zero, we get $F = \iiint \frac{u\,dx\,dy\,dz}{r}$, &c.

$$\frac{du}{dx} + \frac{dv}{dy} + \frac{dw}{dz} = 0 = \frac{dF}{dx} + \frac{dG}{dy} + \frac{dH}{dz},$$

and all the equations of the current field are reproduced.

Only the components α, β, γ, of the magnetic force at *internal* points, being derivable from the potential

$$V = \iiint \frac{1}{r}\left(\frac{dA}{dx} + \frac{dB}{dy} + \frac{dC}{dz}\right) dx\,dy\,dz,$$

are not identical with a, b, c, as they do not satisfy the equations $\frac{dc}{dy} - \frac{db}{dz} = 4\pi u$, &c.

My question is, what is the physical evidence in favour of the existence of A, B, C and α, β, γ?

All we know, and can know, about a magnetised mass is derivable from observations of the *external* field.

Everything, therefore, that we can know is satisfied by expressing the state of the mass in terms of u, v, w, and regarding these quantities as the ordinary electric current components. So that a, b, c are components of force everywhere.

My meaning is that if the order of our investigations had been reversed, commencing with current phenomena and so passing on to magnetic, it seems almost certain that we should have attempted to explain the latter in terms of the former.

Doubtless many of the observed facts of induced magnetism would present grave difficulties, but I do not think these difficulties would have driven us to the hypothesis of permanently polarised molecules, or that we should have derived any additional help from such hypothesis. H. W. WATSON

Berkeswell Rectory, Coventry

Sounding a Crater, Fusion-Points, Pyrometers, and Seismometers

I HAD expected to see some confirmation of the remarks that form the chief part of the letter on this subject by Dr. H. J. Johnston-Lavis in NATURE of the 30th ult. (p. 197), but as no one has taken up the matter yet, perhaps you will allow me, as for years the chief assistant of the late Robert Mallet, to say that it is quite true that elaborate apparatus was devised by him and made by different instrument-makers, with a view to obtaining experimental information on the whole of the questions and more than those referred to by Dr. H. J. Johnston-Lavis. A preliminary report was presented by him to the British Association in 1863, in which the scope of his inquiry and nature of apparatus were mentioned, and other reports were written by him which I have not by me now. I am also able to say that the whole of the apparatus remained for years, through Prof. Guiscardi, in the University of Naples, and that Mallet wrote to him as to its disposition for the use of others, should occasion permit, just before his death. Wolves, Mares, and Foals

WHEN in The Asturias in 1885, I was told of a very curious case of animal instinct, which may be worth recording. Wolves are by no means unfrequent in The Asturias, and often attack the young foals which are sent up to pasturage with the mares in the mountains. The experienced danger seems to have begotten a precautionary instinct of a very intelligent kind. It is said that, on an alarm of wolves, the mares and foals congregate for mutual protection and common defence. The mares form themselves into a sort of cordon, heads outwards, surrounding a space inclosing the young foals, and are ready for attacking with their fore-feet the wolves on their approach.

My informant gave me a graphic account of such an attack, of which he was an eye-witness for nearly an hour, and described to me how the wolves circled round and round the defenders, first at some distance, then gradually approaching nearer and nearer, seeking an opening into the inclosure, till at last they came within striking distance, and he saw one wolf rolled over dead by a blow from the fore-foot of one of the mares.

The fore-foot is not commonly used for defence by any equine species; but it is obvious that the more powerful hind-leg blow would be of little service against the spring of a wolf from behind, without the directing eye to guide the stroke. What a long experience must this mutual protection have been the result of! We can scarcely understand it, without councils of war having been held, the dangers discussed, and signals for concerted action arranged; but now all this instinct may merely be the inheritance of the experience of former generations.

Benthall, Kenley, Surrey, January 6 GEORGE MAW

THE SUN'S HEAT[1]

FROM human history we know that for several thousand years the Sun has been giving heat and light to the earth as at present; possibly with some considerable fluctuations, and possibly with some not very small progressive variation. The records of agriculture, and the natural history of plants and animals within the time of human history, abound with evidence that there has been no exceedingly great change in the intensity of the Sun's heat and light within the last 3000 years; but for all that, there may have been variations of quite as much as 5 or 10 per cent., as we may judge from considering that the intensity of the solar radiation to the earth is 6½ per cent. greater in January than in July; and neither at the equator nor in the northern or southern hemispheres has this difference been discovered by experience or general observation of any kind. But as for the mere age of the Sun, irrespective of the question of uniformity, we have proof of something vastly more than 3000 years in geological history, with its irrefragable evidence of continuity of life on the earth in time past for tens of thousands, and probably for millions of years.

Here, then, we have a splendid subject for contemplation and research in natural philosophy, or physics, the science of dead matter. The sun, a mere piece of matter of the moderate dimensions which we know it to have, bounded all round by cold ether, has been doing work at the rate of four hundred and seventy-six thousand million million million horse-power for 3000 years, and at possibly more, and certainly not much less, than that for a few million years. How is this to be explained? Natural philosophy cannot evade the question, and no physicist who is not engaged in trying to answer it can have any other justification than that his whole working time is occupied with work on some other subject or subjects of his province by which he has more hope of being able to advance science.

I suppose I may assume that every person present knows as an established result of scientific inquiry that the sun is not a burning fire, and is merely a fluid mass cooling, with some little accession of fresh energy by meteors occasionally falling in, of very small account in comparison with the whole energy of heat which he gives out from year to year. You are also perfectly familiar with Helmholtz's form of the meteoric theory, and accept it as having the highest degree of scientific probability that can be assigned to any assumption regarding actions of prehistoric times. You understand, then, that the essential principle of the explanation is this: at some period of time, long past, the sun's initial heat was generated by the collision of pieces of matter gravitationally attracted together from distant space to build up his present mass; and shrinkage due to cooling gives, through the work done by the mutual gravitation of all parts of the shrinking mass, the vast thermal capacity in virtue of which the cooling has been, and continues to be, so slow. I assume that you have not been misled by any of your teachers who may have told you, or by any of your books in which you may have read, that the sun is becoming hotter because a gaseous mass, shrinking because it is becoming colder, becomes hotter because it shrinks.

An essential detail of Helmholtz's theory of solar heat is that the sun must be fluid, because even though given at any moment hot enough from the surface to any depth, however great, inwards, to be brilliantly incandescent, the conduction of heat from within through solid matter of even the highest conducting quality known to us would not suffice to maintain the incandescence of the surface for more than a few hours, after which all would be darkness. Observation confirms this conclusion so far as the outward appearance of the sun is concerned, but does not suffice to disprove the idea which prevailed till thirty or forty years ago that the sun is a solid nucleus inclosed in a sheet of violently agitated flame. In reality, the matter of the outer shell of the sun, from which the heat is radiated outwards, must in cooling become denser, and so becoming unstable in its high position, must fall down, and hotter fluid from within must rush up to take its place. The tremendous currents thus continually produced in this great mass of flaming fluid constitute the province of the newly-developed science of solar physics, which, with its marvellous instrument of research—the spectroscope—is yearly and daily giving us more and more knowledge of the actual motions of the different ingredients, and of the splendid and all-important resulting phenomena.

Now, to form some idea of the amount of the heat which is being continually carried up to the sun's surface and radiated out into space, and of the dynamical relations between it and the solar gravitation, let us first divide that prodigious number (476×10^{21}) of horse-power by the number ($6{\cdot}1 \times 10^{18}$) of square metres in the sun's surface, and we find 78,000 horse-power as the mechanical value of the radiation per square metre. Imagine, then, the engines of eight ironclads applied to do all their available work of, say, 10,000 horse-power each, in perpetuity, driving one small paddle in a fluid contained in a square metre vat. The same heat will be given out from the square metre surface of the fluid as is given out from every square metre of the sun's surface.

But now to pass from a practically impossible combination of engines and a physically impossible paddle and fluid and containing vessel, towards a more practical combination of matter for producing the same effect: still keep the ideal vat and paddle and fluid, but place the vat on the surface of a cool, solid, homogeneous globe of the same size ($\cdot 697 \times 10^9$ metres radius) as the sun, and of density ($1{\cdot}4$) equal to the sun's density. Instead of using steam-power, let the paddle be driven by a weight descending in a pit excavated below the vat. As the simplest possible mechanism, take a long vertical shaft, with the paddle mounted on the top of it so as to turn horizontally. Let the weight be a nut working on a screw-thread on the vertical shaft, with guides to prevent the nut from turning—the screw and the guides being all absolutely

[1] Lecture on "The Probable Origin, the Total Amount, and the Possible Duration, of the Sun's Heat," delivered by Sir William Thomson, F.R.S., at the Royal Institution, on Friday, the 21st inst.

frictionless. Let the pit be a metre square at its upper end, and let it be excavated quite down to the sun's centre, everywhere of square horizontal section, and tapering uniformly to a point at the centre. Let the weight be simply the excavated matter of the sun's mass, with merely a little clearance space between it and the four sides of the pit, and a kilometre or so cut off the lower pointed end to allow space for its descent. The mass of this weight is 326×10^6 tons. Its heaviness, three-quarters of the heaviness of an equal mass at the sun's surface, is 244×10^6 tons solar surface-heaviness. Now a horse-power is 270 metre-tons, terrestrial surface-heaviness, per hour; or 10 metre-tons, solar surface-heaviness, per hour. To do 78,000 horse-power, or 780,000 metre-tons, solar surface-heaviness, per hour, our weight must therefore descend at the rate of 1 metre in 313 hours, or about 28 metres per year.

To advance another step, still through impracticable mechanism, towards the practical method by which the sun's heat is produced, let the thread of the screw be of uniformly decreasing steepness from the surface downwards, so that the velocity of the weight, as it is allowed to descend by the turning of the screw, shall be in simple proportion to distance from the sun's centre. This will involve a uniform condensation of the material of the weight; but a condensation so exceedingly small in the course even of tens of thousands of years, that, whatever be the supposed character, metal or stone, of the weight, the elastic reaction against the condensation will be utterly imperceptible in comparison with the gravitational forces with which we are concerned. The work done per metre of descent of the top end of the weight will be just four-fifths of what it was when the thread of the screw was uniform. Thus, to do the 78,000 horse-power of work, the top end of the weight must descend at the rate of 35 metres per year: or 70 kilometres, which is one one-hundredth per cent. (1/10,000) of the sun's radius, per 2000 years.

Now let the whole surface of our cool solid sun be divided into squares, for example as nearly as may be of 1 square metre area each, and let the whole mass of the sun be divided into long inverted pyramids or pointed rods, each 700,000 kilometres long, with their points meeting at the centre. Let each be mounted on a screw, as already described for the long tapering weight which we first considered; and let the paddle at the top end of each screw-shaft revolve in a fluid, not now confined to a vat, but covering the whole surface of the sun to a depth of a few metres or kilometres. Arrange the viscosity of the fluid and the size of each paddle so as to let the paddle turn just so fast as to allow the top end of each pointed rod to descend at the rate of 35 metres per year. The whole fluid will, by the work which the paddles do in it, be made incandescent, and it will give out heat and light to just about the same amount as is actually done by the sun. If the fluid be a few thousand kilometres deep over the paddles, it would be impossible, by any of the appliances of solar physics, to see the difference between our model mechanical sun and the true sun.

Now, to do away with the last vestige of impracticable mechanism, in which the heavinesses of all parts of each long rod are supported on the thread of an ideal screw cut on a vertical shaft of ideal matter, absolutely hard and absolutely frictionless: first, go back a step to our supposition of just one such rod and screw working in a single pit excavated down to the centre of the sun, and let us suppose all the rest of the sun's mass to be rigid and absolutely impervious to heat. Warm up the matter of the pyramidal rod to such a temperature that its material melts and experiences enough of Sir Humphrey Davy's "repulsive motion" to keep it balanced as a fluid, without either sinking or rising from the position in which it was held by the thread of the screw. When the matter is thus held up without the screw, take away the screw or let it melt in its place. We should thus have a pit from the sun's surface to his centre, of a square metre area at the surface, full of incandescent fluid, which we may suppose to be of the actual ingredients of the solar substance. This fluid, having at the first instant the temperature with which the paddle left it, would at the first instant continue radiating heat just as it did when the paddle was kept moving; but it would quickly become much cooler at its surface, and to a distance of a few metres down. Convection-currents, with their irregular whirls, would carry the cooled fluid down from the surface, and bring up hotter fluid from below, but this mixing could not go on through a depth of very many metres to a sufficient degree to keep up anything approaching to the high temperature maintained by the paddle; and after a few hours or days, solidification would commence at the surface. If the solidified matter floats on the fluid at the same temperature below it, the crust would simply thicken as ice on a lake thickens in frosty weather; but if, as is more probable, solid matter, of such ingredients as the sun is composed of, sinks in the liquid when both are at the melting temperature of the substance, thin films of the upper crust would fall in, and continue falling in, until, for several metres downwards, the whole mass of mixed solid and fluid becomes stiff enough (like the stiffness of paste or of mortar) to prevent the frozen film from falling down from the surface. The surface film would then quickly thicken, and in the course of a few hours or days become less than red-hot on its upper surface. The whole pit full of fluid would go on cooling with extreme slowness until, after possibly about a million million million years or so, it would be all at the same temperature as the space to which its upper end radiates.

Now, let precisely what we have been considering be done for every one of our pyramidal rods, with, however, in the first place, thin partitions of matter impervious to heat separating every pit from its four surrounding neighbours. Precisely the same series of events as we have been considering will take place in every one of the pits.

Suppose the whole complex mass to be rotating at the rate of once round in 25 days.

Now at the instant when the paddle stops let all the partitions be annulled, so that there shall be perfect freedom for convection-currents to flow unresisted in any direction, except so far as resisted by the viscosity of the fluid, and leave the piece of matter, which we may now call the Sun, to himself. He will immediately begin showing all the phenomena known in solar physics. Of course the observer might have to wait a few years for sunspots, and a few quarter-centuries to discover periods of sunspots, but they would, I think I may say probably, all be there just as they are; because I think we may feel that it is most probable that all these actions are due to the sun's own mass and not to external influences of any kind. It is, however, quite possible, and indeed many who know most of the subject think it probable, that some of the chief phenomena due to sunspots arise from influxes of meteoric matter circling round the sun. The energy of chemical combination is as nothing compared with the gravitational energy of shrinkage, to which the sun's activity is almost wholly due, but chemical combinations and dissociations may, as urged by Lockyer, be thoroughly potent determining influences on some of the features of non-uniformity of the brightness in the grand phenomena of sunspots, hydrogen flames, and corona, which make the province of solar physics. But these are questions belonging to a very splendid branch of solar science with which we are not occupied this evening.

What concerns us at present may be summarised in two propositions:—

(1) Gigantic convection-currents throughout the sun's liquid mass are continually maintained by fluid, slightly

cooled by radiation, falling down from the surface, and hotter fluid rushing up to take its place.

(2) The work done in any time by the mutual gravitation of all the parts of the fluid, as it shrinks in virtue of the lowering of its temperature, is but little less than (so little less than, that we may regard it as practically equal to[1]) the dynamical equivalent of the heat that is radiated from the sun in the same time.

The rate of shrinkage corresponding to the present rate of solar radiation has been proved to us, by the consideration of our dynamical model, to be 35 metres on the radius per year, or one ten-thousandth of its own length on the radius per two thousand years. Hence, if the solar radiation has been about the same as at present for two hundred thousand years, his radius must have been greater by 1 per cent. two hundred thousand years ago than at present. If we wish to carry our calculations much farther back or forward than two hundred thousand years, we must reckon by differences of the reciprocal of the sun's radius, and not by differences simply of the radius, to take into account the change of density (which, for example, would be 3 per cent. for 1 per cent. change of the radius). Thus the rule, easily worked out according to the principles illustrated by our mechanical model, is this :—

Equal differences of the reciprocal of the radius correspond to equal quantities of heat radiated away from million of years to million of years.

Take two examples :—

(1) If in past time there has been as much as fifteen million times the heat radiated from the sun as is at present radiated out in one year, the solar radius must have been four times as great as at present.

(2) If the sun's effective thermal capacity can be maintained by shrinkage till twenty million times the present year's amount of heat is radiated away, the sun's radius must be half what it is now. But it is to be remarked that the density which this would imply, being 11·2 times the density of water, or just about the density of lead, is probably too great to allow the free shrinkage as of a cooling gas to be still continued without obstruction through overcrowding of the molecules. It seems, therefore, most probable that we cannot for the future reckon on more of solar radiation than, if so much as, twenty million times the amount at present radiated out in a year. It is also to be remarked that the greatly diminished radiating surface, at a much lower temperature, would give out annually much less heat than the sun in his present condition gives. The same considerations led Newcomb to the conclusion "that it is hardly likely that the sun can continue to give sufficient heat to support life on the earth (such life as we now are acquainted with, at least) for ten million years from the present time."

In all our calculations hitherto we have for simplicity taken the density as uniform throughout, and equal to the true mean density of the sun, being about 1·4 times the density of water, or about a fourth of the earth's mean density. In reality the density in the upper parts of the sun's mass must be something less than this, and something considerably more than this in the central parts, because of the pressure in the interior increasing to something enormously great at the centre. If we knew the distribution of interior density we could easily modify our calculations accordingly, but it does not seem probable that the correction could, with any probable assumption as to the greatness of the density throughout a considerable proportion of the sun's interior, add more than a few million years to the past of solar heat, and what could be added to the past must be taken from the future.

In our calculations we have taken Pouillet's number for the total activity of solar radiation, which practically agrees with Herschel's. Forbes[1] showed the necessity for correcting the mode of allowing for atmospheric absorption used by his two predecessors in estimating the total amount of solar radiation, and he was thus led to a number 1·6 times theirs. Forty years later Langley,[2] in an excellently worked out consideration of the whole question of absorption by our atmosphere, of radiant heat of all wave-lengths, accepts and confirms Forbes's reasoning, and by fresh observations in very favourable circumstances on Mount Whitney, 15,000 feet above the sea-level, finds a number a little greater still than Forbes (1·7, instead of Forbes's 1·6, times Pouillet's number). Thus Langley's number expressing the quantity of heat radiated per second of time from each square centimetre of the sun's surface corresponds to 133,000 horse-power per square metre, instead of the 78,000 horse-power which we have taken, and diminishes each of our times in the ratio of 1 to 1·7. Thus, instead of Helmholtz's twenty million years, which was founded on Pouillet's estimate, we have only twelve millons, and similarly with all our other time reckonings based on Pouillet's results. In the circumstances, and taking fully into account all possibilities of greater density in the sun's interior, and of greater or less activity of radiation in past ages, it would, I think, be exceedingly rash to assume as probable anything more than twenty million years of the sun's light in the past history of the earth, or to reckon on more than five or six million years of sunlight for time to come.

But now we come to the most interesting part of our subject—the early history of the sun. Five or ten million years ago he may have been about double his present diameter and an eighth of his present mean density, or ·175 of the density of water; but we cannot, with any probability of argument or speculation, go on continuously much beyond that. We cannot, however, help asking the question, What was the condition of the sun's matter before it came together and became hot? It may have been two cool solid masses, which collided with the velocity due to their mutual gravitation; or, but with enormously less of probability, it may have been two masses colliding with velocities considerably greater than the velocities due to mutual gravitation. This last supposition implies that, calling the two bodies A and B for brevity, the motion of the centre of inertia of B relatively to A, must, when the distances between them was great, have been directed with great exactness to pass through the centre of inertia of A; such great exactness that the rotational momentum after collision was of proper amount to let the sun have his present rotational period when shrunk to his present dimensions. This exceedingly exact aiming of the one body at the other, so to speak, is, on the dry theory of probability, exceedingly improbable. On the other hand, there is certainty that the two bodies A and B at rest in space if left to themselves, undisturbed by other bodies and only influenced by their mutual gravitation, shall collide with direct impact, and therefore with no motion of their centre of inertia, and no rotational momentum of the compound body after the collision. Thus we see that the dry probability of collision between two of a vast number of mutually attracting bodies widely scattered through space is much greater if the bodies be all given at rest, than if they be given moving in any random directions and with any velocities considerable in comparison with the velocities which they would acquire in falling from rest into collision. In this connection it is most interesting to know from stellar astronomy, aided so splendidly as it has recently been by the spectroscope, that the relative motions of the visible stars and our sun are generally very small in comparison with the velocity (612 kilometres per second) a body would acquire

in falling into the sun, and are comparable with the moderate little velocity (29·5 kilometres per second) of the earth in her orbit round the sun.

To fix the ideas, think of two cool solid globes, each of the same mean density as the earth, and of half the sun's diameter, given at rest, or nearly at rest, at a distance asunder equal to twice the earth's distance from the sun. They will fall together and collide in half a year. The collision will last for a few hours, in the course of which they will be transformed into a violently agitated incandescent fluid mass, with about eighteen million (according to the Pouillet-Helmholtz reckoning, of twenty million) years' heat ready made in it, and swelled out by this heat to possibly one and a half times, or two, or three, or four times, the sun's present diameter. If instead of being at rest initially they had had a transverse relative velocity of 1·42 kilometres per second, they would just escape collision, and would revolve in equal ellipses in a period of one year round the centre of inertia, just grazing one another's surfaces every time they come round to the nearest points of their orbits.

If the initial transverse component of relative velocity be less than, but not much less than, 1·42 kilometres per second, there will be a violent grazing collision, and two bright suns, solid globes bathed in flaming fluid, will come into existence in the course of a few hours, and will commence revolving round their common centre of inertia in long elliptic orbits in a period of a little less than a year. The *quasi*-tidal interaction will diminish the eccentricities of their orbits; and if continued long enough will cause the two to revolve in circular orbits round their centre of inertia with a distance between their surfaces equal to ·644 of the diameter of each.

If the initial transverse component relative velocity of the two bodies were just 68 metres per second, the moment of momentum, the same before and after collision, would be just equal to that of the solar system, of which seventeen-eighteenths is Jupiter's and one-eighteenth the sun's: the other bodies of the system being not worth considering in the account. Fragments of superficially-melted solid, or splashes of fluid, sent flying away from the main compound mass could not possibly by tidal action or other resistance get into the actual orbits of the planets, whose evolution requires some finer if more complex fore-ordination than merely the existence of two masses undisturbed by any other matter in space.

I shall only say in conclusion:—Assuming the sun's mass to be composed of portions which were far asunder before it was hot, the immediate antecedent to its incandescence must have been either two bodies with details differing only in proportion and densities from the cases we have been now considering as examples; or it must have been some number more than two—some finite number—at the most the number of atoms in the sun's present mass, which is a finite number as easily understood and imagined as number 3 or number 123. The immediate antecedent to incandescence may have been the whole constituents in the extreme condition of subdivision—that is to say, in the condition of separate atoms; or it may have been any smaller number of groups of atoms making up minute crystals or groups of crystals—snowflakes of matter, as it were; or it may have been lumps of matter like this macadamising stone; or like this stone, which you might mistake for a macadamising stone, and which was actually travelling through space till it fell on the earth at Possil, in the neighbourhood of Glasgow, on April 5, 1804; or like this—which was found in the Desert of Atacama in South America, and is believed to have fallen there from the sky—a fragment made up of iron and stone, which looks as if it has solidified from a mixture of gravel and melted iron in a place where there was very little of heaviness; or this splendidly crystallised piece of iron, a slab cut out of the celebrated aërolite of Lenarto, in Hungary;[1] or this wonderfully shaped specimen, a model of the Middlesburgh meteorite, kindly given me by Prof. A. S. Herschel, with corrugations showing how its melted matter has been scoured off from the front part of its surface in its final rush through the earth's atmosphere when it was seen to fall on March 14, 1881, at 3.35 p.m.

For the theory of the sun it is indifferent which of these varieties of configurations of matter may have been the immediate antecedent of his incandescence, but I can never think of these material antecedents without remembering a question put to me thirty years ago by the late Bishop Ewing, Bishop of Argyll and the Isles: "Do you imagine that piece of matter to have been as it is from the beginning; to have been created as it is, or to have been as it is through all time till it fell on the earth?" I had told him that I believed the sun to be built up of stones, but he would not be satisfied till he knew or could imagine, what kind of stones. I could not but agree with him in feeling it impossible to imagine that any one of these meteorites before you has been as it is through all time, or that the materials of the sun were like this for all time before they came together and became hot. Surely this stone has an eventful history, but I shall not tax your patience longer to-night by trying to trace it conjecturally. I shall only say that we cannot but agree with the common opinion which regards meteorites as fragments broken from larger masses, but we cannot be satisfied without trying to imagine what were the antecedents of those masses.

PROTOPLASM[2]

IT is a natural and beneficial result of the present energetic pursuit of biological science that every now and again some thinker comes forward to show us where we stand, and to what our thoughts are impelling us. Subordinate to the universal eminence and influence of a Linnæus or a Darwin, the critics of a decade exert no small effect on contemporary investigation by suggesting new modes of viewing or expressing things; and even though the originality is not always happy, and the generalisations are sometimes unfortunate, it is nevertheless a healthy sign that specialists of reputation, led to view matters with a severely critical eye as their work progresses, occasionally turn round and warn us that it would be as well to take stock of the facts, and see what are the chances of solving some large problem. Moreover, it has to be borne in mind that as various branches reach a certain stage their results need overhauling by specialists in other departments, and it becomes a question who is to prepare the problems of biology, for instance, so that the mathematician or the physicist may criticise them.

As much on this account as for his own contributions to the store of facts, we must welcome Dr. Berthold's clever "Studies" as an earnest and important attempt to contribute to a knowledge of the mechanics of life. Of course it is always a difficulty to decide how far a specialist may be expected to take an accurate view of a large problem to the direct solution of which his own researches can contribute but little; but experience has shown that more is to be looked for from the deep insight obtained by close investigation than from the few brilliant suggestions scattered through volumes of merely clever thinking. In the present case, the moderate tone of the book, and the easy earnestness of the writer, should at least insure careful reading of the 324 pages of text in which Dr. Berthold expresses his bold ideas; and whether the conclusions stand or fall, the reader will be amply repaid by the observations collected and the criticisms on several questions now agitating the minds of botanists.

[1] The three aërolites now exhibited belong to the Hunterian Museum of the University of Glasgow, and have been kindly lent me for this evening by the Curator, Dr. Young.

[2] "Studien über Protoplasmamechanik." By Dr. G. Berthold, Professor of Botany in the University of Göttingen. (Leipzig: Arthur Felix, 1886.)

The title of the book must be taken in a comprehensive sense, for the whole "cell-theory" (if we possess one) is under review in the nine chapters into which the text is divided. This extensive aim is justified by the author's treatment of the subject, which affords an admirable survey of current botanical speculation.

Before proceeding to a closer examination of the work, we may state that there are seven well-executed plates, with descriptions which are too short. The index might have been more ample—it includes the names of plants and authors only—but the table of contents is very full and good.

An introduction of eleven pages leads us at once to the chief position assumed by the author. So long as we do not understand the *Amœba*, we must be in the dark as regards the mechanism of life in higher organisms. Nothing has been gained by regarding protoplasm as "living proteid," or as containing "living" as opposed to "dead" proteids, and so forth: moreover, no clearness, but rather the contrary, has so far resulted from hypotheses as to the "structure" of protoplasm, or from distinctions between "idioplasm" and other constituents. The author therefore inquired whether we are not perhaps treading an aimless path, and whether we should not go back and examine earlier views, and proceed anew. The consequence to his mind was the resumption of the old analogy between a drop of protoplasm and a drop of fluid, and he was led to inquire into the analogy more deeply, especially on finding that a detailed analysis of the problem had not before been seriously undertaken. As the general result of investigations begun in 1882, the author decides that protoplasm is to be regarded as a highly complex emulsion, differing in consistence in the different cases. There is nothing in the chemistry and metabolism known which need clash with this view of the fluid nature of the "physical basis of life," and the author decides that the forces upon which the changes of form, internal movements, and so forth, depend, are the same as those which determine whether a fluid shall assume the form of a drop, or drops, or spread out and wet another body, and so on—in fact, the forces concerned in surface-tensions.

The author frankly admits the difficulty, and even seeming impossibility, of imitating some of the conditions, or even of deciding whether the actions of protoplasm accord with the theory. This must naturally be the case; and of course no one expects him to imitate all the conditions experimentally. The method employed is essentially deductive and analytic throughout, and for this reason the greatest possible care must be employed in taking any step forward. Partly on this account, and partly owing to other circumstances, the book needs cautious reading, and great difficulties will be felt in regard to many points. This is apart from an undoubted (though perhaps unavoidable) blemish in the book, which consists in the author so often putting off for some pages the consideration of a subject commenced.

The key-note, as it were, of the work having been indicated, a few words must be said regarding some leading features in the various chapters. The first subject dealt with is the layered or stratified nature of the typical cell. A spore of *Equisetum*, for instance, may be regarded as a system of concentric layers. First there is a central nucleus; then various layers of protoplasm, of which the innermost is colourless and contains certain minute granules, the second is thicker and carries the chlorophyll-corpuscles, the third is hyaline and contains lenticular refractive bodies of peculiar nature; then follows the cell-wall, if nothing further. The cell-wall is usually composed of three or more layers.

If we consider the cells of a tissue, Berthold points out that a given partition membrane must be regarded as dividing and belonging to two symmetrical plasmatic systems, and as being their middle and innermost layer.

But all cells are not systems of concentric layers. Not only are excentric layers found, but a complexity is introduced as soon as the sap-vacuoles appear, in many cases making the cell not monocentric but polycentric. The *normal* order of the layers, as exemplified by the spore of *Equisetum*, or any simple cell with one large vacuole, &c., may be distinguished from the *inverse* order exhibited, for instance, by the cords in a *Caulerpa*, or the central mass in a cell containing raphides, or anywhere where the sap bathes the system of layers referred to.

It is then shown that in many cases where oil-drops, &c., have usually been regarded as lying free in a cell, they are inclosed in an ingrowth from the cell-wall, reminding us of cystoliths. An examination of intercellular spaces follows: the most interesting question is as to the existence of protoplasm in lacunæ between cells. Berthold quotes *Aconitum Napellus* as affording conclusive evidence, and confutes the contention of Gardiner and Schenck against Russow's statements. Berthold goes much further, however. He finds a thin layer of protoplasm overlying the cuticle of the epidermis and of spores, and, to put it shortly, concludes that the cell-wall is formed and embedded in protoplasm, and not excreted on its surface—the cell-wall is a supporting apparatus, not a protective one. Again, a cell forming part of a tissue cannot be forthwith compared with a unicellular Alga, for this reason: the latter may be regarded as consisting of two parts, (1) the inner protoplasmic system with its contiguous share of cell-wall, (2) the outer strata of cell-wall *plus* the hypothetical covering of protoplasm. Only the first of these two parts of the algal cell can be compared with a tissue-cell.

The relation of these ideas to Sachs's view, that we are to regard a plant as a whole cut up into cell-chambers, and not as a whole built up of single cells, is obvious to all who have followed recent speculations in botany.

It is, of course, impossible to go at any length into the contents of all the chapters. The second is concerned with the finer structure of the cell—nucleus, chlorophyll-corpuscles, and other cell-contents. Incidentally we may note the emphatic statement that starch is *not* formed in the *Melanophyceæ* (p. 57); that the word "microsome" has no definite meaning, and had better be discarded (p. 61). Later on the author expressly states his inability to confirm Strasburger's and Schmitz's conclusions that microsomes are employed in building up the cell-wall (p. 208), and even hints at confusion between crystalline particles and microsomes in the case of *Spirogyra!*

If protoplasm is an emulsion, it follows that the various processes of separation of sap-vacuoles, oil-drops, crystalline and other particles, have to be explained as according with similar separations in lifeless mixtures. Berthold finds no difficulties insuperable here, and even discusses the probable origin and disappearance of chlorophyll-corpuscles and nuclei on the assumption that they are part of the protoplasm. Although they now always arise by the division of those previously existing, they must have been formed from protoplasm in the first instance. The action of external stimuli offers a fertile subject for discussion. As regards geotropism, the author regards "the primary effect of gravitation" as consisting in the different rates of movement of substances of different specific gravity.

The supposition that anything is explained by regarding protoplasm as essentially "living proteid," is severely criticised on pp. 74 and 75, and the author agrees with Baumann that the arguments which exalt proteids into the position of being the most essential constituent of protoplasm would apply equally well to water. The "living substance of organisms" is always an extremely complex mixture. At the same time, it would seem that the author here raises some gratuitous difficulties, since no biologist really regards protoplasm as a simple substance, proteid or otherwise. One consequence of the discussion might almost be foreseen: Berthold proposes to recast the definition of protoplasm, and to subordinate to it—the fluid mixture absent from no living cell—cytoplasm, nucleus, chlorophyll-bodies, vacuoles, tannin and oil-drops, &c., as so many parts, of the protoplasm as a whole. He urges that the introduction of the ideas cytoplasm, ectoplasm, and so on, have driven the time-honoured word protoplasm out of the field, whereas its usefulness as a comprehensive word—though with a somewhat different meaning from the current one—for the whole is undoubted. Moreover, it is to be insisted upon that the protoplasm is active as a whole.

The discussion as to the meaning of the term "organised" must be here passed over, with many other points of interest.

In the third chapter we have a long analysis of the movements of naked masses of protoplasm. All turns upon the tendency of a mass of protoplasm to assume the form of a spherical drop; this can only be due to the same causes which impel a drop of any accepted liquid to assume the drop condition. Justice could not be done by summarising this analysis, and the demonstration that cylinders of protoplasm, like cylinders of liquids, tend to break up in a definite way. The end result of a long argument is, that the amœboid condition depends upon the degree of wetting of the environment by the fluid protoplasm and *vice versâ*.

If three fluids which do not mix are in contact with one another, the tensions at their surfaces can be mathematically investigated, and Berthold maintains that the principles here concerned govern the behaviour of a drop of protoplasm as they do that of an ordinary liquid under the given conditions. The phenomena of spreading out, putting forth and withdrawing pseudopodia, rounding off, &c., are due to the same causes and ruled by the same laws as the flowing of one liquid over another, or its withdrawal from it (glycerine and alcohol *e.g.*), or its assumption of the drop form, and so on. Of course amœboid movements are complex, because the liquid amœba is not a simple fluid, but is undergoing rapid changes due to its metabolism and exchanges with the environment, processes which are acting with different energy at different places. It must be clearly understood that a rapid survey of Berthold's position cannot do justice to his argument: whether his position is accepted or rejected, there is no doubt that he clearly sees and provides for many important difficulties, some of which seem to have been overlooked. It will be regarded as a startling idea by some (though the idea is not altogether new) that fine pseudopodia are not the results of activity on the part of the amœba: such pseudopodia must be looked upon as *drawn out by* the surrounding medium, not *put out into* it. Here, again, exceptions occur where blunt processes are driven forth by local contractions and other causes, but the sum total of all the argument is (as expressly stated again on p. 109) that the amœboid condition is the symptom that the organism wets the substratum and displaces the surrounding medium, indicating that the intensity of the tension between the medium and the protoplasm is but small. The discussion as to the causes and effects of the internal movements in protoplasm must here be passed over, with the simple remark that the author sees no difficulty which cannot be explained from our knowledge of the mechanics of liquids. On p. 106 is proposed an explanation of the remarkable filaments observed by F. Darwin on *Dipsacus sylvestris*.

Chapter IV. deals with what is practically a continuation of the second chapter—the symmetry or arrangement of the cell-contents. The stratified or shell arrangement is again expressly referred to, and an attempt made to explain it on the main assumption of the book. The arrangement referred to is a consequence of exchanges (diffusion, absorption, &c.) with the environment: passive particles suspended in the cell would have to assume positions which are definite; active particles (*i.e.* particles which themselves exchange with the layer in which they are embedded) might interfere with the simple shell arrangement, and we have systems within a system. After examining what occurs in the case of a spherical system or cell, the author extends the analysis to an ellipsoid and other anisodiametric systems, and finds the results accord with what is found in Nature. The question of the "Hautschicht" is then attacked, and De Vries' late statements as to the existence of a pellicle or "wall" around the vacuole are criticised. Berthold, to put it shortly, condemns this pellicle as an artificial product—a "precipitation-membrane"—in many if not in most cases. On p. 154 it is still more emphatically stated that the cell-wall inside the cell is formed "always in the interior of the protoplasm, never on its surface," and it is probable "that the same is the case even when free masses of protoplasm surround themselves with a membrane." The membrane stated to exist around the nucleus is condemned, with a certain reserve, as a probable precipitation-membrane. Other interesting points must be passed over.

The fifth chapter is practically concerned with showing that in spite of the great variety of forms exhibited by the chlorophyll-bodies of different plants, especially Algæ, their position, consistence, changes in form, division, &c., can be explained in accordance with the view that they are parts of an emulsion. Other cell-contents are considered also—oil-drops, tannin, nucleus, vacuoles, &c.—but at less length. The chlorophyll-corpuscles of higher plants are compared to drops resting on a substratum which they do not wet, their shape being in part due to radial pressures. When they are more extended and amœboid, their actions are explained according to the principles (contact of three surfaces, &c.) employed before. *Spirogyra* and other Conjugatæ present difficulties. While the "chlorophyll-apparatus" displays a relatively large surface, the converse is the case with nuclei and other cell-contents, and the form of the spherical drop (maximum cubic contents with minimum superficial area) is usual; though exceptions exist and are investigated.

The division of chlorophyll-corpuscles is then examined, and this leads naturally to the division of the nucleus and cell, which is treated separately. A spherical mass of fluid must increase its surface if it divides: this implies a diminution of tension at the common surface (as with the formation of pseudopodia), and concentric shells in the medium or in the mass of fluid in question. All the conditions fulfilled, pseudopodia can be formed either from the medium into the mass, or from the mass into the medium. An annular pseudopodium would divide the spherical (or spheroidal) mass into two. This is, shortly put, the position as Berthold views it. He then again applies the analysis of dividing cylinders, and proceeds to apply the results to what is observed in a cell. The radial pressure, and growth in one direction of the cell, may be important factors. But the real difficulty is met with when considering the division of spherical bodies in the cells of the growing-points, for instance; and the same applies to cell-division. Why should a sphere—a stable form—pass over into an elongated body, which then divides? It must be assumed that "under the influence of its own metabolism, and that of its environment a bi-polar symmetry arises in the chlorophyll-corpuscle, in consequence of which the division takes place equatorially."

This leads to the sixth chapter, which is in many respects the most important, as it is the most interesting. After reviewing the process of cell-division generally, the author separates the essential from the unessential processes, and agrees with Strasburger that the division of the nucleus must be regarded as an accompanying phenomenon. The division of the ovum of *Echinus* and *Ciona* is described: soon after the male and female nuclei have fused, two centres appear in the egg, each with radii—the required bi-polarity is established. The exchanges and movements in the protoplasm are then followed; the result is that certain constituents accumulate to excess in the equator between the two radiating centres, or "suns." The chief points are illustrated by diagrams. The two "suns" are the centres of the future daughter-cells; the still single nucleus lies between them in a bridge of the same protoplasm as the "suns" (these "suns," by the bye, are the *Attractions-Kugeln* of Van Beneden, and the *Pol-Kugeln* of others) are embedded in: the more peripheral protoplasm of the cell (ovum) has accumulated chiefly around the nucleus—*i.e.* in the equatorial plane. This equatorial protoplasm then begins to cut in two the nucleus, which has assumed the "karyokinetic" condition. Passing over many details, we may sum up the explanation shortly. The superficial shells of protoplasm are assumed to put forth pseudopodia between the "suns"—*i.e.* the author regards it as fundamentally a wetting process, due to changes at the surfaces. The processes are essentially of the same nature in vegetable cells, though it is impossible in a short space to summarise Berthold's discussion as to the relative importance of the numerous details which occur in different cases. Obviously the stumbling-block which is best worth further attack is the origin of bi-polarity in a spherical mass: that Berthold's suggestions do not satisfy the requirements will probably occur to everyone. The explanation offered to account for the complex karyokinesis cannot be regarded as fully satisfactory. At the same time some advantage may accrue from the new lights in which he puts the central figures of cell-division. We are here only half through the book however, and must proceed, confining our remarks still more closely.

Chapter VII. treats of the cell-network of plants, and the directions of cell-divisions, &c. It is in great measure a criticism of Sachs's celebrated view of the structure of the higher plants, and deals at some length with several of his positions. Of course, Berthold assumes primarily that the plant is to be regarded as chambered—cut up into cells, not built up of them. Two main principles are then employed. (1) The cell-divisions are, as a rule (at least in growing-points, &c.), halvings—*i.e.* each daughter-cell has the same cubic contents. This leads to a discussion of very many cases. Of course the shape of a segment does not forthwith enable us to judge of its relative contents, and difficulty occurs sometimes on this account: it is impossible to summarise the remarks, and especially since reference to the figures is necessary. (2) The second fundamental principle is that which regulates the position of fluid lamellæ elsewhere—the principle of least areas. The rule is that the new cell-wall takes such a direction that its area is the smallest possible. There are exceptions, *e.g.* cambium cells; but at least one feature appears to indicate a tendency to follow the principle—cell-walls never abut in the angles of cells. Sachs's law of rectangular division is comprehended as a particular case of Berthold's more general law: it fails where simultaneous divisions result in the formation of polygonal cells—*e.g.* in the embryo-sac—with walls inclined at angles greater than the right-angle.

The eighth chapter deals with the sculpturing on the interior of cell-walls, and allied phenomena; while Chapter IX. (the last) is devoted to "free cell-formation."

Enough has been said to show the wide scope of the book, though full criticism of it will only be possible after some of Berthold's test-cases have been worked over. Of course, from the nature of the work, it is open to the charge of being transcendental; but at the same time it must be allowed that we are getting into serious difficulties with protoplasm, and good, bold, shaking criticism is beneficial. In any case, several investigators will, no doubt, have something to say to Berthold's statements, for there is no lack of observations, old and new, as well as hypothesis, in the book we dismiss with this short review.

H. MARSHALL WARD

ON THE EXPLOSION OF METEORITES

WE have received from M. Hirn a *tirage à part* of a communication to *L'Astronomie*, in which he discusses the various phenomena accompanying the explosion of meteorites, with a view to explaining their causes.

M. Daubrée, a long time ago, pointed out how very striking and difficult of explanation the noises are which are often heard in connection with the passage of meteorites, and called in question the explanation which had been given of their being really due to a veritable explosion.

M. Hirn, in his paper, begins by considering the causes which are at work in the production of the thunder which accompanies electric discharges, and of this he writes as follows:—"The sound, which we call thunder, is due, as everybody knows, to the fact that the air traversed by an electric spark, that is, a flash of lightning, is suddenly raised to a very high temperature, and has its volume moreover considerably increased. The column of gas thus suddenly heated and expanded is sometimes several miles long; as the duration of the flash is not even a millionth of a second, it follows that the noise bursts forth at once from the whole column; but for an observer in any one place it commences where the lightning is at the least distance. In precise terms, the beginning of the thunder-clap gives us the minimum distance of the lightning; and the length of the thunder-clap gives us the length of the column. It must be remarked that when a flash of lightning strikes the ground, it is not necessarily from the place struck that the first noise is heard." M. Hirn then gives an interesting case which proves the truth of this remark. He next points out that a bullet whistles in traversing the air, so that we can to a certain extent follow its flight; the same thing happens with a falling meteorite just before striking the earth. The noise actually heard has been compared to the flight of wild geese or the sound produced when one tears linen: it is due to the fact that the air rapidly pushed on one side in front of the projectile, whether bullet or meteorite, quickly rushes back to fill the gap left in the rear.

The most rapid cannon-shots scarcely attain a velocity of 600 metres a second, while meteorites penetrate the air with a velocity of 40,000 or even 60,000 metres per second; and this increased velocity gives rise to phenomena, which, although insignificant where cannon-shots are in question, become very intense and important when we consider the case of the meteorite. With that velocity the air is at once raised to a temperature of from 4000° to 6000° C. The matter on the surface of the meteorite will be torn away by the violence of the gaseous friction produced, and will be vaporised at the same time by the heat. This is undoubtedly the origin of the smoke which meteorites leave trailing behind them.

We have, then, precisely as in the case of lightning, a long narrow column of air, which is expanded, not so instantaneously certainly as by lightning, but at all events in an extremely short time and through a great length. Under these circumstances we should have an explosion in one case as in the other: a clap of thunder followed by a rolling noise more or less prolonged. If a cannon-ball could have imparted to it a velocity of 100,000 metres per second, it would no longer whistle, it would thunder, and at the same time it would produce a flash, as of lightning, and would be instantly burnt up. M. Hirn depends upon this line of reasoning to show that meteoric thunder need not necessarily have anything to do with an actual explosion. He then points out that the intensity of the noise produced in every point of its trajectory depends, (1) on the height; (2) on the velocity of the meteorite; (3) on its size; and (4) on the configuration of the country over which it passes. He refers to the observation of Saussure that a pistol fired at a height of 5000 metres makes very little noise: he then points out that at a height of 100,000 metres the density of the air is reduced to the small value of 0·000,000,004 krg.; the temperature being supposed to be − 200° C. In such a medium as this a meteorite could produce no sound, although it might give out a very brilliant light, because its temperature and light depend not on the absolute value, but on the rapid change of density.

SIR JOSEPH WHITWORTH

On Saturday night last, Sir Joseph Whitworth died at the English Hotel, Monte Carlo. In the department of mechanical engineering there is, perhaps, no greater name, and his career was one upon which his countrymen may well look back with pride and pleasure. He was born on December 21, 1803, at Stockport, where his father was a schoolmaster. At the age of twelve he was sent from his father's school to Mr. Vint's academy at Idle, near Leeds, where he remained until he was fourteen, when he was placed with his uncle, a cotton-spinner in Derbyshire. Here he made himself familiar with the construction and working of all the machines then used in cotton-spinning. If he had chosen, he might perhaps have inherited his uncle's property, but he was already conscious of the true bent of his genius, and after six years' service, being unable to emancipate himself in a more regular manner, he ran away to Manchester. At Manchester he remained for four years, working in the shops of Messrs. Crighton and other employers, and obtaining a thorough mastery of the methods of manufacturing cotton-machinery. Recognising the necessity of wide experience, he went to London when he had secured all the practical knowledge that could be obtained in his special line at Manchester, and he was fortunate enough to be employed by Maudslay, who soon learned to appreciate his exceptional gifts, and took him into his own private workroom, and placed him next to Hampson, the best workman in the establishment. From Maudslay's, Mr. Whitworth went to Holtzapfel's, and afterwards to Clements's, where Babbage's calculating-machine was being constructed. During his residence in London, Mr. Whitworth began the splendid series of inventions which were to secure for him the foremost place among the mechanical engineers of his period. His first important self-imposed task was to construct the true plane, by which tool-makers might be enabled to produce, for all kinds of sliding tools, surfaces on which the resistance arising from friction would be reduced to a minimum. The work to be achieved was one of immense difficulty, and his fellow-workman, Hampson, used to laugh at him for having undertaken an impossible job. Mr. Whitworth, however, was a man of extraordinary tenacity of purpose, and did not allow himself to be discouraged. At last he succeeded, and showed his friend the perfect plane he had produced. "You've done it," said Hampson, who was astounded by a result which he had always thought to be beyond the reach of human effort.

In 1833, at the age of thirty, Mr. Whitworth, feeling that he might now safely trust to his own energies, returned to Manchester and opened a shop for the manufacture of engineers' tools. He was far from thinking that his first triumph had given the full measure of his powers. Already he had been working at another very complicated problem—how to do away with the inconveniences caused by variations in the pitch and thread of the screws used in the construction of machinery. In this enterprise he was as successful as in his first great undertaking. Obtaining specimens of the screws made by leading manufacturers, he constructed one which, without being exactly like any one of those before him, was the average of them all. It was everywhere accepted, and its introduction marked an era in the history of the manufacture of machinery. The advantage derived from the invention is that every screw of the same diameter has now a thread of the same pitch and of the same number of turns to the inch, and that all screws of the same size are interchangeable. His next achievement was the construction of an instrument capable of measuring the one-millionth part of an inch. This instrument was so delicate that when a steel bar 3 feet in length was warmed by momentary contact with a finger-nail, it at once indicated the expansion due to this slight cause.

As a maker of engineers' tools Mr. Whitworth of course soon became famous, and in 1853 he was sent to America as one of the Royal Commissioners to the New York Exhibition. Afterwards he drew up a remarkable report on American manufacturing industry. On his return to England it was suggested by the late Lord Hardinge that the great mechanician, whose fame was now firmly established, should be asked by the Government to design and produce machinery for the manufacture of rifles for the army. The rifles at that time issued to the army were carefully examined by him, and he decided that if his services were to be of any avail it would be necessary for him to determine the form and dimensions which would produce the best results. With an alacrity very unusual in such matters, the Government consented to erect in his private grounds at Rusholme, near Manchester, a shooting-gallery 500 yards long. Here Mr. Whitworth laboured assiduously, trying many kinds of experiment, and at every stage of his progress making absolutely sure of his ground before advancing a step towards fresh conclusions. The result of his investigations was to revolutionise the manufacture of rifles. As the *Times* has said, "he determined, by absolute and precise experiment, the effects of every conceivable pitch and kind of rifling, and of every length of projectile, from the sphere to one of twenty diameters in length; and he settled once for all the conditions of trajectory and of accuracy of flight." The significance of his efforts began to be understood by every one when, at the first Wimbledon meeting, Her Majesty fired the first shot from a Whitworth rifle, placed on a mechanical rest sliding upon true planes. At 400 yards' range the bullet struck the target on its vertical diameter, one inch and a quarter above the intersection of the horizontal. What he established with regard to rifles he found to be in the main true with regard to weapons of a larger calibre, and he proved the importance of this fact by constructing a series of magnificent cannon.

In the course of his inquiries as to the principles which ought to be observed in the manufacture of rifled small arms and ordnance, Mr. Whitworth became penetrated by the conviction that a new material must be provided, since mild steel was apt to be rendered unsound by the imprisonment of escaping gases during the process of cooling from the molten state. He solved the problem by using great hydraulic presses for the squeezing of the molten metal in the act of cooling, so that the particles might be brought into closer contact and the gases liberated. The steel produced by this method is remarkable for its lightness, strength, and tenacity, and is largely used in the construction of boilers, screw-propeller shafts, and for other purposes.

In 1869 Mr. Whitworth was created a baronet, and he had already been for some years a Fellow of the Royal Society and a D.C.L. of Oxford. He had amassed wealth, and thoroughly appreciated all the advantages it secured for him. He was, however, a man of enlightened ideas and generous impulses, and early in 1869 he did splendid service to mechanical and engineering industry by founding the Whitworth Scholarships, which he endowed to the extent of 100,000*l*. He was twice married—first, in 1825, to Fanny, youngest daughter of Mr. Richard Ankers; then, in 1871, to Mary Louisa, widow of Mr. Alfred Orrell. Notwithstanding his unwearied attention to business, he contrived to have some leisure time, and he spent it very agreeably at his estate of Stancliffe, in Derbyshire, where he devoted himself to landscape gardening. He also derived a great deal of pleasure from his horses and his herd of short-horns. For some time his health had been failing, and until lately he went every winter to the Riviera. Two years ago he made for himself at Stancliffe a winter garden, hoping that he might thus be able to spend the winter at home. Last year he went abroad again, and now, at the age of eighty-three, his long and great career has come to an end. The whole civilised world may be said to be familiar with his name, and he will always be remembered as the most illustrious English mechanician of the present age. Few men of his time have done more for the nation than Whitworth. His "Scholarships" have had the most important influence upon the knowledge and training of the rising generation of engineers. There are now nearly 200 Whitworth Scholars throughout the land, and they will doubtless be largely represented at his funeral.

NOTES

SINCE our last week's number was issued, Prof. Huxley has sent an important letter to the *Times* on the subject of the true functions of the Imperial Institute. From this letter we make the following extract:—"That with which I did intend to express my strong sympathy was the intention which I thought I discerned, to establish something which should play the same part in regard to the advancement of industrial knowledge which has been played in regard to science and learning in general, in these realms, by the Royal Society and the Universities. I pictured the Imperial Institute to myself as a house of call for all those who are concerned in the advancement of industry; as a place in which the home-keeping industrial could find out all he wants to know about colonial industry and the colonist about home industry; as a sort of neutral ground on which the capitalist and the artisan would be equally welcome; as a centre of intercommunication in which they might enter into friendly discussion of the problems at issue between them, and, perchance, arrive at a friendly solution of them. I imagined it a place in which the fullest stores of industrial knowledge would be made accessible to the public; in which the higher questions of commerce and industry would be systematically studied and elucidated; and where, as in an industrial University, the whole technical education of the country might find its centre and crown. If I earnestly desire to see such an institution created, it is not because I think that or anything else will put an end to pauperism and want—as somebody has absurdly suggested—but because I believe it will supply a foundation for that scientific organisation of our industries which the changed conditions of the times render indispensable to their prosperity. I do not think I am far wrong in assuming that we are entering, indeed have already entered, upon the most serious struggle for existence to which this country has ever been committed. The latter years of the century promise to see us embarked in an industrial war of far more serious import than the military wars of its opening years. On the east, the most systematically instructed and best informed people in Europe are our competitors; on the west, an energetic offshoot of our own stock, grown bigger than its parent, enters upon the struggle possessed of natural resources to which we can make no pretension, and with every prospect of soon possessing that cheap labour by which they may be effectually utilised. Many circumstances tend to justify the hope that we may hold our own if we are careful to 'organise victory.' But, to those who reflect seriously on the prospects of the population of Lancashire and Yorkshire—should the time ever arrive when the goods which are produced by their labour and their skill are to be had cheaper elsewhere—to those who remember the cotton famine and reflect how much worse a customer famine would be, the situation appears very grave. I thought—I still think—that it was the intention of the Prince of Wales and his advisers, recognising the existence of these dangers ahead, to make a serious effort to meet them, and it was in that belief that I supported the proposed Institute." We are glad to see that in the pamphlet which is now being circulated by the organisers of the Imperial Institute it is acknowledged that in this communication Prof. Huxley "has clearly defined the functions of the Imperial Institute as recognised by the propounders of the scheme."

THE Royal Society of New South Wales offers its medal and a prize of 25*l*. for the best communication (provided it be of sufficient merit) containing the results of original research or observation upon any one of a list of subjects which it has published. Communications on the following subjects must be sent in not later than May 1 next:—On the silver ore deposits of New South Wales; origin and mode of occurrence of gold-bearing veins and of the associated minerals; influence of the Australian climate in producing modifications of diseases; and on the Infusoria peculiar to Australia. A year later the Society will receive papers on the anatomy and life-history of the Echidna and Platypus; the anatomy and life-history of Mollusca peculiar to Australia; and the chemical composition of the products from the so-called kerosene shale of New South Wales. The subjects on which communications must be sent in not later than May 1, 1889, are:—On the chemistry of the Australian gums and resins; on the aborigines of Australia; on the iron ore deposits of New South Wales; list of the marine fauna of Port Jackson, with descriptive notes as to habits, distribution, &c. The competition is open to all without any restriction whatever, excepting that a prize will not be awarded to a Member of the Council for the time being; neither will an award be made for a mere compilation, however meritorious in its way. The communication to be successful must be either wholly or in part the result of original observation or research on the part of the contributor.

THE Compagnie du Congo pour le Commerce et l'Industrie is organising an expedition, composed of geologists and others, for the exploration of the Upper Congo and its tributaries.

WE regret to announce the death of Mr. Edward Livingstone Youmans, a well-known American writer on science. Mr. Youmans was born in New York in 1821, and though suffering much from defective vision, prosecuted from his early youth the study of science. He became well known as a public lecturer. He planned the "International Scientific Series" in 1871, in connection with which he made several visits to Europe. In 1872 he established the *Popular Science Monthly* in New York. Mr. Youmans died on Thursday last, January 20.

IT is sometimes said that intellectually Scotland does not stand on so high a level as in former times. This may be true so far as literature is concerned, but it is certainly not true with regard to science. At a recent meeting of the Royal Society of Edinburgh Mr. John Murray, of the *Challenger*, one of the Vice-Presidents, declared that he questioned whether any country in the world, taking its size into consideration, could show a better record of scientific work or a greater mass of scientific literature than Scotland during the past ten or twenty years. In making this statement Mr. Murray's object was not to glorify his own country but to show that its scientific establishments have a solid claim to better treatment than they have hitherto received at the hands of the Government. Money grants, he stated, of considerable annual value are devoted to the maintenance of learned Societies in London and Dublin. In Scotland, according to Mr.

Murray, the only grant of the kind is 300*l*. annually to the Royal Society of Edinburgh, and this is repaid to a Government Department in the form of rent. With regard to London, Mr. Murray, we think, should verify his references, as we know of no Society which receives "a money grant of considerable value."

THE death is announced of M. Feil, the well-known glass-founder, who prepared so many disks for the large telescopes in use in several Observatories; and of M. Mercadier, Professor of Physics to the Polytechnic School of Paris, and author of the only French book on electrical measures. M. Feil was seventy-four years of age; M. Mercadier ten years younger.

THE French are making use of their occupation of Madagascar to gain a thorough knowledge of the natural history of the island. There have already issued from the national press several fascicules of a magnificent "Histoire physique, naturelle, et politique de Madagascar," edited by M. Alfred Grandidier, to be completed in thirty volumes quarto. The subjects to be comprised in this work are: (1) physical and astronomical geography; (2) meteorology and magnetism; (3) ethnology, anthropology, and linguistics; (4) political, colonial, and commercial history; (5) natural history of mammals; (6) natural history of birds; (7) natural history of fishes; (8) natural history of reptiles; (9) natural history of Crustacea; (10) natural history of terrestrial and freshwater mollusks; (11) natural history of plants; (12) geology and palæontology. The various sections are intrusted to competent authorities; and the geological portion is to be illustrated by about 500 chromolithographs or coloured plates, the anatomical details being represented in lithography and photography. The total number of plates will not be less than 1200.

PREPARATIONS for the first general meeting, at Rome, of the International Statistical Institute are being made by the Executive Committee, consisting of Sir Rawson W. Rawson, K.C.M.G., C.B. (the President), M. E. Levasseur and Prof. von Neumann-Spallart (Vice-Presidents), Signor Luigi Bodio (General Secretary), and Mr. John Biddulph Martin (Treasurer). The arrangements will be announced by the Committee in due course.

ON Friday evening last an important lecture on "Modern War-Ships" was delivered at the Mansion House by Mr. W. H. White, Director of Naval Construction and Assistant Controller of the Navy. The lecture, which was illustrated by diagrams and models, was one of a series given by members of the Company of Shipwrights. Mr. White's object was to place before the meeting facts and figures illustrating the progress of war-ship building in recent years, and he confined his attention almost exclusively to the period between 1859, when the ironclad reconstruction of the Royal Navy began, and the present year. He presented a very lucid and interesting account of the extraordinary changes which have taken place during this time in the methods of war-ship building.

DR. HOPKINSON'S account of the electric lighthouses of Macquarie and of Tino, which was read before the Institution of Civil Engineers last month, has just been issued in pamphlet form, with a report of the oral and written discussion to which it gave rise.

IT is stated that the Lake District in New Zealand is showing signs of fresh disturbances. Tremors have been felt at Rotorua, and Tarawera has emitted dense volumes of steam. The Wahanga Peak appeared most active. No fire was visible, and after this outburst everything quieted down again.

WE have before us the first number of the "Bulletin of Miscellaneous Information," issued from the Royal Gardens, Kew. The "Bulletin" will appear from time to time as an occasional publication, and will contain notes, too detailed for the Annual Report, on economic products and plants to which the attention of the staff of the Royal Gardens has been drawn in the course of ordinary correspondence, or which have been made the subject of particular study at Kew. These notes will serve the purpose of an expeditious mode of communication to the numerous correspondents of Kew in distant parts of the Empire, and they will be useful to members of the general public interested in planting or agricultural business in India and the colonies. The present number contains much valuable information about Teff, one of the cereals indigenous to Abyssinia, and about Oil of Ben.

MESSRS. GINN AND CO., publishers, Boston, U.S.A., are about to issue a *Journal of Morphology*, which will be devoted principally to embryological, anatomical, and histological subjects. Mr. C. O. Whitman, Milwaukee, Wis., will be the editor. For the present only two numbers a year will be issued. The agent for Great Britain is Mr. W. P. Collins.

MESSRS. DE LA RUE AND CO. have in the press the second volume of "A Treatise on Electricity and Magnetism (Methods of Measurement and Applications)," by E. Mascart, Professor in the Collège de France, and Director of the Central Meteorological Bureau, and J. Joubert, Professor in the Collège Rollin. The work is translated by Dr. E. Atkinson, Professor of Experimental Science in the Staff College.

MESSRS. CASSELL AND CO. have just issued the first part of "Our Earth and its Story," a serial which will be completed in thirty six parts, and they are about to publish "Practical Electricity," by Prof. Ayrton.

M. BÉCLARD has presented some interesting statistics to the Academical Council of Paris on the number of female students in the Faculty of Medicine in the University there. He reports that since Germany closed the doors of its Universities to women, the number in Paris has been constantly increasing. At present the numbers of the various nationalities are: Russians 83, English 11, French 7, Americans 3, Austrians 2, Roumanian 1, and Turk 1. The greater number of these do not pursue their studies as far as the doctor's degree. The large proportion of Russian ladies is due to the closing of the female medical school recently founded at St. Petersburg. M. Béclard thinks that the number of students has now reached the maximum, and will probably decline, since the preliminary studies of the Faculty for both sexes have been ma de alike.

ALTHOUGH the competition which takes place annually for the vacancies in the assistantships in the Paris hospitals is not over, it is known that among the *internes* whose names will be published in some days, there will be one woman. Miss Klumpke is the first woman who has successfully competed for the *concours de l'internat*. In the written examination she ranked second (*ex æquo* with one or two others). She obtained 27 marks, the maximum being 30, and the highest number secured being 28. A good deal of grumbling is going on among the students. The idea of being distanced by a woman is not agreeable to them. Miss Klumpke has done very good work in neuro-pathology, and her name is known to all who study this branch of medicine.

THERE are at present nine female students at the Upsala University, three of whom study medicine, five philosophy, and one jurisprudence.

THE Aquarium constructed by the Executive of the Fisheries Exhibition in 1883 has just been sold by the Royal Commissioners by public auction, the property realising 100*l*. in the aggregate. Until recently it was expected that this Aquarium would be maintained as a part of the Buckland Museum. Many of the fish with which it made the British public familiar were hatched from ova of foreign fish. There were various Trans-atlantic forms; and fishes indigenous to India, China, Brazil, Austria, and many other countries were exhibited. Considering the fact that this Aquarium was the only one in London worthy of note, naturalists and the public have good reason to regret that it has been abolished.

MR. Z. NUTTALL, of the Peabody Museum, Cambridge, Mass., has been led to some interesting results by the study of the Mexican codices. Familiarity with certain phonetic symbols of frequent recurrence in these picture-writings enabled him to perceive that identical symbols are reproduced on the so-called Calendar Stone, the Sacrificial Stone, and other equally well-known Mexican monoliths. The Calendar Stone was, he maintains, the Market Stone of the city of Mexico, and he thinks that from the fixed market days recorded on it the Mexican calendar system may have sprung. The so-called Sacrificial Stone seems to him to have been a Law Stone, recording the periodical collection of certain tributes paid by subjugated tribes, and by others whose obligation it was to contribute to the common wealth of Mexico. Mr. Nuttall expresses his belief that many of the large stone receptacles which are generally called "vessels for containing the hearts and blood of human victims," were in reality standard measures kept for reference in the market place.

WE regret to hear of the death of Dr. Julius Lüttich, the well-known astronomer, who died in Rome on January 3; also of Prof. Jean Louis Trasenster, who died on the same day. M. Trasenster was Professor of Engineering and Mining at the Liége University.

THE Report of the Kew Committee for 1886, lately published, shows that the well-known work of the Kew Observatory has been actively carried on during the year. To particularise in certain subjects, it may be mentioned that in the magnetic observations four notable magnetic disturbances were recorded, occurring severally in the months of January, March, July, and October, and that the diurnal range of the declination for the summer and winter seasons, as well as the whole year, is given in a table in the Appendix. In solar observations the results of sketches of sunspots in continuation of Schwabe's enumeration are also recorded in the Appendix. The adoption of a new graphic process for determining cloud heights and motions, devised by Prof. Stokes, has been very satisfactory in saving computation when reducing the photographic pictures. Whilst thus adding its valuable yearly contributions to science, the Observatory is becoming more and more useful in results of immediate utility to the general public. In this respect the rating of watches is a matter of growing convenience to those who require a good time-keeper accompanied with a trustworthy certificate as to the performance of the watch they are about to purchase. Chronometers are also now rated here, and from the 35 days' period of trial in a range of 30° of temperature to which these instruments are subjected by the staff of the Observatory, there is every reason to believe in the ascertained rates. It is encouraging to note that increasing good work points to the necessity for enlarging the existing accommodation afforded by the buildings.

WE have received the third volume of the Proceedings and Transactions of the Royal Society of Canada. It relates to the year 1885. Among the scientific articles may be mentioned "The Artistic Faculty in Aboriginal Races" and "Palæolithic Dexterity," by Dr. Daniel Wilson; "A Natural System in Mineralogy, with a Classification of Native Silicates," by Dr. T. Sterry Hunt; "The Mesozoic Floras of the Rocky Mountain Region," by Sir W. Dawson; "Illustrations of the Fauna of the St. John Group, continued," by Mr. G. F. Matthew; "Catalogue of Canadian Butterflies, with Notes on their Distribution," by Mr. W. Saunders; and "The Skull and Auditory Organ of the Siluroid Hypophthalmus," by Mr. R. Ramsay Wright.

AN elaborate paper on "The Right Hand and Left-Handedness" was lately read before the Royal Society of Canada by Dr. Daniel Wilson, President of University College, Toronto. His final conclusion on this difficult subject, which he has repeatedly discussed from various points of view, is, that left-handedness is due to an exceptional development of the right hemisphere of the brain. Dr. Wilson, who is himself left-handed, concludes his paper with the expression of a hope that after his death his own brain may be "turned to account for the little further service of settling this physiological puzzle." "If my ideas are correct," he says, "I anticipate as the result of its examination that the right hemisphere will not only be found to be heavier than the left, but that it will probably be marked by a noticeable difference in the number and arrangement of the convolutions."

THE additions to the Zoological Society's Gardens during the past week include a White-whiskered Swine (*Sus leucomystox* ♀) from Loochoo Islands, presented by Mr. H. Pryer, C.M.Z.S; two Blackiston's Eagle Owls (*Bubo blackistoni*) from Yesso, Japan, presented by Mr. J. H. Leech, F.Z.S.; two Schlegel's Doves (*Chalcopelia puella*) from West Africa, presented by Mr. H. C. Donovan; a Macaque Monkey (*Macacus cynomolgus*) from India, a Suricate (*Suricata tetradactyla*) from South Africa, deposited; a Red Kangaroo (*Macropus rufus* ♀), a Yellow-footed Kangaroo (*Petrogale xanthopus* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THREE NEW COMETS.—The discovery of a great comet is telegraphed from several southern Observatories. So far as is yet known it was discovered by Mr. Thome at Cordoba on January 18. It was then situated in the constellation Grus; apparently not far from γ Gruis. On the following evening the tail only was seen at Melbourne, projecting some 30° above the south-western horizon. On January 20 it was remarked at Adelaide; here again the tail only was seen. In its physical appearance the comet strongly recalls the great southern comet of 1880, being long, narrow, and straight. It is not brilliant, though readily visible to the naked eye in the twilight. The tail was traced as far as α Toucani. It is expected that the comet will become very brilliant. The nucleus was observed at Adelaide and Melbourne on January 23. The Melbourne observation is as follows:—January 23d. 8h. om., R.A. 21h. 20m. 28s.; daily motion + 7m. 44s., Decl. 44° 17′ S., daily motion + 51′.

Another comet was discovered on January 22 by Mr. W. H. Brooks, of the Red House Observatory, Phelps, New York. Its place on that day at 6h. 54m. was R.A. 18h. om., Decl. 71° N. It was faint, and was moving slowly in an easterly direction. A third comet has been discovered by Mr. E. E. Barnard, Nashville, Tennessee; and observed at Harvard College as follows:—January 24d. 17h. 55·7m., R.A. 19h. 10m. 17·4s., daily motion + 2m. 36s., Decl. 25° 57′ 45″ N., daily motion − 0° 35′. The comet is faint.

NEW VARIABLES.—Mr. S. C. Chandler, Jun., writes in Gould's *Astronomical Journal*, No. 149, to state that the period of the new variable of the Algol type, D.M. + 34° No. 4181, the discovery of which we announced last week (p. 282), is not yet precisely known. It is either 5·997d. or some aliquot part thereof, but not either the third or fifth part. The approximate elements supplied by Mr. Chandler are as follows:—

$$\text{1886 December 9·458d. G.M.T.} + \left(\frac{5\text{·}997\text{d.}}{n}\,\text{E}\right),$$

where n can be neither 3 nor 5. The period may therefore be about three days, one day and a half, or a shorter period still. An examination of the relation which the duration of the oscillation in the light of the other stars of the type bears to the whole period leads Mr. Chandler to conclude that the most probable period is one of 1d. 11h. 59m., or if not that, 20h. 34m., or possibly 18h. 6m. The following table shows that the shorter the period of the variable, the higher is the ratio which the period of oscillation bears to it. In the present star the oscillation probably occupies about six hours; a period so great as three days or much shorter than one day would make it, therefore, an exception to the rule followed by the other seven stars of the same order.

Star	Period h.	Oscillation h.	Ratio
U Ophiuchi	20·13	5·0	0·248
δ Libræ	55·85	12·0	0·214
U Cephei	59·82	10·0	0·167
Algol	68·81	9·15	0·134
U Coronæ	82·85	9·75	0·118
λ Tauri	94·87	10·0	0·105
S Cancri	227·63	21·5	0·094

The variable was discovered by Mr. Chandler and not by Dr. Gould as at first reported.

Mr. Espin, in Circular No. 12 of the Liverpool Astronomical Society, notes the variability of a star 0m. 35s. *p* and 0° 8′ *n* of θ^1 Tauri. It is probably a variable of long period ranging from 9 m. ± to below 12 m. Its place for 1885·0 is R.A. 4h. 21m. 25s., Decl. 15° 50′·7 N.

The Washington Observatory.—The Annual Report of the U.S. Naval Observatory, dated October 30, 1886, has recently been issued. Commodore G. E. Belknap, who was Superintendent of the Observatory at the date of the last Report, retired from that post on June 7, and was succeeded by Commander Allan D. Brown, who therefore is the writer of the Report now before us. In connection with the Chronometer and Time-Service Department, under Lieut. S. C. Paine, it is remarked that the time-service continues to increase in popularity, and its usefulness is daily becoming more apparent to the public. The time-balls that have been established have been much appreciated, and are of great value to the shipping and commercial interests. Much attention appears also to have been given to the chronometer trials, it evidently being the desire of the Observatory to afford makers every assistance in its power in obtaining data that will tend to the improvement of chronometers. The 26-inch refractor, in charge of Prof. Asaph Hall, has been used in observations of satellites, of double stars, and of Saturn. Observations of stellar parallax have also been made. The reduction of the observations of Iapetus and of the six inner satellites of Saturn, as well as those for stellar parallax, have been completed, and the results published. The transit-circle has been employed in observations of stars of the American ephemeris, of the sun, moon, and planets, and such miscellaneous stars as were necessary to complete the data for the proposed transit-circle Catalogue. The whole number of observations since the last Report has been 5180. The reductions have also been proceeded with as rapidly as possible. The instrument remains in charge of Prof. J. R. Eastman. Photographs of the sun have been taken with the photo-heliographic apparatus lately belonging to the Transit of Venus Commission, whenever practicable. The work was commenced on January 11, 1886; and up to and including September 30, 1886, there have been obtained ninety-eight negatives showing spots on the sun's surface. Hitherto no photographs have been taken, except when the sun showed spots on his disk, and then one only near noon. This work has been intrusted to Ensign A. G. Winterhalter, who hopes that in the future the number of photographs in a given period will be considerably increased, better arrangements having been made for securing them between 10 a.m. and 2 p.m.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 JANUARY 30—FEBRUARY 5

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 30

Sun rises, 7h. 44m.; souths, 12h. 13m. 31·8s.; sets, 16h. 43m.; decl. on meridian, 17° 39′ S.: Sidereal Time at Sunset, 1h. 21m.

Moon (at First Quarter on February 1) rises, 10h. 23m.; souths, 16h. 50m.; sets, 23h. 27m.; decl. on meridian, 4° 40′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	7 46	11 55	16 4	20 56 S.
Venus	8 25	13 11	17 57	14 51 S.
Mars	8 31	13 29	18 27	12 40 S.
Jupiter	0 35	5 37	10 39	12 3 S.
Saturn	14 29	22 36	6 43*	22 11 N.

* Indicates that the setting is that of the following morning.

Occultations of Stars by the Moon (visible at Greenwich)

M signifies maximum; *m* minimum; m_2 secondary minimum.

GEOGRAPHICAL NOTES

In connection with Major Macgregor's paper on his journey from Upper Assam to the Irrawadi, read at a recent meeting of the Royal Geographical Society, and printed in the new number of the Proceedings, Dr. G. Watt made some valuable remarks on his own observations in the Manipur district. Manipur is a small valley surrounded by mountain-ranges, and in this valley the rainfall was found to be only about 39 inches, but seventeen miles off, in the mountains which formed the north-east ranges, the rainfall was as much as 120 inches, and towards the Naga country to the north it became greater and greater in certain limited tracts. In the Khasia Hills 600 inches might fall in one place, and twenty miles off only 50 inches. Nothing in Manipur struck Dr. Watt so much, as a botanist, as the remarkable transitions of vegetation in that small region. Dr. Watt gathered twelve or more species of oaks, many of which were new to science, and ten or twelve species of rhododendrons, in Manipur alone. The *Rhododendron Falconeri*, found in the Naga Hills by Sir Joseph Hooker, is nowhere met with in the immense tract between the Naga Hills and Sikkim. This and the epiphytic *R. Dalhousiæ*, which grows on a hill thirty miles north of Darjeeling, Dr. Watt found in the Naga Hills at an altitude of 6000 to 8000 feet, and these rhododendrons never occur in Sikkim below 10,000 to 13,000 feet. There were many instances of plants falling in their altitude as the traveller passed to the east and south-east from Sikkim, until at Moulmein a rhododendron was found growing near the sea, a circumstance which was not met with in any other part of Asia. There is something in that region which, apart from pure geography, is of vital interest. Sarameti, which is under 13,000 feet high, the natives said, had snow all the year round, whereas on the Himalayas the lowest point at which snow occurs is 17,000 feet. In Manipur, the whole valley, 3000 feet high, was covered with hoar-frost in December. Dr. Watt thought this was a point that should be thoroughly investigated: what is the cause of this falling in altitude in the vegetation? General Strachey, who was in the chair, considered that the peculiarities of the vegetation of Manipur compared with Assam were connected with the evident lowering of temperature indicated by the low snow-line. There could be no doubt that the warm currents of air coming up the valleys of the Irrawadi and the Salween and meeting the snowy mountains to the north produced an enormous precipitation of rain, which during winter fell as snow. The consequence seemed to be that there was snow there at a very much lower level than in the mountains further to the north. That an immense quantity of rain fell in the upper portions of the valley of the

Irrawadi there could be no question. Such a rainfall seemed in itself quite sufficient to account for the large volume of water that was drained off by the lower portions of the Irrawadi; and anybody who knew what Tibet was, General Strachey stated, must be aware that, even with a course of several hundred miles, the river would pick up but a small quantity of water in comparison with the enormous volumes which were collected from the rain which fell in Upper Burmah. General Strachey had roughly calculated that a monthly fall of rain of 18 inches over a square degree would mean 65,000 cubic feet per second for the whole month.

THE latest news from Dr. Bunge, chief of the Russian Polar Station at the mouth of the Lena, is encouraging. Telegraphing from Orkinga, a telegraph-station on the road to Yakutsk, Dr. Bunge informs the Academy of Sciences at St. Petersburg that his expedition has had a successful issue. They passed the summer in two islands of the New Siberia Archipelago; Bunge on Great Liakovsky, and Toll on Kotelnoy Island. During spring all the five islands of the group were explored, New Siberia especially by Toll. The mainland was reached at the end of October. The scientific results are very considerable, and, as we know so little about these islands, are likely to be novel.

MM. POTANIN, SKASSY, AND BÉRÉSOFSKY have lately returned from their expedition to China and Mongolia, bringing numerous collections in anthropology, zoology, and botany, besides maps of the country which they have traversed during their three years' journey (1884-86). The Russian Geographical Society has nominated a committee, consisting of MM. Stebnitsky, Tillo, Mushketoff, and Schmidt, to make inquiries as to the desiccation of Siberian lakes. It is expected that an expedition will be despatched to investigate the subject on the spot.

WE learn that the geographical results achieved by the Survey officers on the Afghan Frontier Commission extend over 100,000 square miles of country. The Indian Survey officers have been very busy in Upper Burmah. Captain Hobson's map, prepared from all available sources, in 14 sheets, is all published already. A reduction therefrom, on the scale of 16 miles to an inch, has been prepared in the Surveyer-General's Office, Calcutta, and published also. The Survey party, which has lately completed the Andaman Islands survey, left Calcutta on November 19, under the charge of Major G. Strahan, R.E., to undertake the survey of the Nicobar Islands.

THE ESKIMO

SPECIAL interest attaches to a paper on "The East Greenlanders in their relations to the other Eskimo Tribes," contributed by Dr. H. Rink to the current number of the *Deutsche Geographische Blätter* (Bremen, 1886). Hitherto these hyperboreans have been studied by independent observers, chiefly in Alaska at the eastern, and in Greenland and Labrador at the western extremity of their domain, while through lack of sufficient materials the intermediate branches thinly scattered round the Arctic shores from the Mackenzie to Baffin Bay have been mostly neglected. Here, however, we have for the first time a comprehensive ethnological survey of the whole field by perhaps the greatest living authority on the subject, based on the rich collections recently brought to Europe by Capt. Holm from East Greenland, by the brothers Krause and A. Jakobsen from Alaska, and by F. Boas from the central region of Baffin Land.

With these materials before him, and keeping in view the facts already determined by previous students, Dr. Rink is able to throw much light, if not on the origin, at least on the general line of dispersion, and still more on the social evolution and art history, of the Eskimo race. He makes it sufficiently evident that their primæval home must be placed in the extreme northwest, on the Alaskan shores of the Bering Sea, where they probably acquired a knowledge of some of the useful industries connected with navigation, fishing, and hunting from the neighbouring Indian tribes of Athabascan stock. From this point the migratory movement appears to have been partly across the neck of the Alaskan Peninsula to the Copper River, where their further progress in this direction was arrested by the Thlinkit Indians on the coast and by the Athabascans in the interior. But their wanderings were chiefly directed towards the north and east, that is, along "the line of least resistance" around the unoccupied Arctic seaboard down to Baffin Bay, which seems to have formed a fresh point of dispersion, southwards to Labrador and eastwards to East and West Greenland. Dr. Rink is inclined to accept the view of Capt. Holm, that the Angmagsaliks, or East Greenlanders, found their way round the unexplored north coast of Greenland to their present homes, and that the West Greenlanders passed from Baffin Bay directly southwards, while a mixed race, most probably including old Norse elements, was developed at the southern extremity of the peninsula. In the extreme west there has also been a slight intermingling, with Thlinkits about the Copper River, and with Athabascans, back of Kotzebue Sound; but elsewhere the Innuit and Karalik (Western and Eastern Eskimo) have kept entirely aloof, nowhere amalgamating with the Red Man, and keeping mainly to the seaboard throughout the whole extent of their domain, which, between the Copper River and Cape Farewell, Greenland, cannot be estimated at less than 7000 miles in extent, although scarcely anywhere exceeding 150 miles inland from the coast. This explains the curious fact that the social organisation of the Indian tribes in families, gentes, phratries, confederacies, and nations can nowhere be detected amongst the Eskimo, unless to it is to be attributed a certain restriction in the choice of a wife, and an obligation to lend each other mutual aid, universally recognised amongst all branches of the race. Even the general distribution into tribes, assumed by most writers, appears to be quite groundless, and the final syllable, *mût*, *miût*, of the so-called tribal names, meaning "dweller," "inhabitant of," shows that they are purely *topographical* terms without any ethnical significance whatsoever. Thus, Angmagsalingmiût, Mahlemiût, Aglemiût = inhabitants of the *Angmagsalik*, *Mahle*, *Agle* districts, and so on; so much so, that a family migrating from one of these districts to another changes its name accordingly. Hence Dr. Rink considers it sufficient for all practical purposes to class the whole race into the following seven *geographical* groups:—(1) South Alaskan; (2) North Alaskan; (3) Mackenzie; (4) Central (Baffin Land, &c.); (5) Labrador; (6 and 7) West and East Greenland. Between these various groups there certainly exist differences, by which they may often be readily distinguished; but these are mainly of a social and linguistic, and to a less extent of a physical character; and such is the great uniformity even in the structure of the Eskimo tongue, that an East Greenlander and an Alaskan, if fortuitously thrown together, would soon begin to understand one another. It is noteworthy that in Greenland, where the language has been most carefully studied, greater differences are observed between the eastern and western than between the northern and southern dialects—a circumstance doubtless due to the different routes followed by the two streams of immigration from the central region. Compared with the West Greenland dialect, taken as the written standard, the Labrador is found to contain 15, the Central 20, the Mackenzie 31, and the Alaskan 53 per cent. of different root-words—relations which correspond remarkably well with the conclusions arrived at, on other grounds, regarding the general migratory movement from Alaska, the assumed cradle of the race.

But here an important exception is formed by the Aleutian Islanders, who are treated by Dr. Rink as a branch of the Eskimo family, but whose language diverges profoundly from, or rather shows no perceptible affinity at all to, the Eskimo. The old question respecting the ethnical affinities of the Aleutians is thus again raised, but not further discussed by our author. To say that they must be regarded as "ein abnormer Seitenzweig," merely avoids the difficulty, while perhaps obscuring or misstating the true relations altogether. For these islanders should possibly be regarded, not as "an abnormal offshoot," but as the original stock from which the Eskimos themselves have diverged. It is remarkable that in his new work on "Alaska and the Seal Islands" Henry W. Elliott discovers a striking resemblance between the Aleutians and the Japanese. They constantly remind him of "Japanese faces and forms in another costume," so much so that in his opinion they form "a perfect link of gradation," not between the Eskimo and Red Man, nor between the Eskimo and Asiatic hyperboreans, but "between the Japanese and Eskimo" (p. 173). Mr. Elliott may have here unconsciously hit upon the solution of a very interesting ethnological problem, for in his "Classification of the Varieties of the Human Species" (*Journal* of the Anthropological Institute, May 1885), Prof. Flower also connects the Eskimo with the Japanese:—"Every special characteristic which distinguishes a Japanese from the average of mankind is seen in the Eskimo in an exaggerated degree, so that there can be no doubt about their being derived from the same stock. It has also been shown that these special characteristics gradually increase from west to east, and are seen in their greatest perfection in the inhabitants of Greenland, at all events in those where no crossings with the Danes have taken place."

The Aleutians would thus help to bridge over the somewhat abrupt gap still undoubtedly separating the Eskimo and Japanese groups. At the same time this view suggests a primæval line of migration from Japan through the Kurile Islands and Kamchatka to the Aleutian chain and Alaska, which again presents other difficulties of a somewhat formidable character. In the first place, the Japanese appear to be themselves only comparatively recent intruders in Niphon, whose primitive inhabitants were the Ainos, a people of totally different physical type. Hence it is not easy to understand how they could have thrown off an easterly branch, which has had time to develop into the Eskimo, probably the most specialised of all existing races. In the second place, in his "Tales and Traditions of the Eskimo," Dr. Rink himself advances some solid reasons for bringing the Eskimo, not from Asia at all, or at least not in the first instance, but from the interior of the North American continent. He holds in fact, with some other ethnologists, that they were originally inlanders, who, under pressure from the American Indians, gradually advanced along the course of the Yukon, Mackenzie, and other great rivers, to their present homes on the Bering Sea and Frozen Ocean.—But a discussion of these contradictory theories, for which a solution may yet be found, must be deferred to another occasion. Meantime enough has probably been said to show the highly suggestive character of the paper under review.

A. H. KEANE

SCIENTIFIC SERIALS

L'Astronomie: Revue mensuelle d'Astronomie populaire, de Météorologie, et de Physique du Globe, January 1887.—We have received the January number of the above periodical, edited by Camille Flammarion. M. Flammarion has done a great work in popularising astronomy in France, and the success which has attended this review—for it is entering on its sixth year—proves how widespread an interest is now taken in the science in that country. The present number contains an "Annuaire astronomique pour 1887," by the editor, a series of descriptive notes of a general character on the principal objects of astronomical observation for the current year, the sun, moon, eclipses, occultations, and the planets. M. Daubrée follows with a paper on some recent meteorites. M. Flammarion gives an account of the storms of October 16 and December 8, and of the general principles of weather prophecy. The notes chiefly relate to the two comets of the season, those of Barnard and Finlay, three diagrams being given of the first, showing the position and character of the two tails, and one of the second. A sort of general observing ephemeris for the month January 15 to February 15, of a popular rather than of a scientific character, concludes the number. M. Flammarion and his co-workers frequently affect a somewhat magniloquent and sensational style, and deal principally with the more popular, easy, and interesting aspects of astronomy; the wonders of our own globe, earthquakes, volcanoes, &c., receive much attention, so that the field embraced is not confined to pure astronomy alone. But after every allowance is made and every drawback admitted, *L'Astronomie* has done much good in circulating astronomical information and in arousing and fostering scientific tastes, and it must be confessed that for an astronomical journal containing forty well-printed imperial octavo pages and, as in this case, more than thirty illustrations, to command a remunerative circulation at the price of a franc a number is highly creditable alike to editor, to publishers, and to the public which supports it. It may well be doubted whether such an enterprise would meet with the same success either here or in America.

Bulletin de l'Académie des Sciences de St. Pétersbourg, tome xxx., No. 4.—The appearance of Encke's comet in 1885 compared with its previous appearances, by O. Backlund. The paper is the first of a series, and contains, besides the numerical data of the observations made in 1885, an inquiry into the disturbances due to the attraction of the earth. The summer parallax of the earth is taken to be 8"·80, and the elements of the comet are determined accordingly.—On the formation of buds among the Phanerogams, by A. Famintzin.—The period of the rotation of the sun, according to the magnetic disturbances, as observed at Pawlowsk, by P. A. Müller. The average value of 25·66 is deduced from observations made from August 1, 1882, to August 31, 1883.—Photography applied to astronomy; abstract of a lecture by Otto Struve.—On several new Trilobites and kindred forms from East Siberia, by Fr. Schmidt. The following species (nearly all new) are described, with plates:—From the Cambrian, on the Vilui River, *Anomocare pawlowskii* and *Liostracus* (?) *maydeli*; from the Cambrian on the Olenek, *Agnostus czekanowskii*; from the Lower Silurian of the Middle Tunguska, *Phacops lopatini* and *P. sibiricus*; from the Devonian limestone at Krasnoyarsk, *Proetus slatkowskii*, *Cyphaspis sibirica*; *Eurypterus* (?) *czekanowskii*, and *E. punctatus* from the Devonian on the Angara at Padun.—A new form of *Opalina* (*spiculata*), by Warpachowsky.—On a new *Otomela* (*bogdanowi*), by V. Bianchi.—Remarkable hail at Bobruisk, by H. Wild (with plates). On November 28, 1885, with an absolutely clear sky, not a cloud being visible, hail fell for five minutes. The fall was quite local, and did not extend farther than five miles from Bobruisk. Many pieces were like broken pieces of ice, others apple-shaped, with conical depressions at the poles.—On the electromotory difference and the polarisation of electrodes on telegraphic lines, by P. Müller.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 13.—"On the Crimson Line of Phosphorescent Alumina." By William Crookes, F.R.S., V.P.C.S.

In a paper which I had the honour of communicating to the Royal Society in March 1879 (Phil. Trans., Part 2, 1879, pp. 660, 661), I described the phosphorescence of alumina and its various forms when under the influence of the electrical discharge *in vacuo*, in the following words:—"Next to the diamond, alumina in the form of ruby is perhaps the most strikingly phosphorescent stone I have examined. It glows with a rich full red; and a remarkable feature is that it is of little consequence what degree of colour the earth or stone possesses naturally, the colour of the phosphorescence is nearly the same in all cases; chemically precipitated amorphous alumina, rubies of a pale reddish yellow, and gems of the prized 'pigeon's blood' colour, glowing alike in the vacuum, thus corroborating E. Becquerel's (*Annales de Chimie et de Physique*, vol. lvii. 1859, p. 50) results on the action of light on alumina and its compounds in the phosphoroscope. . . . The appearance of the alumina glow in the spectroscope is remarkable. There is a faint continuous spectrum ending in the red somewhere near the line B; then a black space, and next an intensely brilliant and sharp red line to which nearly the whole of the intensity of the coloured glow is due. . . . This line coincides with the one described by E. Becquerel as being the most brilliant of the lines in the spectrum of the light of alumina, in its various forms, when glowing in the phosphoroscope."

In the *Comptes rendus* for December 6 last (vol. cii. p. 1107) appears a brief note by M. de Boisbaudran, in which he announces, "to that date, that alumina, calcined and submitted to the electrical discharge in a vacuum, has not given him a trace of red fluorescence. This fluorescence, as well as its special spectrum, shows itself brilliantly when the alumina contains 1/100 and even 1/1100 of Cr_2O_3. With the 1/10,000 part of Cr_2O_3 we still obtain very visible rose colour. . . . From these observations the presence of chromium appears to be indispensable to the production of the red fluorescence of alumina."

This statement being opposed to all my experience, I immediately instituted experiments with a view, if possible, to clear up the mystery. I started with aluminium sulphate which I knew to be tolerably pure, and in which ordinary tests failed to detect chromium. On ignition and testing in the usual manner in a radiant-matter tube the alumina line was brightly visible in the spectrum of the emitted light. Different portions of this aluminium sulphate were now purified by various processes for the separation of chromium. All gave as a result the absence of this impurity. The most trustworthy process being that devised by Wöhler ("Select Methods in Chemical Analysis," second edition, p. 124), I used it to purify the bulk. The salt was dissolved in water, and excess of caustic potash added till the precipitate first formed re-dissolved. Chlorine was now passed through till no more precipitate fell down and the liquid retained a strong odour of chlorine. The whole of the chromium would now be in solution, whilst the alumina would be in the precipitate. The alumina was filtered off, well washed, and a portion tested in the radiant-matter tube. It gave as good an alumina spectrum as did the original sulphate; the crimson line being very prominent.

The alumina thus purified was a second time dissolved in caustic potash and submitted to the chlorine purification. Again in the radiant-matter tube the alumina gave its characteristic crimson line spectrum.

Many other experiments are given, and the paper concludes as follows:—

These experiments are perhaps too few to permit any important inference being drawn from them. There seems, however, to be four possible explanations of the phenomena observed:—

(1) The crimson line is due to alumina, but it is capable of being suppressed by an accompanying earth which concentrates towards one end of the fractionations.

(2) The crimson line is not due to alumina, but is due to the presence of an accompanying earth concentrating towards the other end of the fractionations.

(3) The crimson line belongs to alumina, but its full development requires certain precautions to be observed in the time and intensity of ignition, degree of exhaustion, or its absolute freedom from alkaline and other bodies carried down by precipitated alumina, and difficult to remove by washing; experience not having yet shown which of these precautions are essential to the full development of the crimson line and which are unessential.

(4) The earth alumina is a compound molecule, one of its constituent molecules giving the crimson line. According to this hypothesis alumina would be analogous to yttria.

Zoological Society, January 18.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of December 1886, and called attention to a young male of the true Zebra (*Equus zebra*), purchased December 11; and to a young male Indian Rhinoceros, presented by H.H. the Maharajah of Cooch Behar, through the kind intervention of Dr. B. Simpson, and received December 25.—Mr. F. W. Styan exhibited and made remarks on a series of Chinese birds' eggs which he had collected at Kiukiang and Shanghai.—Mr. Howard Saunders exhibited and read some notes on a skin of the Mediterranean Black-headed Gull (*Larus melanocephalus*), killed on Breydon Water, near Great Yarmouth, and sent for exhibition by Mr. G. Smith, of that town. This was stated to be the first absolutely authentic occurrence of this southern species on the British coasts.—Mr. Sclater exhibited and made some remarks on an example of a rare Amazon Parrot (*Chrysotis bodini*) from British Guiana.—Various other specimens were exhibited, and papers read.

Edinburgh

Royal Society, January 17.—Sheriff Irvine, Vice-President, in the chair.—Mr. John Murray read a paper on the total rainfall of the globe, and its relation to the discharge of rivers. 2243 cubic miles of rain fall annually on areas with inland drainage. Such areas extend to 11,486,350 square miles. The land draining directly to the ocean has an area of 44,211,000 square miles. If from this quantity we subtract all areas having less than 10 inches of annual rainfall, we get 38,829,750 square miles. The mean discharge from this area into the ocean is 6569 cubic miles annually. The total weight of substances carried by this means to the ocean is rather more than 5,000,000,000 tons each year.—Mr. W. Durham read a paper on chemical affinity and solution.—The fourth part of a paper on thermometer-screens was communicated by Mr. John Aitken.—Prof. Armstrong read a paper by Mr. A. C. Elliot, containing an extension and improvement of Rankine's formula for the pressure of earth on a retaining wall.—Prof. Tait communicated the third part of his paper on the foundations of the kinetic theory of gases. In the first division of this part the author discusses the modifications which are introduced into his previous formulæ by the consideration of the effects of molecular attraction of small range, but great intensity, on the behaviour of a group of hard, smooth, impinging spheres. In the second division he makes the assumption that the spheres are not perfectly hard, but possess a definite coefficient of restitution. He then endeavours to make an approximation to the conditions of the liquid state by considering the action of spheres whose relative speed of approach is such that, after impact, they are unable to pass out of the range of molecular attraction in consequence of the loss of translational energy by impact.

Dublin

Royal Society, December 15, 1886.—The physical properties of manganese steel, by Prof. W. F. Barrett. The author pointed out that Mr. J. T. Bottomley had sent a brief note on the feebly-magnetic character of manganese steel to the Aberdeen meeting of the British Association, and had kindly furnished him with a specimen of this steel, and the name of the makers and patentees, Messrs. Hadfield and Co., of Sheffield. The steel contains 12 to 14 per cent. of manganese. Through Messrs. Hadfield, the author had obtained wire drawn from manganese steel, a process that first presented great difficulties, but was ultimately accomplished with ease by heating the steel to whiteness, and quenching in cold water after a reduction through every two sizes had been drawn. Sudden cooling softens this steel; slow cooling hardens it. A No. 19 S.W.G. wire (diameter 0·98 millimetre) was thus obtained of two kinds—hard and soft; the density was 7·808. The *electric conductivity* was found by Prof. Barrett to be very low. The No. 19 wire had a resistance of about an ohm per metre, the exact specific resistance in C.G.S. units being 77,000 for 1 cubic centimetre; ordinary iron is only 9800, and German silver 21,170 in the same units; so that some use might be made of manganese steel wire for resistance-coils in electric lighting. The variation of resistance with temperature is now being examined. The *magnetic character* of this steel was then carefully tested by the author. Mr. Bottomley found the intensity of magnetisation of this steel, after submitting it to the most powerful magnetising force, was 2·55 in C.G.S. units, or the magnetisation per gramme was 0·013 in C.G.S. Ordinary steel gives a number varying from 40 to 90, and even 100, C.G.S. units per gramme. So that, if ordinary steel of average quality be 100,000, manganese steel is 20. This represents the permanent magnetism. Prof. Barrett, by different methods, has determined the susceptibility—that is, the induced magnetisation—in a uniform field. Compared with iron as 100,000, manganese steel was found to be 300. In fact, it is very wonderful, judging by muscular sense, to find no sensible force required to move this steel, even in the most powerful magnetic field that could be obtained. Hence, as the author suggests, the use of manganese steel for the bed plates of dynamos and the plating of iron vessels is obvious. Ships built of such steel would have no sensible deviation of the compass. As excellent castings can be obtained from this steel, it ought to have many applications from its extreme hardness, enormous tenacity, and feebly-magnetic character. Dr. Hopkinson's important memoir on the magnetisation of iron contains a measurement of the magnetic susceptibility of manganese steel, of which Prof. Barrett was unaware until his paper had been written. Though Dr. Hopkinson's method of determination was wholly different, the ratio of the susceptibility of iron to manganese steel which he obtained is fairly accordant with the number obtained by the author, the composition of the specimen being the same in both cases. As regards the *tenacity* of manganese steel, the author had found the hard wire had the extraordinary tenacity of 110 tons per square inch, or 173·5 kilogrammes per square millimetre—a number confirmed by independent tests which the chief engineer of the Irish Great Southern and Western Railway Works had kindly made for Prof. Barrett. The tenacity of ordinary steel wire is from 80 to 100 kilogrammes per square millimetre, the best pianoforte steel wire alone showing a higher tenacity than the manganese steel wire. The soft manganese steel wire had a tenacity of only 48 tons per square inch, with an elongation of nearly 20 per cent. The *modulus of elasticity* was also determined by the author by direct stretching. It was found to be lower than wrought iron, the mean number for the hard manganese wire being 16,800 kilogrammes per square millimetre, the soft manganese wire having a still lower modulus. The modulus for ordinary steel wire is 18,810, and for iron wire 18,610 kilogrammes per square millimetre; so that, though hard manganese steel has an enormous tenacity, it "gives" more than steel under sudden stress, recovering itself, of course, if the limits of elasticity are not passed. Obviously this is a most useful property for many purposes to which the steel may be applied. Further experiments on this interesting material are in progress in the Physical Laboratory of the Royal College of Science.

PARIS

Academy of Sciences, January 17.—M. Gosselin, President, in the chair.—Obituary notices of M. Paul Bert on the occasion of his obsequies at Auxerre, by M. Janssen in the name of the Academy of Sciences, and by M. A. Chauveau on behalf of the Biological Society.—Observations of the minor planets made with the large meridian instrument of the Paris Observatory during the third quarter of the year 1886, communicated by M. Mouchez. Comparative observations are here tabulated for Electra, Aletheia, Olympia, Juno, Pallas, Ceres, and several other minor planets. Those for the three last mentioned are referred to the ephemerides of the "Nautical Almanac," all the others to those of the "Berliner Jahrbuch." The observations were taken by MM. F. Boquet, O. Callandreau, and P. Puiseux.—Study of the horizontal flexion of the telescope of the Bischoffsheim meridian-circle of the Paris Observatory, by MM. Lœwy, Leveau, and Henri Renan.—On the solar statistics of the year 1886, by M. R. Wolf.—Letter addressed to the Academy by M. Em. Barbier, thanking it for the Francœur Prize recently awarded to him, and submitting a means by which he has succeeded in converting an ordinary watch into a repeater. A process is also explained by which a person both deaf and blind may tell the time by this repeater.—On the accelerations of the points of an invariable system in motion, by M. Ph. Gilbert. Two cases are considered: (1) that of a solid revolving round a fixed point, O; (2) that of a free solid body.—On the laws determining the absorption of light in crystals, and on a new method enabling the observer to distinguish in a crystal certain absorption-bands belonging to different bodies, by M. Henri Becquerel. His researches in this branch of physics have led the author to several important conclusions here specified on the absorption of light in crystals. He finds generally that in different crystals the characters of the phenomena of absorption differ considerably from those that one might expect to observe, regard being had to the optical properties of the crystal.—Heat of formation of some alcoholates of soda, by M. de Forcrand. Having already determined the heat of formation of the methylate and ethylate of soda, the author passes here to the study of the alcoholates of soda formed by the propylic, isobutylic, and amylic alcohols.—On some combinations of the bioxide of tin, by M. A. Ditte. Sulphuric acid is known to readily dissolve the hydrates of the bioxide of tin derived from various sources, yielding a liquor soluble in water and alcohol. Here the author studies the products of this reaction, which have not yet attracted the attention of chemists.—Action of some metalloids on the nitrates of silver and copper in solution, by M. J. B. Senderens. The author deals here with powdered selenium, tellurium, sulphur, arsenic, phosphorus, and bromium.—Note on the composition of the grain of starch, by M. Em. Bourquelot. From his researches the author concludes that the grain of starch is formed neither of one nor of two chemical species (granulose and amylose) as has been hitherto supposed, but of a larger number of hydrates of carbon.—On the plastidogene body, or pretended heart of the Echinoderms, by M. Edmond Perrier.—On some new parasites of the Daphnidæ, by M. R. Moniez.—On some Crustaceæ, parasites of the Phallusiæ, by M. Paul Gourret.—On the removal of Lamarck's Herbarium to the Museum of Natural History, by M. Ed. Bureau. After remaining for some fifty years in the University of Rostock, this famous historical collection, containing over 10,000 specimens in good condition, has just been purchased and transferred to the Paris Natural History Museum. The tickets, descriptions, and other accompanying documents are all in the handwriting of the illustrious naturalist.—On the genus *Plesiadapis*, a fossil mammal of the Lower Eocene from the neighbourhood of Rheims, by M. Lemoine. Various remains are described by means of which the author determines two sub-genera of the genus *Plesiadapis* (Gervais), presenting lemurian characters with a marsupial facies.—Note on giovannite, a new cosmic rock, by M. Stanislas Meunier.—On the deterioration of vaccine, by M. P. Pourquier. An experiment is described showing the deterioration of this virus, with suggestions on a means of preventing its attenuation.—Note on the copper detected in wines from vineyards treated with the sulphate of copper against mildew, by M. A. Andouard. An analysis of several samples shows that the quantity of copper detected in such wines is infinitesimal, and in no way injurious to health.

STOCKHOLM

Royal Academy of Sciences, January 12.—Prof. S. Lovén gave an account of the researches effected at the zoological station of the Academy at Christineberg, in the province of Bohus, during last summer.—Prof. Rubenson gave an account of a posthumous memoir by the late Col.-Lieut. Klercker on the so-called anomalous dispersion.—Determination of some physical constants of germanium and titanium, by Profs. Nilsson and Petterson.—On experiments on the electrical conducting power of the air, by Prof. Edlund.—On bryological researches in the province of Småland, by Herr R. Tolf.—Annotations on the vegetation in the west of Herjeådalen, particularly as to the occurrence of the Hymenomycetæ within different formations of the vegetation, by Dr. E. Henning.—A comparative research on the monosulphon-combinations of benzol and toluol, by Dr. Weibull.—Construction of the curves of the fourth order and second kind by means of rules and compasses, by Prof. Björling.—On the pleochroism and light-absorption in epidote from Sulzbachthal, by Herr W. Ramsay.—On the amido-naphthaline-sulphon acid, by Herr S. Forsling.—On the sponges of the province of Bohus, by Dr. Fristedt.

A HISTORY OF THE THEORY OF ELASTICITY

A History of the Theory of Elasticity and of the Strength of Materials, from Galilei to the Present Time. By the late Isaac Todhunter, D.Sc., F.R.S. Edited and completed for the Syndics of the University Press by Karl Pearson, M.A., Professor of Applied Mathematics, University College, London. Vol. I. Galilei to Saint-Venant, 1639–1850. (Cambridge: at the University Press, 1886.)

THIS work was projected by the late Dr. Todhunter on the same lines as his well-known Histories of the "Theory of Probabilities," of the "Figure of the Earth," and of the "Calculus of Variations," and will doubtless equal them in usefulness to the mathematical student.

The first object of a writer in the preparation of such a work would be to draw up as complete a bibliography as possible of all books and papers relating to the subject, arranged in chronological order. Afterwards, in reading these memoirs, he would make copious notes, extracts, and criticisms; and then, on reaching the end of this self-imposed task, he would find his materials for a book like the present ready to place in the printer's hands. Incidentally, enough material and ideas would accumulate to form an independent treatise on the subject. Such a task was undertaken by Dr. Todhunter on the "History and Theory of Elasticity," from the standpoint of the mathematician, but he did not live, unfortunately, to complete it.

Prof. Karl Pearson explains in the preface the circumstances in which he undertook to edit and complete the work, and, from his own account, the labour thus devolved on him would have been sufficient to enable him to complete the "History" *ab initio.*

The present volume, like the previous "Histories," carries the subject and commentaries only to the year 1850, although Dr. Todhunter had analysed the chief mathematical memoirs from 1850 to 1870. The preparation of the second volume, to carry the history from 1850 up to date, is a task from which Prof. Pearson appears to recoil, with some justification; but it is to be hoped that he will enlist in his service some of the junior elasticians mentioned in his preface, and, by the application of the modern principle of the subdivision of labour, carry this invaluable work to its proper conclusion.

At the outset Prof. Pearson gives the palm to Galileo Galilei (1638) as the founder of the subject of elasticity and the strength of materials, while Dr. Todhunter asserts in § 18 that "the first work of genuine mathematical value on our subject is due to James Bernoulli . . . 1695." Galileo treated only the question of the breaking moment of a beam, or rather what we should call the *bending* moment, exactly as is done now in calculating the *stresses* in a structure, before proceeding to determine the consequent *strains* and deformations.

At this point the law enunciated by Hooke (1678) must intervene, which goes by his name, "Ut tensio, sic vis," originally published by him, in the fashion of those times, as an anagram, *ceiiinosssttuu.* Stated in the modern form, this law asserts that

$$\frac{\text{tension}}{\text{extension}} = \frac{\text{pressure}}{\text{compression}} = \frac{\text{stress}}{\text{strain}} = \text{modulus of elasticity},$$

and is the law universally employed to connect mathematically the corresponding stresses and strains in an elastic substance, as pointed out by Saint-Venant [8].

When the stresses and strains are large enough for variations on Hooke's law to become observable, a fresh set of phenomena depending on the ductility and viscosity of the substance came into play, and the previous mathematical investigations no longer hold. Much of the confusion pointed out by Dr. Todhunter in the treatment of the subject by experimentalists is due to the fact that in experiments it has been usual to test the strength of structures to the breaking-point, and hence the use of the term *breaking* instead of *bending* moment. The modern experiments of Wöhler show that this point, at which ductility manifests itself, is much sooner reached than was formerly supposed; consequently, modern engineering practice is much less bold than formerly in large iron structures like bridges. For this reason, the diagrams of the frontispiece, though physically extremely interesting, cannot be considered to bear on the mathematical theory.

Returning again to the treatment of the subject by the mathematicians, we find a picturesque diagram given by Galileo (p. 2) of a beam built into an old wall and supporting a weight, the cross-grained character of the wood of the beam being carefully shown; so that it is not surprising that Galileo does not attempt any molecular theory to account for the flexure of the beam. This theory, supplied by Hooke's law, was applied by Mariotte, Leibnitz, De Lahire, and Varignon; but they neglect the compression of the fibres, and so place the neutral plane in the lower face of Galileo's beam. The true position of the neutral plane was assigned by James Bernoulli in 1695, who, in his investigation of the simplest case of the bent beam, was led to the consideration of the curve called the "elastica." This "elastica" curve speedily attracted the attention of the great Euler (1744), and must be considered to have directed his attention to the elliptic integrals. Probably the extraordinary divination which led Euler to the formula connecting the sum of two elliptic integrals, thus giving the fundamental theorem of the addition equation of elliptic functions, was due to mechanical considerations concerning the "elastica" curve; a good illustration of the general principle that the pure mathematician will find the best materials for his work in the problems presented to him by natural and physical questions. The result obtained by Euler for the thrust at which a straight column begins to bend, when the corresponding "elastica" differs from a straight line very slightly in a curve of sines, is of the utmost importance to the architect and engineer; and, as Prof. Kennedy can testify, is employed with the greatest confidence in the design of the highest columns and pillars.

It is interesting to find the complete treatment of the problem of lateral vibrations of elastic bars is also due to Euler, though the analytical difficulties of the *period equations* seem to have puzzled him. If we employ the modern notation of the *hyperbolic* functions, we shall find his period equations all reduced to the form—

$$\cos\omega \cosh\omega = \pm 1,$$

or,

$$\tanh\omega = \pm \sin\omega;$$

and this again is equivalent to

$$\tanh\tfrac{1}{2}\omega = \pm\tan\tfrac{1}{2}\omega, \text{ or } \mp\cot\tfrac{1}{2}\omega,$$

whence a graphical determination of the values of ω is easily inferred (pp. 50, 51, footnote).

Another interesting paper due to Euler is "De altitudine columnarum sub proprio pondere corruentium" (1778), investigating the height at which a mast or tree will begin to bend under its own weight. To this paper he might well have prefixed the old German proverb, quoted by Goethe in "Wahrheit und Dichtung":—"Es ist dafür gesorgt, dass die Baüme nicht in dem Himmel wachsen." We know now that the functions of Bessel are required for the complete analytical solution of this question, though the *Theorema maxime memorabile* enunciated by Euler, "Maxima altitudo, qua columnæ cylindricæ ex eadem materia confectæ, proprium pondus etiamnunc sustinere valent, tenet rationem subtriplicatam amplitudinis," is interesting as one of the first applications of the principle of mechanical similitude, showing why the proportions of the giant of the forest are stunted compared with those of the young tree, and also why it is hopeless to attempt the problem of human flight while g is 32.

Lagrange considered the same subject in "Sur la figure des colonnes" (1770), examining and disproving the dictum of Vitruvius that the *renflement* of a column was necessary for strength: the dictum can hardly be called an architectural fallacy, as the *renflement* corrects the tendency, due to *irradiation*, of a perfectly cylindrical column to appear attenuated in the middle; for a similar reason it is necessary to slightly blunt the neighbourhood of the point of a Gothic spire to avoid the appearance of concavity.

Coulomb, a well-known name to electricians, is mentioned by Saint-Venant as giving about this time (1780), in "Remarques sur la rupture des corps," the true position of the neutral line of a beam, although it is asserted by Dr. Todhunter that the ancient erroneous idea prevailed into the present century.

In Chapter II. the work of Young, Gregory, Eytelwein, Plana, Dupin, Belli, Binet, Biot, Rennie, Barlow, Tredgold, Fourier, Nobili, Bordoni, Hodgkinson, and others is analysed. Of these the English writers, who generally were experimentalists as well as theorists, are severely handled by Dr. Todhunter for their heresies on the neutral axis. Considering that the neutral axis is a mathematical fiction, depending on an ignoration of the shearing stress, and the consequent warping of the normal sections of a beam, this treatment of Dr. Todhunter is too severe, compared with the leniency with which he views the metaphysical speculations of the pure theorists. These experimentalists were trusted in their advice on important constructions, and took care their formulæ erred on the right side of strength.

To Navier (1821) we are first indebted for the general mathematical equations of the equilibrium and vibrations of an elastic solid, to be satisfied in the interior and at the surface, and henceforth the researches of mathematicians take a bolder flight from the treatment of the simple beam of former investigators.

Mlle. Sophie Germain's "Recherches sur la théorie des surfaces élastiques" (1821) appears to afford Dr. Todhunter gratification in showing that sex can make itself apparent even in mathematics. However, it is dangerous to argue from this instance, as hardly any mathematician has yet written on elastic surfaces without falling into error in the boundary conditions, and the subject is even now not yet certainly settled.

The vibration of elastic surfaces is important in its bearing on acoustics and music, and received about this time experimental and theoretical treatment from Chladni, Strehlke, Pagani, and Savart.

Chapters IV. and V. give an account of the treatment of the subject by the celebrated mathematicians Poisson and Cauchy, who practically exhausted the soluble problems, if we except the torsion questions considered by Saint-Venant. Poisson's results are generally expressed by means of definite integrals, most of which we see now can be classified as Bessel's functions. Both Poisson and Cauchy appear to have considered the subject of elasticity principally in its bearing on the new theory of physical optics, then receiving such important experimental and theoretical treatment at the hands of Fresnel.

Henceforth the theory receives development at the hands of so many writers that it is possible only to specify the honoured names of Gerstner, Green, McCullagh, Poncelet, and Maxwell as having contributed important advance to the subject.

Lamé's "Theory of Elasticity," carefully analysed in Chapter VII., still remains a standard text-book, in conjunction with the treatises of F. Neumann and Clebsch.

The volume concludes with an account of Saint-Venant's researches before 1850, the subsequent work to be recorded in the second volume. Saint-Venant is the name most honoured by practical elasticians and engineers, inasmuch as he has developed his theories from the definite practical problems presented by the large and daring constructions in iron and steel which mark the middle of this century.

In the appendix Mr. Pearson has carefully analysed the conflicting notations of different writers, and proposed a very convenient terminology and notation, which would save great trouble if universally adopted. He has also given an account of experiments carried out by Prof. Kennedy in his mechanical laboratory, which have an important bearing on the limitations of the truth of Hooke's law, or, in the language of elasticity, the constancy of the ratio of stress to corresponding strain.

The present volume is an indispensable hand-book of reference for the mathematician and the engineer, and in the editing and printing must be considered a very fitting tribute to the wonderful industry and application of its projector, the late Dr. Todhunter.

A. G. GREENHILL

THE ENCYCLOPÆDIA BRITANNICA

The Encyclopædia Britannica. Vol. XX. Pru—Ros. Vol. XXI. Rot—Sia. (Edinburgh: A. and C. Black, 1886.)

THE leading scientific articles in these two volumes are mainly biological. In Vol. XX. Prof. A. Newton contributes the articles on the various important groups of birds; and in those on the Quail, Screamer, Secretary Bird, Seriema or Cariama, it is truly surprising to find so many facts condensed into so small a compass. Mr. C. T. Newton's article on Pterodactyles gives us the newest information on this strange group of fossil reptiles. In the article on Reproduction only the broadest aspects of the phenomena attending it are glanced at, Mr. P. Geddes treating of the Animal, and Mr. S. H.

Vines of the Vegetable, group; though, as was to have been expected, the early phenomena in the two kingdoms are to some extent the same. The facts mentioned are well up to date, and both portions of this article are worthy of their authors. Animal reproduction is illustrated by a few useful woodcuts; but this help to the understanding of the text is wanting in the section on vegetable reproduction. Mr. Vines very correctly criticises Strasburger's idea that the cause of sexuality in cells is purely quantitative. In the article on Reptiles Dr. Günther finds himself on familiar ground, and in the forty pages placed at his disposal he gives a most excellent account of the history and literature of the group, and of the evolution of their classification, from Linnæus to Cope, followed by a brief record of some of the more important systematic works on reptiles, in which the need of a general work on the subject is pointed out. The principal faunistic works are alluded to, and then follow the systematic portions, the anatomy of the chief forms characteristic of the orders, and a paragraph about the distribution of reptiles in time and space. Prof. A. Gamgee, in an article on Respiration, dwells chiefly on the phenomena attending this function in mammals, the phenomena to be observed in all the other groups of the animal kingdom being scarcely even alluded to. The articles on the Rhinoceros and the Seal, by Mr. Flower, are quite models of encyclopædic articles, for in them we have just the information a general reader would require, and this of a thoroughly trustworthy kind. The same may be said of an article on Rhubarb, by Mr. E. W. Holmes.

The article on Rotifera, in Vol. XXI., by Prof. A. G. Bourne, was probably printed ere the finely illustrated monograph of this group by Gosse and Hudson had made its appearance, but the classification given is based on that of Hudson. The account of the general morphology and anatomy is well done, and in a few very pertinent remarks on their affinities the author concludes that, while the high development of the mastax, the specialised character of the lorica in many forms, the movable spines in Polyarthra, the limbs of Pedalion, and the lateral appendages in Asplanchna, the existence of a diminutive male, the formation of two varieties of ova—all point to a specialisation in the direction of the groups of the Mollusca, Arthropoda, and Chætopoda; yet such phenomena would not justify the definite association of the Rotifera in a single phylum with any of them. The phenomena of rotifers being desiccated, and then coming into active existence, are mentioned as if actually proved by exact experiment; but is this so? It certainly does not always succeed, as, no doubt, numerous observers have often noted: too frequently, from inattention, all the water will evaporate from a slide with rotifers; and so far, general experience proves, that if this evaporation be carried to desiccation, not all the drops of water in the world will set up the rotifers that were on such a slide into life again. No doubt it is quite different with their ova.

Mr. J. T. Cunningham contributes an interesting article on Salmonidæ, in which he presents a pretty full synopsis of most of the genera and of all the British species. The life-history of the British forms is given, and some account of the legislation on the subject of our fisheries. The salmon-disease is described. From whence the fresh salmon gets affected would seem to be an, as yet, unsettled problem. Might not one source be frog-spawn? After the tadpoles escape, the gelatinous nidus remaining will sometimes be found permeated with *Saprolegnia ferox*, with ripe oosporangia.

The next biological article of importance in the volume is on the Schizomycetes, by Prof. Marshall Ward, including within this term all those Schizophyta devoid of chlorophyll. The history of these forms, though dating only from 1860, has of late years made rapid progress, and the epitome of this history as here given is full of interest. Most judiciously, while selecting the facts from writings of scientific worth, the author ignores a lot of the rubbish that has appeared in print on the subject. The section on the morphology is very ably written, and the illustrative figures are excellent. Very thoroughly do we agree with the author, that to deny the existence of species in this group is to deny the existence of species altogether. No doubt, before they can be properly defined, the whole life-history of any one of these forms must be known; and equally certain is it that immense advance in a knowledge of the life-history of many of them has been made since the date of Cohn's brilliant researches. As to the important question, Are the Schizomycetes accompaniments only of disease, or have they any causal relation to the diseased condition? no decided answer is given, the discussion as to details being still an active one. The theory that, by the growth and development of certain forms under certain conditions, the medium in which these forms live may be so atomically altered that new and deadly ptomaines may arise, is not alluded to. To the references to authorities given it may be useful to add Just's *Botanischer Jahresbericht*, which year by year laboriously works out the immense literature of this subject.

Dr. Günther's article on Sharks is well illustrated, and well up to date. There is a capital figure of that most interesting and novel form, *Chlamydoselachus anguineus*, S. Garman, from Japan, of which but two specimens are known, one of these being in the British Museum. In reference to the economic use of these fish, allusion is made to the oil abstracted from the larger forms. We may mention that the oil from the basking shark is of considerable commercial value, and that in the case of the immense *Rhinodon typicus*, which abounds during certain seasons in the seas around the Seychelles Islands, the oil is of excellent quality, and there is little doubt would pay well for collecting, although owing to the differences in the respiratory functions, the difficulty in capturing large fishes is vastly greater than in capturing big mammals.

When we turn from the biological to the mathematical and physical sciences, we do not find such a great wealth of articles, but on the other hand some of them are of the highest order, the only fault about them being, perhaps, their shortness. Such are the articles on "Quaternions" and "Radiation," by Prof. Tait. Prof. Dittmar writes on sea-water, and Prof. Ewing on seismometers. Mr. Herbert Rix, the Assistant Secretary of the Royal Society, gives an account of the history and doings of it, which will be read with interest by many. The chemists have their fair share of interest in the volumes; prussic acid, pyrotechny, salts, being among the subjects treated of in all their aspects.

Midway between pure science and its applications, we find an important article on screws by Prof. Roland, while in the various applications of science there is a great wealth of admirable articles: railways, river engineering, roads and streets, shipbuilding, public health, are among the subjects of this nature treated of; and always, so far as we can judge, by the best man.

Of the contributions relating to geography, ethnography, and statistics in these volumes, one of the most important is Prince Krapotkine's part of the article "Russia," in which he presents a very lucid account of the leading facts connected with his subject. Like all other races, the Russians are, of course, to some extent a mixed race. In the course of their history they have taken in and assimilated a variety of Finnish and Turco-Finnish elements. The author, however, points out that, notwithstanding this process, the Slavonian type has maintained itself with remarkable persistency, Slavonian skulls ten and thirteen centuries old exhibiting the same anthropological features as are seen in those of our own day. This he accounts for chiefly by the fact that the Slavonians, down to a very late period, maintained gentile organisation and gentile marriage. Dealing with the circumstances of Russia at the present day, Prince Krapotkine says that much still remains to be done for the diffusion of the first elements of a sound education throughout the Empire, and that the endeavours of private persons in this field, and of the *zemstvos*, are for political reasons discouraged by the Government. The Government also does what it can to check the movement in favour of secondary schools where instruction would be based on the study of the natural sciences. It prefers classical gymnasiums. As every one knows, the natural sciences are much cultivated in Russia; and now the scientific societies of old and recognised standing have to compete with a group of new societies which have sprung up in connection with the Universities.

The geography and statistics of Prussia are dealt with by Mr. J. F. Muirhead. Although somewhat hampered by the fact that the physical features of Prussia had already been fully described under "Germany," Mr. Muirhead has brought together much valuable and interesting information both about the country and about the Prussian people. He has, of course, a good deal to say about the flourishing condition of education in Prussia. Of the recruits levied to serve in the army in 1882–83 the proportion of men unable to read or write was only 2 per cent., the rate varying from 9·75 per cent. in Posen to 0·03 in Schleswig-Holstein, where there was only one illiterate recruit among 3662. Mr. Muirhead contributes several other geographical articles—among them, the one on the Rhine, of which he thinks that probably the Tiber alone is of equal historical interest among European rivers. After a full account of the physical aspects of the river and of its relations to industry and trade, he shows how its whole valley was probably occupied at one time by Celtic tribes, and how they were gradually displaced by the advancing Teutons.

The topography and archæology of Rome have been intrusted to Mr. J. H. Middleton, whose thorough knowledge of his subject has enabled him to make the most of the limited space at his disposal. The article is devoted mainly to those buildings of which some remains still exist. The plan of the Forum and nearly all the cuts were measured and drawn by the author specially to illustrate this article.

Mr. George G. Chisholm gives a clear description of the physical features, with an adequate account of the agriculture, mineral wealth, and trade, of Roumania and Servia. He has also a good article on Sardinia. There is an excellent article on the St. Lawrence, by Sir Charles A. Hartley, who points out that the great prosperity and growth of Canada are owing to its unrivalled system of intercommunication, by canal and river, with the vast territories through which the St. Lawrence finds its way from the far-off regions of the Minnesota to the seaboard The statistics of Scotland have been carefully done by. Mr. T. F. Henderson, but the scientific part of the article "Scotland" is remarkable chiefly for Dr. Archibald Geikie's masterly sketch of the physical features of the country and his summary of the facts relating to its geological formations. The article on Siam, by Mr. Coutts Trotter, contains all the information that ordinary readers are likely to want about the physical characteristics and resources of the country, and about Siamese law, education, religion, and art.

It will be evident from what we have said, that although the "Encyclopædia" has already reached its twenty-first volume, there is no falling off either in the care or in the zeal of the editors. If all goes well, it is expected that the whole work will be completed in four more volumes; and we may certainly say that the work has been conducted in such an admirable manner that science will be a great gainer by it, and that it is a production of which everybody concerned may be justly proud.

A TREATISE ON CHEMISTRY

A Treatise on Chemistry. By Sir H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S., Professors of Chemistry in the Victoria University, Owens College, Manchester. Vol. III. "The Chemistry of the Hydrocarbons and their Derivatives, or, Organic Chemistry." Part III. (London and New York; Macmillan and Co., 1886.)

IN the present instalment of the organic section of this valuable work the authors begin the consideration of the so-called aromatic compounds—the members of the benzene series.

The attention of chemists had long been directed to a group of organic compounds remarkable for their richness in carbon, and apparently unconnected in any way with the ordinary "fatty compounds"—richer in hydrogen, and correspondingly poorer in carbon—with which organic chemistry chiefly busied itself. Many of the compounds of this anomalous class occurred in Nature as odoriferous principles; this physical property was made the basis of a rough classification, and the name "aromatic compounds," originally employed in its strict sense, was extended so as to embrace the whole class, thus including compounds destitute of aroma. Much was known, in a more or less disjointed fashion, concerning these aromatic compounds; but no attempt had been made to solve the problem of their constitution until Kekulé, in 1865, proposed his well-known benzene formula. This formula has at no time, since it was first introduced, met with universal acceptance; and although, at the present day, most chemists employ it, they generally write it in an elliptical form, shirking or ignoring the difficulties which the fully-expanded formula too obviously suggests. But, in spite of these drawbacks, we may say, without exaggeration, that no formula ever exercised such an influence upon the progress of organic chemistry. Right or wrong, final or only provisional, the benzene formula grouped round it the scattered facts: each member of the mysterious aromatic series found its proper place and appeared in its proper light; cases of isomerism were predicted, even to their exact number; and the synthesis of important natural compounds, so high in the scale of complexity as alizarin and indigo, was rendered possible. The obscure corner is now a vast field, cultivated alike by the scientific and by the practical chemist, and far exceeding in extent the whole of the rest of organic chemistry.

The present work opens with an account of the benzene theory. A very valuable feature in the mode of treatment is the way in which the historical method is employed. The much-enduring student of organic chemistry at the present day is generally loaded with facts; occasionally the teacher condescends to furnish him with reasons; but not one student in fifty has any idea of the historical genesis of the facts and reasons presented to him. The ordinary text-books do little or nothing to supply this want; the exhaustive records of facts, like Beilstein's "Handbuch,"[1] and the short text-books written for the student can neither of them, although for different reasons, spare the necessary space. Here the present work comes to our aid. Nothing could well be more instructive than the historical treatment of this very subject of the benzene theory as here given. The student is enabled to see how the views at present held have been evolved, step by step, from Kekulé's formula. And in this connection the earliest tentatives, however we may despise them now, are in their way as instructive as the latest and most carefully-considered deductions. Witness, for example, the historical tables which the authors give in illustration of "orientation in the aromatic series"—the determination of the position of the substituting atoms or groups in the derivatives of benzene. The reader can follow in detail the process by which errors of method or of experiment were gradually eliminated, until, ultimately, the present satisfactory condition of things was reached, in which the same problem, attacked by half a dozen independent methods, yields in every case the same result. The student who knows these things can give reasons for the faith that is in him, and he knows that, no matter how the theory itself may change, the relations worked out under the theory are permanent, and that when the new theory comes, these relations will find their places in it, differently expressed perhaps, but unchanged in their interdependence.

The descriptive portion of the work deals with benzene and its derivatives, using the latter term in its narrow sense, as excluding all derivatives which are homologous or derived from homologues. There are certain disadvantages in this arrangement: thus, it separates widely compounds which are closely related: toluene is not treated of along with benzene, which it most closely resembles; the toluidines are separated from aniline, and so on. But no system of classification is perfect; and the authors, as practical teachers, have doubtless satisfactory reasons for adopting the foregoing arrangement.

There is little further to be said about the descriptive portion, the nature of which is sufficiently indicated by the above account of its scope. The information is very full. The interesting theoretical and historical discussions are continued throughout the volume, and impart to it a character of "readableness" rather unusual in a work of this nature. Finally, the student of technology will find the various manufacturing processes treated of in some detail.

[1] *Handbuch* in German means, not a *hand-book*, but—*lucus a non lucendo*—an exhaustive treatise which in most cases it would be physically impossible to hold in the hand.

OUR BOOK SHELF

Photography the Servant of Astronomy. By Edward S. Holden. (Reprinted from the *Overland Monthly*, November 1886.)

HALF a century ago the attention of astronomers was almost entirely confined to the study of the movements of the heavenly bodies; indeed, Bessel actually defined astronomy as consisting therein. But since then an entirely new department of astronomy has been developed, to which the name "Astro-physics" has been given, and this new department proceeds along three principal lines—spectroscopy, photometry, and photography. The great Observatory founded by the munificence of the late James Lick is to be chiefly engaged in the development of the third of these methods, though spectroscopy will also receive a large share of attention. Having therefore in view the chief purpose to which the great powers of his Observatory will be devoted, the Director of the Lick Observatory has here given a clear and concise account of the principal services which photography has rendered to astronomy in the past, and an analysis of those which may be expected from it in the future. A description of the facilities for photographic research possessed by the Lick Observatory completes this interesting and instructive paper. Prof. Holden mentions incidentally that Mr. Grubb's ingenious device for placing the observer in position for using the telescope, by raising or lowering the entire floor, will be adopted in the great dome of the Observatory.

Observations nouvelles sur le Tufeau de Ciply et sur le Crétacé supérieur du Hainaut. Par A. Rutot et E. Van den Broeck. (Liége: H. Vaillant-Carmanne, 1886.)

IN view of the stratigraphical gap that exists in this country between the Chalk with *Belemnitella mucronata* and the Thanet Sands, the papers thus re-issued in a collected form have an interest considerably beyond the district with which they immediately deal. The value of passage-beds being that they blur over the hard-and-fast lines laid down by our earlier conceptions, it may seem ungrateful to define the exact upward limit of deposits such as those which close in the Danian series. The observations of the authors, however, go to show that the Tufeau de Ciply of the Mons basin, which has been hitherto referred to the Maestrichtian—a fact incorporated in ordinary text-book information—is in reality intimately connected with the Montian. A close examination of 3000 kilogrammes of the conglomerate that forms its base has yielded rolled *Thecideæ* and Cretaceous Bryozoa; but the principal fauna, as indicated by casts of unrolled shells, is of distinctly Tertiary type, containing such representative forms as *Cerithium montense*, *Voluta elevata*, and *Turritella montensis*. The beds near St. Symphorien, correlated with those of Ciply by MM. Cornet and Briart, are divided by the authors into the true Tufeau de Ciply, with its conglomeratic base, and the "Tufeau de St. Symphorien," with *Belemnitella mucronata*, *Thecidea* (*Thecidium*) *papillata*, &c., which is seen to rest, also with the intervention of a conglomerate, on the Senonian. The lower of these horizons is incontestably Maestrichtian; it remained to show that the Tufeau de Ciply, on the other hand, passes up continuously through the *Cerithium*-limestone of Cuesmes into the Calcaire de Mons. To outsiders, unfortunately, the evidence is not complete. The junctions in the field are still obscure, and even the lack of parallelism between the Tufeaux of Ciply and St. Symphorien is mainly based on palæontological arguments, both beds alike resting in places on the uppermost Senonian. The sharp distinction of the two faunas leaves, however, little room for doubt; and the alliance of the Ciply beds with the Montian is still further emphasised by the occurrence in them of large *Cerithia*, of which the authors record two new species, appropriately named *corneti* and *briarti*. It is probable, then, that when, by fortunate excavations in this phosphatic area, the necessary junctions become exposed, MM. Rutot and Van den Broeck may be congratulated on having added beyond recall some 20 or 30 feet to the Tertiary beds of Europe.

The papers also include a revision of the classification of the Senonian of South-West Belgium. G. C.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

On Two Jade-handled Brushes

SOME years ago, I purchased from Mr. Bryce-Wright, of London, two specimens of jade which I then presumed to be "brushes," the handle and sheath of each being of jade, of that faint greenish-gray so characteristic of the finest specimens of that mineral. I was not led to entertain any further opinion as to their true character until the appearance of a paragraph in NATURE, vol. xxviii. p. 207, being an extract from the *North China Herald*, respecting the foot-measures in China. I was particularly struck by the statement made that "in A.D. 274 a new measure exactly 9 inches in length was made the standard," and further "that the lengths of certain jade tubes used according to old regulations as standards" were employed as terms of comparison. It was further mentioned "that of the jade tubes above mentioned there were twelve, and these formed the basis for the measurement of liquids and solids four thousand years ago. . . . They are mentioned in the oldest Chinese documents, with the astrolabe, the cycle of 60 years, and several of the oldest constellations. It is likely that they will be found to be an importation from Babylon, and in that case the Chinese foot is based on a Babylonian measure of a span, and should be 9 inches in length."

This article led me to measure the lengths of the two jade instruments, which I found to be 9 inches, with some slight difference for one of them. I endeavoured to obtain further information as to the nature of these instruments and whence they came. Mr. Bryce-Wright could only tell me that to the best of his recollection he had procured them from the Chevalier von Siebold, son of Dr. von Siebold, and promised to make further inquiries. As I also learned that no such specimens exist in the British Museum, I was led to attach some importance to them in connection with their lengths. This was strengthened by an article which appeared in NATURE, vol. xxx. p. 565, "On the Connection between Chinese Music, Weights, and Measures," which seemed to confirm the statements made in the *North China Herald*, while adding many others of very great interest for the determination of the real nature of these jade tubes.

The subject was treated by Dr. Wagener in a paper read before the German Asiatic Society of Japan some years ago, in which it was stated that the common origin of the Chinese weights, measures, and musical notes is based on native legends, and is also treated of in the Jesuit "Mémoires concernant les Chinois." Dr. Wagener says that there is not the slightest doubt that the Chinese system of weights and measures is more than four thousand years old, and that it possesses all the advantages for which the French metrical system is so much praised. The paper states that in the reign of the Emperor Hoang-ti, who ruled over China in the twenty-seventh century B.C., the scholar Lyng-Lun was commissioned to complete the musical system, which had been discovered two hundred and fifty years earlier, and particularly to lay down fixed rules for making musical instruments; that he betook himself to the province of Si-yung in North-West China, where, on the northern slope of a range of high mountains, a species of bamboo grew which, on account of its uniformity and its structure, being neither too hard nor too soft, was exceedingly suitable for a wind-instrument. This range appears to contain the head-waters of the Hoang-ho, the rippling of its waters producing a sound similar to the first or fundamental note which he obtained from the bamboo. He determined a scale of twelve notes: these are the notes which are called the six male and six female tones in the scale discovered by Lyng-Lun. Having reproduced the notes by means of bamboo pipes, he proceeded to lay down fixed rules as to the length of the pipes, so that thenceforth they could be easily constructed anywhere. For this he required a unit of length, and sought out an adequately small natural unit for his measurements. He selected for that purpose the seeds of the red millet (*Sorghum rubrum*), which present greater hardness and uniformity than the other kinds of millet. Lyng-Lun fixed the length of the pipe giving the key-note at 81 grains of the seed placed lengthways in a row: placed breadthways, it took 100 grains to give the same length. Thus the double division of 9×9 and 10×10 was naturally arrived at. Lyng-Lun also laid down rules for the breadth as well as the length of the pipe, because, although the note is essentially dependent on the length, it is nevertheless necessary for its purity that the pipe should be neither too broad nor too narrow. He therefore fixed the circumference on the inside at 9 grains laid lengthways. With these dimensions—namely, a length of 81 grains and an internal circumference of 9—the pipe which gave the key-note contains just 1200 grains, and this volume accordingly was made the unit of dry measure, and was called a *Yo*. Thus the units of length and dry measure were connected with the musical key-note. The twelve notes of the scale are all derived from the key-note. "Hence if the 1200 grains contained in the pipe are divided among the twelve notes it gives to each a hundred, and the weight of these hundred grains was made by Lyng-Lun the unit of weight" (as I understand this, it means that the twelve pipes were arranged to represent a series of cubical contents, commencing with 1200 and ending with 100 millet-seed contents). Dr. Wagener concluded by stating that this system of measures dates back 4600 years.

Analysing the statement made by Dr. Wagener, it is evident that the earliest form of pitch-pipe known to the Chinese was a bamboo tube, the sound being produced as in the Pandean pipes. The northern slope of a range of high mountains on the northwest frontier of China, in which lie the head-waters of the Hoang-ho, corresponds fairly well, as locality, with the district whence is supposed to come the jade so prized in China. The twelve bamboo pipes or tubes fixed as standards of musical notes by Lyng-Lun, correspond apparently with the twelve jade tubes mentioned by the *North China Herald* as having formed the basis for the measurement of liquids and solids four thousand years ago. The jade tubes were used as standards of length, and being spoken of as tubes, similarly as the bamboo tubes, it may be inferred that they were also standards of volume-measurement and of musical pitch, therefore that the hollow portion or tube had a depth corresponding to the particular note which it was intended to reproduce. Hence these twelve jade tubes would thus represent a set of Pandean pipes, while the requisite length, so as to allow of their being used each as standards of 9-inch length, could be attained by the addition or insertion of a stick or stop of sufficient length, just as is represented by the two "brushes" in question. The lengths of these were found to be in millimetres, for the longer (which I will call A), 228·4; for the shorter (which I will call G), 227·3; the length of 9 English inches in millimetres being 228·6. The "handle" penetrates into the sheath about 17·7 mm. These handles are tapered to the end penetrating the sheath. The two "sheaths" are not alike in interior form: the sheath A is hollowed out conically to a depth of 46·5 mm., the remainder of its length having a hole drilled through it of about 2·6 mm. diameter; the sheath G is 70 mm. long, is hollowed out to a depth of 50·5 mm., and has no hole through the bottom or end part.

I was led to conjecture that these tubes or "sheaths" might be musical pitch-pipes; and on blowing across their orifices, the shorter produced the sound of high G, the longer or perforated one that of high A. By stopping with the finger the hole which passes through the bottom of the "sheath" A, the sound of high G sharp was produced. These notes I tested with a pitch-pipe.

This led me to further conjecture that they should present an interior diameter in accordance with the condition laid down therefor by Lyng-Lun; that is, such as to give an interior circumference equal to 9 grains of *Sorghum rubrum* laid lengthways. Having carefully calibered the interior diameters, I obtained a series of values, giving for the interior circumference of the G sheath or tube a mean value of 28·32 mm., and for that of the A tube 28·44. Through the kindness of Messrs. J. Carter and Sons, of High Holborn, London, I obtained a sample of *Sorghum rubrum*, and operating on this, as also on a sample obtained in Dublin, I got for the length of nine millet seeds placed end to end the following values in millimetres: 26, 26·50, 27·10, 27·38, and 28. I took as mean the value 27 mm. (the exact mean being 26·995 mm.), so that the difference from that of the interior circumferences found is only 1·44 mm. in the mean. I may add that from a series of ten measurements kindly made micrometrically by Dr. McNab, it appears that the lengths of the grains measured by him vary, and would give for the lengths of nine placed end to end, the limits 28·804 mm. and 24·689 mm.

I consider therefore that, so far, the interior circumferences determined point to the "sheaths" being pitch-pipes having the standard interior dimension laid down by Lyng-Lun.

I thought it worth while furthermore to verify the cubical contents of the tubes in millet seeds. The pipe G gave a contents of 421 red millet seeds, and the pipe A of 375; or a mean capacity in seeds of 398. The white seeds gave me for G 400.

What, however, is interesting, is that the end of the "handle" which penetrates the G sheath is hollowed out cylindrically, and this space holds 39 red seeds, and would seem to represent a standard of one-tenth volume. The corresponding end of the A sheath gives for two measurements 37 seeds, or as near as possible one-tenth the capacity of that sheath measured in seed contained.

With the measures of lengths of millet seed determined, we may attempt to fix the probable or approximate length of the fundamental pitch-pipe; that is, the length of 81 millet seeds placed end to end. Taking 27 mm. as the approximate length of nine grains, this length, or rather depth, would be $9 \times 27 = 243$ mm. Now there is found for the combined lengths of the "sheaths" and "handles" when placed end to end, the values:

$$\text{For the G tube, } 227{\cdot}3\text{ mm.} + 17{\cdot}65\text{ mm.} = 244{\cdot}95\text{ mm.},$$
$$\text{,, A tube, } 228{\cdot}4 + 17{\cdot}7 = 246{\cdot}10;$$

both differing little from the approximate value found above.

Taking, on the other hand, the mean interior circumferences of the two tubes as probably representing the lengths of nine millet seeds, we have from the measurement

$$\text{Of the G pipe, } 28{\cdot}32\text{ mm.} \times 9 = 254{\cdot}88\text{ mm.},$$
$$\text{,, A-pipe, } 28{\cdot}44 \times 9 = 255{\cdot}96.$$

It is worthy of remark that by multiplying the mean, end or bottom, diameters of the two sheaths, $\frac{12{\cdot}96 + 12{\cdot}47}{2} = 12{\cdot}715$, by 20, the product comes out 254·3 mm.

Such coincidences can hardly be fortuitous, and to some extent justify the presumption that the two jade instruments which I originally took to be "brushes," are either original standard measures of very great antiquity, or copies more or less exact therefrom. A further determination of the lengths of the Chinese red millet seed is evidently desirable as a matter of metrical and historical research.

J. P. O'REILLY

The Cambridge Cholera Fungus

IN reply to Dr. Klein's letter, I wish to state that although the specimens figured by Prof. Roy in the Royal Society's Proceedings appear to be branched, the one shown to me did not.

Dr. Klein is of course perfectly right as to his statements concerning branching Bacteria; and his remarks, if he rigorously distinguishes between real and false branching, are true also of all the Schizomycetes. At the same time, the existence of such a form as *Cladothrix dichotoma* is not without interest, more especially since Cienkowski has described for it an involution form.

WALTER GARDINER

Clare College, Cambridge, January 31

AS bearing on the subject of the "Cambridge cholera fungus," it may interest some readers to learn that methylene-blue has long been known as a good stain for fungi. My friend Mr. T. Hick, Botanical Lecturer at Owens College, showed me, some years ago, beautiful preparations of moulds stained with this substance, and I have frequently used it for the same purpose, as also chinoline-blue, known as "blue No. 13" of the aniline dyes. It is impossible to keep an aqueous solution of the latter for any length of time free from fungoid growth, the hyphæ of which, at a certain stage of development, exactly resemble the forms described by Messrs. Roy, Brown, and Sherrington, and my specimens, when grown on a slice of potato, developed into *Aspergillus glaucus*. Remembering the very varied appearances assumed by the barren hyphæ of fungi, depending on nature of substratum, relative amount of moisture, &c., I believe that morphological agreement of vegetative parts by no means proves specific identity, even when both can be examined in a fresh state—a great advantage, as the chemical and physical properties of the hyphæ can be compared; but an expression of opinion as to relationship based on the comparison of barren hyphæ with drawings is simply valueless, and only proves a very slender acquaintance with the characters of admitted specific value in the determination of fungi. Members of the Chytridiaceæ are common only in books; during years of practical mycological work I have only once met with a species belonging to this group, and this one I could not succeed in staining with either methylene- or chinoline-blue, but Bismarck-brown gave good results. I was inclined to attach a certain amount of value to this selective power exercised by fungi in connection with dyes, until I discovered that the hyphæ producing the zygospores of *Syzygites megalocarpa* could not be stained with blue, but readily with methyl-green, while the hyphæ of the conidial stage (grown by us from the zygospore) readily absorbed methylene-blue, but had no affinity for green. Interstitial swellings and knob-like outgrowths are not uncommon on mycelium belonging to widely separated groups, especially when the spores are caused to germinate under abnormal conditions, as described in the *Journal of Botany* for October 1882. The protoplasm frequently becomes concentrated in these portions, which are then cut off from the thread by a septum, and serve as centres for a fresh growth, when placed under favourable conditions. The absence, presence, or relative number of septa vary much in the same plant at various ages and under different conditions of growth.

Kew G. MASSEE

Earthquakes

IN NATURE of October 14 (p. 570) you published a letter from Prof. O'Reilly regarding the great earthquake of Carolina, and drawing attention to the tendency of earthquake-lines to assume the direction of great circles. So far his observations were identical with a theory I had myself elaborated, and which I embodied in a paper written at the beginning of the year 1884, now in the hands of the Committee of the Geological Society of London, but never presented to the Society. So long ago as that period I had drawn attention to what I pointed out as the two principal earthquake great circles—one, the Japan and Rocky Mountain system, with one of its poles in 170° W. long., 25° S. lat.; the other, the Himalayic, with its north pole approximately in 45° N. lat., 160° W. long. The former has been frequently described, and Scrope ("Volcanoes," p. 303) suggested a theory to explain it occurrence. The latter is little less remarkable, and is at the moment even more interesting, as, with the exception of the Carolina earthquake, all the great earthquakes and volcanic eruptions of the last five years may be referred to it. I may instance the cases of Krakatão, Kashmir, the Caucasus, Spain, Cotopaxi, New Zealand, and the recent Mediterranean disturbance, all of which occurred within a few degrees of the line or actually on it. Now it is remarkable that this line is marked through a considerable portion of its course by the presence of disturbed Miocene rocks, so much so that I have felt justified in calling it the Miocene line.

The paper referred to contained a theory too long to be worked out in the compass of a let er, but founded on the changes in form which must occur when a plastic body falls by the action of gravity towards a primary. A little consideration will show that, as the action of gravity is inversely proportionate to the square of the distance, the forward portion of such a body will be continually pulled away from the posterior, and an original sphere will in its descent become deformed into a prolate spheroid. Now the result is, I believe, calculable for a body like the earth, even under the present conditions of its annual approach to the sun, in other words its *fall* from aphelion to perihelion. During periods of extreme eccentricity of the orbit the fall and consequent deformation were much greater. The main factors in the calculation are of course: (1) the distance from the primary of the commencement of the fall; (2) the diameter of the falling body; (3) the distance fallen; and (4) the comparative masses of the primary and the attracted body. Beyond this, consideration has to be given to what we may term the specific resistance to deformation of the particular body. The latter, indeed, seems to be the principal factor in determining the amplitude and periodicity of earthquakes.

It is difficult for the geologist at this remote spot in the Far East to keep in touch with the daily progress of geology at home, but there is one probably counterbalancing advantage—in the enlarged view he has to take of the mid-Tertiary epoch as a factor in geologic change. THOMAS W. KINGSMILL

Shanghai, November 30, 1886

THE CALENDAR AND GENERAL DIRECTORY OF THE SCIENCE AND ART DEPARTMENT

THERE is a general impression on the Continent, and even in England, that English teachers of science carry on their work with little direct relation to one another. Twenty-five years ago this impression was not incorrect, but any one who will take the trouble to read the "Calendar and General Directory of the Science and Art Department for the year 1887," lately published, will see that it is no longer true, and that very important steps have been taken towards the establishment of an organised and efficient system of scientific instruction. At South Kensington we have now a School of Science, which maintains the most intimate connection with a vast number of science schools and classes in all parts of the United Kingdom. Here we have at least the germs of a proper system, and it depends upon the country itself whether we are to remain content with what has been achieved, or are to continue the work we have begun until it can be pronounced completely adequate to the needs of modern times.

The movement which has led to these results may be said to have begun in 1853, when the Department of Practical Art was expanded into the Department of Science and Art. The immediate object of this change was to secure that the advancement of practical science should be directly encouraged, and it was decided that the end could be most surely attained by "the creation in the metropolis of a school of the highest class, capable of affording the best instruction and the most perfect training," and by help rendered to local institutions for scientific education. For some time it seemed not improbable that the scheme would be, at least in part, a failure. No general system of making grants applicable to the whole country was devised until 1859. Experimental schools were established by special Minutes, the arrangement usually being that the teachers were to receive payments from the Department in the nature of certificate allowances, and that their incomes, from fees, subscriptions, and other sources, were to be guaranteed by the Department for a certain number of years at amounts varying in different places. In this way science schools were opened at Aberdeen, Birmingham, Bristol, Barking, Leeds, Newcastle-on-Tyne, Poplar, Stoke-on-Trent, St. Thomas's Charterhouse, Truro, Wigan, and Wandsworth. It was found, however, that there were but few places where a man could earn his living by teaching science alone; and in 1859 the only science classes in operation under the Department, irrespective of the Navigation Schools, were those at Aberdeen, Birmingham, Bristol, and Wigan, the number of persons in attendance being 395. Then a new plan was tried. In 1859, when the late Lord Salisbury was Lord President, the first General Science Minute was passed, enabling any place to establish science classes, and to obtain State aid according to certain fixed rules. The effect of this measure surpassed the hopes of those by whom it had been suggested. A number of new schools and classes were rapidly formed, so that, in May 1861, at the first general and simultaneous examination of classes, there were 38 classes with 1330 pupils, not including some 800 pupils in classes not under certificated teachers. Since that time there has been constant progress, as the following table will show:—

1862 ...	70 schools with	2,543	pupils in	140	classes
1872 ...	948	,,	36,783	,,	2803	,,
1882 ...	1403	,,	68,581	,,	4881	,,
1885 ...	1542	,,	78,810	,,	5649	,,

In some schools there are classes both for science and for art, and in such cases it is interesting to note the relative proportion of the number of pupils in the two departments. At the School of Science and Art in Reading, for instance, there are 200 art students, and only 90 students of science. At the Central Board School, Rochdale, on the other hand, while there are only 50 students of art, there are 190 science students. In some instances the numbers are evenly, or almost evenly, balanced. At a school in Deptford there are in each department 160 students, and at another, in Bristol, art has 360 students, science 350.

The number of teachers varies, of course, very considerably. The following tables, compiled from the details presented in the "Calendar and General Directory," show the number of schools which have each three or more teachers:—

I.

Schools in which both Science and Art Classes are held

Schools .	110	83	40	32	24	15	14	9	4	1	2	3	2	1
Teachers .	3	4	5	6	7	8	9	10	11	12	13	14	16	18

II.

Schools in which Science Classes only are held

Schools . . .	105	36	24	11	1	2	4	2	1	1	1
Teachers . .	3	4	5	6	7	8	9	10	11	13	14

The progress of the central institution—the "school of the highest class, capable of affording the best instruction"—has been in its own way not less remarkable. The removal of some of the courses of the School of Mines to South Kensington greatly increased the number of students, partly because the instruction was rendered more thorough and efficient by the addition of laboratory and practical instruction in physics, mechanics, biology, and geology, and partly because South Kensington was more convenient for students than Jermyn Street or Oxford Street. The school was also rendered more useful by the fact that, after the transfer, a few teachers, and promising students who undertook to become teachers, were brought up to London to be trained. This system has been developed, and now from fifty to sixty teachers are annually trained in different branches of science. A system of short summer courses for teachers has also been organised, and this opportunity of improving themselves is highly valued by the teachers, about 180 or 200 of whom are selected annually from some 500 or 600 applicants.

The affiliation of the School of Mines to the Normal School of Science in 1881 marked an era in the history of the institution and in the history of scientific work and education in this country. Students of all classes receive in these united schools systematic instruction in the various branches of physical science. The institution is primarily intended for the instruction of teachers and of students of the industrial classes selected by competition in the examinations of the Science and Art Department, but other students are admitted so far as there may be accommodation for them, on the payment of fees fixed at a scale sufficiently high to prevent undue competition with institutions which do not receive State aid.

All this is fully and clearly set forth in the "Calendar and General Directory," where also the reader will find ample details as to the Science Collections, the aid granted to local museums, the Committee on Solar Physics, the relation of the Government to scientific research, the Geological Survey, the Museum of Practical Geology, the Mining Record Office, and the scientific establishments of Edinburgh and Dublin.

In an article on "National Education in Science and Art," the *Times* on Monday last expressed a doubt whether, after all, any country can be much ahead of England in the number and excellence of its scientific institutions. The *Times* takes far too favourable a view of the relative position of the United Kingdom in such matters. Recent Consular reports have shown that our traders are being steadily beaten by German competitors in many great foreign markets; and the explanation is that, notwithstanding the progress we have made, our system of scientific instruction will not compare, in comprehensiveness and thoroughness, with that which has grown up in Germany. The *Times*, although unwilling to admit the superiority of our rivals, readily grants that as a nation we do not yet do enough for the promotion of science. It says:—

"When the general condition of popular artistic and scientific instruction is viewed, there can be no question that it is not in accordance with national responsibilities, whatever the average may be elsewhere. A primary result of the discovery is to abate some of the admiring content which study of the contents of the Science and Art Department's 'Calendar and Directory' is calculated to produce. To the Science and Art Department has been committed the task of imbuing the nation with those two extensive branches of human learning. The depreciatory estimates so freely offered in these days of the industrial attainments of the nation in each of them suggest either that the Department is not altogether equal to the enterprise, or that it has not been provided with the proper instruments."

The *Times* urges, with much force, that wealthy men have a magnificent opportunity of serving their country by following the example of the late Sir Joseph Whitworth in the endowment of scholarships, exhibitions, and prizes for students of science. With its remarks on this point all who are interested in science will agree; but it is necessary to point out that, however generous private persons may be, they cannot possibly meet the wants of England, with regard to science, in our time. This task can be properly undertaken only by the community as a whole, acting through its organ, the State. If it is not undertaken on the scale which circumstances have rendered necessary, we must be prepared to pay the penalty in diminished commerce and industry. On the other hand, the success which has attended our efforts in the right direction in the past ought to encourage us to make further sacrifices. There cannot be the slightest doubt as to the eagerness with which increased opportunities for scientific education of the highest order would be taken advantage of. At South Kensington there is not nearly room enough for the large number of students who annually seek admission, and like pressure will probably soon be experienced at many less important centres of scientific training. Here the *Times* speaks out strongly and well:—

"If the industrial classes in England be more or less deficient in taste and technical intelligence, it is from absence, not of natural aptitude, but of educational opportunities. Keenness of Continental competition may be far from an unmixed evil if it frighten Englishmen who have the ability into using it for the remedy of the shortcoming. Dulness and mental lethargy are in themselves evils, apart from the danger they cause of a loss of trade. A workman without insight into the meaning of the work he is doing, and with no perception of its real capabilities, is a mere bondsman to his occupation, instead of its master. While we suspect, as we have intimated, the existence of an exaggerated tendency to extol foreign technical training, the British mechanic will have no reason to regret the propensity, if it conduce to his equipment with the means of industrial enlightenment needed to convert his vocation from base drudgery into an art."

That the working classes are becoming alive to the necessity of an improved system of scientific and technical instruction may be inferred from the resolution on the subject which Mr. Howell proposes to move in the House of Commons. This resolution we print elsewhere, and our readers will agree with us in wishing Mr. Howell all success in the admirable enterprise he has undertaken.

THE PROGRESS OF ASTRONOMICAL PHOTOGRAPHY

IN the *Annuaire* for the present year, published by the Bureau des Longitudes, is an important article by Admiral Mouchez, the Director of the Paris Observatory. The article is really a history of the various applications of photography used by astronomers up to the present time, and the history is very well done. The article contains many details relative to the work which has recently been going on in the Paris Observatory, which we think will be read with very general interest.

In the new instruments which the Brothers Henry have recently constructed at the Observatory, before a plate is taken the telescope is pointed approximately to a bright star, which is examined with an ordinary eye-piece, armed with a blue glass. In this way a slide can be placed very near the chemical focus, but in order to determine the focus exactly, an image of a star is made to run six or seven times along a very small plate at different marked distances inside and outside the focal point, as previously determined. An inspection by a magnifying glass of the different trails left by the star on the *cliché* shows which was the most exact chemical focus employed to produce them. This when once done really needs no repetition, but as a matter of fact the operation is repeated once a month.

Another point which the Brothers Henry have already settled is, that in the case of very many photographic plates of extreme sensitiveness the plates are practically useless unless they are prepared almost immediately before they are required, so that as a matter of fact very sensitive plates are now avoided.

Another limit to the sensitiveness which can be utilised is the diffused light proceeding from the atmosphere, either from the gas of a large town, as in Paris, or from the presence of the moon. Very sensitive plates are liable to be fogged even by diffused light in the case of very long exposures.

We have before referred to the arrangements employed for enabling the images of stars to be differentiated from any accidental spots or dots on the plate. The plate is practically exposed three times to the region of the heavens, with such a small variation of position, however, that the three images of the star on the plate appear as one to an observer who looks at it casually, and a magnifying glass is really necessary to discover the triple nature of the image. This method of working has been found to have advantages which were not anticipated in the first instance; thus, for the same total time of exposure the images of much more feeble stars are recorded with the three successive exposures than with one alone. This arises from the fact that the stars of the lower magnitudes, only being represented by very small points from 1/30 to 1/40 of a millimetre in diameter, would escape all observation by the naked eye, and would not be visible at all on paper copies; while the three exposures give a larger image visible to the naked eye, and perceptible on a paper positive. Moreover, if a small planet is included in the region being photographed, the deformation of the small triangle would instantly betray its presence, even with an exposure of a quarter of an hour. Admiral Mouchez has calculated that a planet at twice the distance of Neptune would be easily recognised in three successive exposures of an hour each,—the motion of Neptune in half an hour quite destroying the triangle which it, like the stars, would make were it at rest.

The real and serious objection to the triple exposure is the wonderful patience and skill that are required to keep the instrument for three consecutive hours, without a moment's relapse, pointed rigorously towards the same spot in the sky. This is very trying work, and apt to overstrain those who perform it. Admiral Mouchez is alive to the fact that the way to obviate this difficulty is to increase the aperture of the object-glass, and this is what probably will be done before very long.

Some very interesting information is given regarding the microscopical appearances of the images of the stars seen on the negatives:—"The microscopical study of the *clichés* presents, moreover, much interest from many points of view, and the appearances of the images of the stars is so characteristic that it is impossible to confound them with accidental spots, as has been generally supposed; were this point of view alone regarded, it would perhaps be useless to multiply the exposures of the same plate. The stars appear on the plate, in fact, not under the simple form of a round spot of uniform black tint diminishing and becoming clearer as the star gets smaller, but as a mass of small, round, black points, very close together towards the centre for stars of the ten or twelve larger magnitudes, and more and more sprinkled, still retaining their blackness, for the fainter stars; and at the extreme limit beyond those stars which give a definite and certain image, there still appear on the *cliché* some small groups of little points scattered sparsely, but evidently recording still fainter stars, the existence of which can only be suspected without any means of further confirmation.

"Unfortunately, whatever progress we may make in optics or in photography whatever, penetrating and sensitive power we may hope to give to our instruments, it is evident that we shall never succeed in seeing the most distant stars, and that at whatever limit we may arrive, there will always be beyond it an infinity of others lost in the profundity of the heavens which will always escape our knowledge, but it is by photography and the scientific study of negatives that we shall be able to go further than by any other means. From a chemical point of view also the microscopical examination of the stellar images will not be without interest, because it will help us to understand how the light acts upon the molecules of the insoluble salts of silver which are contained in the stratum of organic material which forms the sensitised plate. It is not, as I have already stated, in giving a uniform tint, more or less decided, according to the magnitude of the star, over the whole image, but really in decomposing a greater or less number of particles of salts of silver over this area, that the light works; so that we can define the image of a very feeble star as a resolvable nebula, and the others as insolvable nebulæ surrounded by a resolvable portion. I have never seen around any of these images the rings referred to by several astronomers, which have the appearance of diffraction rings seen in telescopes.

"To establish the relationship between the scales of the optic and photographic magnitude of the stars, Bond has made a series of interesting experiments by varying the time of exposure and the aperture of the object-glass. These experiments have led him to an interesting result on the mode of action of light. He has found that a certain time elapsed before the action manifested itself at all, and then that it did so suddenly, ten or a dozen molecules of salts of silver in each superficial second of arc were attacked by the light; after this the number increased very rapidly according to the time of exposure. This mode of action seemed to him obscure and difficult to explain. But it seems to follow from these facts, and from the examination of our *clichés*, that in the manufacture of the bromide of silver, and the preparation of sensitive plates, it is of the highest importance to obtain the finest possible pulverisation of the salt."

As there is to be a Conference of Astronomers at Paris next Easter to discuss the whole question of astronomical photography, it is well that Admiral Mouchez and his staff are accumulating so many facts to help in the discussion.

METEOROLOGICAL CONDITIONS AT THE TIME OF THE ERUPTION OF MOUNT TARAWERA, NEW ZEALAND

IN the Government Sanatorium at Rotorua there is a self-registering barometer kept by Dr. Ginders. This shows that at 9 a.m. on June 9, the atmospheric pressure was 29·30 (at about 1000 feet above the sea). It decreased and reached its lowest point of 29·00 at 4 p.m. on the 9th. It then began to rise. At midnight it was 29·08, and at 1 a.m. on the 10th—just before the eruption—it was 29·10. This pressure was maintained all through the principal part of the eruption, after which the glass began to rise again, reaching 29·25 at noon on the 10th. The curve, elsewhere smooth and even, shows from 3.30 a.m. to 6 a.m. a number of small oscillations which treble its thickness. None of these oscillations are recorded before and none after 6 a.m. on the 9th, except a single one at 5 p.m. on Friday, the 11th. These oscillations are attributed to earthquakes, but, whatever may have been their cause, they certainly mark the outburst of Rotomahana and the crisis of the eruption.

Another barometer at Ohinemutu, belonging to Mr. Edwards, of the Native Lands Court, read as follows:—

June 9,	10 a.m.	29·30 inches
,,	4.30 p.m.	29·00 ,,
,, 10,	1.55 a.m.	29·20 ,,

The following is the rainfall at Rotorua:—

June 4	1·26 inches
,, 5	0·58 ,,

There was no rain at Rotorua between the 5th and the eruption, but it rained on the 9th at Wairoa and at Ateamuri, on the Waikato.

At Rotorua the slight mud-shower fell in directions from south-east to south-west, but most from the south-east, as ascertained by an examination of the telegraph poles. At Taheke, on Lake Rotoiti, the mud must have fallen with a south-south-east wind. At Galatea, eighteen miles east-south-east from Rotomahana, no mud fell; but the scoria was thicker on the north-west than on the south-east side of the houses: evidently no strong wind was blowing.

The night of the 9th was calm and fine. During the earlier portion of the eruption there was a slight south-westerly wind at Wairoa, which increased to a strong gale at 3 a.m. At Rotorua there was a slight south-easterly wind up to 4 a.m., when the south-westerly gale reached there from Wairoa. At Taheke, on Lake Rotoiti, the wind changed to south-west at 9 a.m, but there was no gale. At Napier a southerly gale commenced at 4 a.m.; at Gisborne, in Poverty Bay, a south-westerly gale was blowing; at Waiapu a strong north-westerly wind was blowing from 3.15 a.m. to 4.30 a.m., when it changed to the south-west. At the East Cape there was a strong southerly gale. It appears therefore that the south-westerly gale at Wairoa had no direct connection with the eruption, for it commenced about the same time all over the east coast from Napier to the East Cape.

I was surprised to find that the eruption had caused no great atmospheric disturbance, except in its immediate neighbourhood, and that there was no evidence at all of any indrawing currents. The reason for this, no doubt, is that the area over the openings which was violently disturbed is small, so that equilibrium was restored at very short distances around. For this reason a volcanic eruption has none of the effects of a cyclone. The eruption was, as usual, the cause of much electrical disturbance, but this did not affect the weather. F. W. HUTTON

A FEW OF OUR WEATHER TERMS

A RECENT skirmish in the *Times*, on certain words in common use among English meteorologists, and prevalent in our weather reports, suggests that a little overhauling of these and similar terms may be from time to time desirable. In a branch of knowledge which, simultaneously with its growth, becomes more and more popular, new terms expressive of new ideas should not only be accurately descriptive of facts, but should be adapted to popular imagination.

If we cannot have such terms as "helix" and "anthelix," the Meteorological Department cannot be on safer ground than in their adoption of the terms "cyclone" and "cyclonic," "anticyclone" and "anticyclonic"; these words being precisely antithetical, and expressive of phenomena which are the opposites of each other in almost all their characteristics. To both of these words, however, objections have been raised, and these objections have been somewhat inconsistently based on different reasons. The word cyclone has been objected to because it terrifies our women; but its equivalent, "revolver," would produce at least as alarming an effect. They would soon, however, get accustomed to the use of either. The most unscientific people will quickly understand that when the laws which govern a particular kind of atmospheric circulation have once been proved to be identical, whether that circulation be violent, moderate, or feeble, it becomes desirable to have a single term descriptive of such a circulation. Such nouns as "hurricane," "storm," &c., can be employed, if we please, to denote that the disturbance is of a violent or severe character; while we have plenty of adjectives, strong or mild, to be employed at discretion. Perhaps this will be still more fully realised when the public understands that, in any particular instance, the circulating winds may vary between the most violent and the lightest during the progress of the disturbance. As Mr. Abercromby clearly states it: "The same cyclone may develop the energy of a hurricane soon after its birth in the West Indies, and, after a long and stormy life in its passage across the Atlantic, die surrounded by gentle summer winds on the rocky coasts of Norway." The original use of the term "cyclone" was almost limited to the phenomenon in its acutest stage; and, owing partly to this fact, meteorologists have been disposed to apply the expressions "cyclonic system" and "cyclonic disturbance," &c., to the gentler instances or stages of this kind of circulation, rather than the word "cyclone" itself; but the latter word might now be used without hesitation, for it is most true that "a progressive science uses words provisionally to express provisional ideas, and as the ideas increase in clearness and precision" (and, we may add, in extension) "the word has to take on new meanings."

The term "anticyclone" has been recently objected to as possessing absolutely no significance, an objection which is not in itself worthy of discussion in these pages. This objection is, however, probably founded on one of a more serious nature, viz. that anticyclones are merely interspaces between cyclones. Such interspaces do, of course, exist, and they occasionally travel on without undergoing any very rapid change of form in company with the cyclones. But the interspaces between circles or ovals are not circular or oval; and further (as is more important to observe, and as has long ago been shown to be true) the anticyclone proper has characteristics of its own which distinguish it from these interspaces: its movements are often slow, or it is stationary for a considerable period, while in both hemispheres it has the power of deflecting the course of the cyclones moving in its vicinity more or less towards the right, except in particular positions.

Now let us look at the word "depression" and the ideas associated with it. It would probably be an impossible as well as an undesirable task to get rid of this term altogether, but for this reason it becomes all the more necessary clearly to define its meaning. Originally it signifies a lowering of the surface of the barometric column due to a diminution of pressure on the surface of the mercury in the cistern. It is equally well employed to designate a "taking off" or diminution of atmospheric pressure. In any case, it might be employed to designate such a diminution of pressure as takes place during the lessening or the passing off of an anticyclone. But by common usage it has come to be practically equivalent to cyclone, the only difference being (1) that it naturally refers to the diminution of pressure within the cyclone, and not the circulating winds, and (2) that it can be usefully applied to areas diverging considerably from the circular form. The ease with which the idea of a saucer-shaped hollow in the ocean of atmosphere is entertained, and the associations of the word "gradient" (a word valuable, suggestive, but figurative—a word for which I can find no substitute, unless it be a coined one), have certainly led to some misconceptions. Over the front or ascensional part of a cyclone, atmospheric pressure is greater at the level of four, five, or six miles above the earth's surface than over surrounding regions at the same level. It would be well for our storm-warnings if more people were careful to observe the violent north-westerly upper-current prevailing immediately in front of, and over, the southerly winds which we feel when a cyclonic disturbance is coming upon us from west-south-west. The few who have noticed this cannot fail to be struck by the fact that at the level of the cirrus the pressure must increase with extreme rapidity at the same time that pressure is decreasing at the earth's surface. It is true that in the rear of the disturbance an extension of the great polar area of depression in the higher regions of the atmosphere is shown by the movements of the higher clouds. Any one who will be at the trouble to chart out these phenomena will feel that the neat little orographical maps of the atmosphere with which some of our popular writers on weather would present us are exceedingly different from the realities.

The terms "col," ridge," "trough," &c., for a similar reason, while assisting the popular imagination, perhaps assist it in the wrong direction, and I would, though with much deference to better authorities, suggest that such terms as "arm," "band," "belt," "extension," &c., might be employed with a little more safety. To the terms "deep," "depth," "high," "height," might not my own respectable old words, "intense," "intensity," even now be found preferable? and for the word "shallow" the word "slight" in many cases be advantageously substituted? I am aware that in a magazine article or in a weather report some variation of terms and expressions is frequently desirable, but the cover has not yet been fairly drawn; and an abundance of useful words is still available, without recourse being had to terms either borrowed from foreign languages or expressive of incorrect ideas.

W. CLEMENT LEY

NOTE ON INSTANTANEOUS SHUTTERS

THE introduction of rapid dry plates having made a general demand for mechanical shutters, a large variety are now offered for sale by the various makers. Many of these shutters are neat and ingenious, but nearly all have a tendency to shake the camera during exposure, and in the only one which I have seen for sale in which this mistake has been avoided the photographic efficiency of the arrangement has been impaired by the opening being made to assume the form of a gradually expanding and contracting hole; the idea being, I am told, that while the opening is small it will act as a stop and secure definition. This, of course, is true to a certain extent—how far, I will inquire presently.

I do not know whether the general theory of mechanical shutters has been discussed, but if it has it is certainly not well known, and perhaps the following remarks, which point out what the photographic efficiency of the various classes of shutters is and their effect on the steadiness of the camera, may be of some use.

Shutters may be divided into two chief classes, viz. those in which the principal moving part consists of a single piece, and those where the moving parts are multiple; the great difference between them being that, while the first class must exert either a force or a couple on the camera during exposure, the second class may be so designed as to exert neither. The first class consists of drop-shutters and revolving disks with an aperture which passes across the lens, and of those shutters where a sliding piece rises and falls or a hinged piece opens and shuts. Of the second class I only know of one as being in the market, though probably many amateurs may, like myself, have made them for their own use. In this shutter two plates, occupying the position of the ordinary stop in the lens, separate and come together again. Each plate has a deep V-shaped notch in it; the apex of each V when the shutter is closed being in the axis of the lens. The opening is therefore a quadrilateral figure which gradually expands and contracts.

The mechanical arrangements of nearly all the shutters, except those belonging to the revolving disk and drop-shutter class, are such as to make the motion of the shutter a simple harmonic function, or nearly so, of the time from the commencement of exposure, while in the drop-shutters and disks the aperture may be taken as moving across the lens with a nearly uniform velocity. This, of course, would not be true if the motion of the parts was quite free under the action of the driving force, but friction enters largely into the account; and even if it did not, no large error will be introduced in calculating the photographic effect of shutters of this class by assuming that velocity of the moving part is uniform during exposure and equal to its mean velocity.

The photographic effect of a shutter is measured by the sum of the products of each element of aperture brought into action by the shutter and the time for which that element acts. This measures the total amount of light which passes through the lens during exposure, but it does not necessarily follow that the light should be uniformly distributed on the sensitive plate. This, indeed, only happens when the shutter is at the optic centre of the combination.

In mathematical notation, if the path of a point in the shutter be along a line x, and if U be the area of the lens expressed in terms of x, and T_x the time for which dU, the element of area exposed in passing from x to $x + dx$, acts, then the photographic effect of the shutter is $\int T_x dU$, taken between the proper limits of x.

The photographic efficiency of a shutter may be taken as the ratio of this quantity to the whole area of the lens, multiplied by the whole time of exposure, or $T'U'$.

The result of integrating the above expression may always be put in the form

$$aT'U',$$

where a is a numerical constant, which therefore expresses the efficiency of the particular shutter considered.

I subjoin a few results showing the efficiency of several different types of shutter:—

	Efficiency
(1) Drop-shutter with circular aperture (uniform velocity)	$a = \cdot 43$
(2) Harmonic opening from one side (x proportional to $\cos pt$)	$a = \cdot 5$
(3) Harmonic opening from centre, the opening being a circular hole of radius ρ (proportional to $\sin pt$)	$a = \cdot 5$
(4)[1] Harmonic opening from centre, the aperture being formed by the edges of two plates which recede from a diameter of the lens and the boundary of the lens (x proportional to $\sin pt$)	$a = \cdot 764$

It will be seen that as far as efficiency goes the drop-shutter is lowest on the list.

The next two have the same efficiency, but while the second has a tendency to shake the camera the third has not. If, instead of assuming that the aperture in this case was circular, we had made it square, as in the shutter before referred to, the efficiency would not have been quite as great as ·5.

No. 4 has the highest efficiency of any, viz. ·764, and differs from the last merely in having no V-shaped notches in the plates which close the aperture, so that the opening begins as a slit instead of a point. Thus by the adoption of the square expanding aperture nearly 40 per cent. of possible efficiency is lost.

The gain in definition caused by the aperture acting as a stop may be estimated by comparing the amount of light (L_1) admitted while the opening is small enough to make the definition good, with the total amount of light admitted (L) minus (L_1), remembering that the greater the aperture up to which the shutter may open without sensibly impairing the definition the less is the possible gain in definition from the use of a stop. Thus, suppose the greatest aperture consistent with good definition to be $\rho^2 \times$ full aperture (R^2). Then the use of a stop of radius ρ can only reduce the radius of the circle of confusion about the image of a point by $\frac{R - \rho}{R}$ times what it would have

[1] This is the form which I use, but I am not aware of any shutter of the kind being in the market.

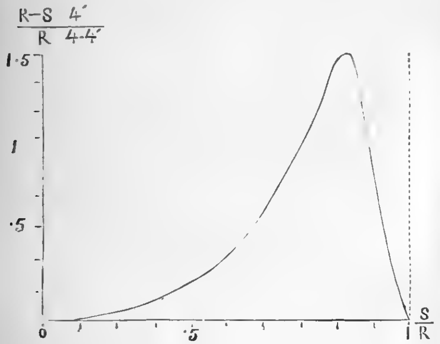
been had the whole aperture been employed. The improvement in definition, then, due to the expanding shutter acting as a stop is given by the expression—

$$\frac{R-\rho}{R} \cdot \frac{L_1}{L-L_1}.$$

The curve below shows the improvement in definition calculated from this expression, the abscissæ being proportional to $\frac{\rho}{R}$. It has a maximum value of 1·5 nearly when $\frac{\rho}{R}$ is about ·8, but falls away rapidly on either side of this value.

Thus when a stop of ·8 times the full aperture is sufficient to secure definition, the square expanding aperture may be said to answer the purpose. But a better result with less exposure could be obtained by the use of shutters of type (4) with a separate stop of the right size; for it may be shown that with the square expanding aperture the amount of light admitted while more than eight-tenths open is not more than 8 per cent. of the whole, and not more than 8 per cent. of the light would be lost if a ·8 stop were used. But a shutter of type (4) admits nearly 40 per cent. more light than the expanding square, so that there would be a gain of something more than 30 per cent. in light by using it.

This is rather understating the case, for the efficiency of a shutter as defined above is increased by the use of a stop,



the whole aperture of the stop being uncovered for a finite time while the whole aperture of the lens is only uncovered for an instant.

To see what effect an unbalanced shutter has on the steadiness of the camera and definition of the image, the mass of the unbalanced moving part of the shutter, the mass of the camera, its period of vibration on its support, and its radius of gyration must be taken into account, as well as the time of exposure. The exact investigation of the motion is very much like that given by Helmholtz of the motion of a pianoforte-wire when struck by a hammer. But without entering into mathematical details it is easy to approximate to the required result in a large group of cases, viz. where the time of exposure is short compared with the natural period of the camera on its supports. This will apply to cameras held in the hand for all exposures which could be effectively used with such a support, and in most other cases when the exposure is less than a fiftieth of a second.

The camera and shutter may now be compared to a fly-wheel free to turn with a small load on its rim, which, by some mechanism on the wheel, can be made to vary its position. If the fly-wheel is at rest to begin with, the motion of the system when the load is caused to move is given by the condition that the moment of momentum of the fly-wheel and load together is nothing, which implies that

$$\frac{\text{velocity of rim of wheel}}{\text{velocity of load}} = \frac{\text{mass of load}}{\text{mass of rim}}.$$

Suppose that the camera is replaced by a fly-wheel which has the same moment of inertia and a radius equal to the distance of the centre of oscillation of the camera on its support from the shutter, the mass of the equivalent fly-wheel will be less than that of the camera on account of its distribution, so that the angular motion of the camera about the centre of oscillation will be somewhat greater than

$$\frac{\text{mass of shutter} \times \text{travel of shutter}}{\text{mass of camera} \times \text{radius of oscillation}}.$$

As an example, suppose the ratio of the masses to be 1/100 and the travel of the shutter one inch, if the radius of oscillation lies between one foot and six inches, the augular movement of the camera will be between three and six minutes of arc, or from one-tenth to one-fifth of the apparent diameter of the sun or moon.

In the case of drop-shutters acting by gravity, the camera begins to move upwards at the moment the shutter is released, and will go on moving upwards until it is as much above the new position of equilibrim which it would assume on the removal of the weight of the shutter as it was below it when the latter was attached. So that if the time of exposure be half as long as the natural period of the camera, the whole extent of the angular motion will show on the sensitive plate.

I have recently made some experiments to see how, when the camera was held in the hand, the accidental motions of the support compared with those due to the action of the shutter. It would, I think, at first sight be supposed that the former were the more important of the two. The experiments were made by weighting a piece of looking-glass to represent the camera, and then, holding it as the camera would be held, reflecting the sun on a distant screen and noting the displacement of the patch of light. I found it in my own case to be continual, vibrating at a rate of something like four per second, through an angle of about one in six hundred to one in eight hundred, implying, of course, half this motion in the camera; that is, from three to two minutes of arc. The time of the whole vibration being about one-fourth of a second, if the time of exposure was as much as one-eighth of a second the whole of this would show on the plate, but for exposures of one-twentieth of a second the loss of definition from this source would hardly be appreciable. The weight of the camera in this case was small—little more than a pound—and so unfavourable for steadiness.

The general conclusions to be gathered from the foregoing remarks are: (1) That there is room for great improvement in the photographic efficiency of shutters; (2) that all the ordinary kinds shake the camera when the exposure is rapid; but that (3) for comparatively long exposures, say more than one-tenth of a second, almost any kind of shutter will do when the camera is mounted on a stand; and (4) that for cameras which are to be held in the hand, in order to secure fine definition the shutters must be dynamically balanced or exceedingly light.

A. MALLOCK

ON SOME PHENOMENA CONNECTED WITH THE FREEZING OF AËRATED WATER

THE elimination in the gaseous form, on the freezing of liquids, of the air and gases held in solution presents some features in its process which may be worth recording.

Bubbles in ice are familiar; but their arrangement and progressive development in the process of freezing-over present some points which I do not think have been generally observed.

Aquatic plants at the bottoms of ponds give off oxygen gas, and marsh gas is emitted from decaying vegetable matter. These two sources of supply will, to some extent, account for the entanglement of bubbles in ice on a pond surface, but only to a very small extent, and may be left out of consideration in dealing with the development of air-bubbles in ice. This takes place independently of any extraneous source of supply other than atmospheric air, and may be as well seen in a glass or earthenware vessel as over a weedy pond surface.

The following facts must be noticed:—

(1) Ice over deep water invariably contains fewer bubbles of included air and gas than ice formed over shallow water, and probably from this cause ice obtained from over deep water is more durable for storage than ice obtained from shallow pools.

(2) The upper or surface portion of a coating of ice invariably contains less included air than its under or lower portion, and this is more obvious in ice formed over shallow than in that over deep water. In each case there is a fairly regular gradation in the quantity of entangled air, increasing from the surface downwards. I ascertained that the included air from the upper surface (*a*, Fig. 1) of

Fig. 1.

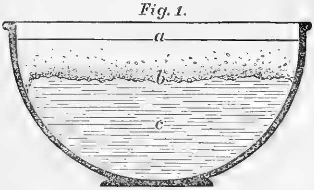


Fig. 2.

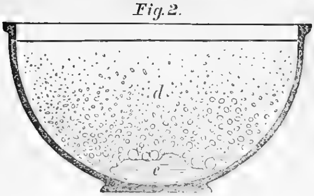

a thin coat of ice was scarcely appreciable in quantity, and one pound weight from its lower surface (*b*, Fig. 1) contained 0·08 of a cubic inch of entangled air.

(3) There is more included air in ice formed over water in a small vessel (Fig. 1) than in ice formed over a large body of water.

(4) There is more included air (weight for weight of ice) in an entirely frozen mass of ice (Fig. 2, *d*) than in surface ice from a partly frozen vessel of water. In an entirely frozen mass (Fig. 2, *d*) 1 pound of ice contained 0·59 cubic inch of included air; and surface-ice (*a*, *b*, Fig. 1), over unfrozen water, one pound weight contained 0·15 cubic inch.

(5) In freezing separately the water from which the first frozen coat of ice had been removed (Fig. 1, *c*), the ice contained a much larger proportion of included air (0·89 cubic inch) than either the surface ice (Fig. 1, *a*, *b*) or the ice obtained from entirely freezing a body of water (Fig. 2, *d*).

(6) On re-freezing water which had been frozen and thawed, there was but a very slight further release of air, which had been almost entirely released in the first freezing: one pound of the second ice contained but 0·005 cubic inch of air.

(7) In completely freezing a vessel of water (Fig. 2), not only does the entangled air increase in quantity downwards, but at the base of the frozen mass occurs a large air-cavity (*e*, Fig. 2).

All these facts, and the results of the experiments, seem to point to the fact that, in the process of freezing, the elimination of the air and gases in solution is taking place in two directions: (1) a part of the air is taken into solution by the *un*frozen water as it is progressively rejected by the thickening coat of ice; and (2), a part of it is extruded as bubbles of air, which become entangled in the ice.

If each stratum of ice eliminated the whole of its own proportion of air in solution in the gaseous form, the bubbles would be distributed with fair regularity throughout the collective mass, but their progressive increase in a descending direction exactly agrees with the continuous surcharging of the underlying unfrozen water with the air in solution rejected by the ice above, till, at the end of the freezing process of the mass, the remnant is extruded as one large bubble (Fig. 2, *e*) at its base.

The rejection of the air into continued solution would seem to take precedence of its extrusion in the gaseous form, and would go on as long as there was a sufficient body of adjacent water in a condition to receive it; but the gradual surcharging of a limited body of water with the rejected air is necessarily accompanied by its progressively increased extrusion in the gaseous form.

The comparative absence of air-bubbles in ice over deep water is accounted for by the fact of there being a sufficient body of adjacent water in a condition to receive the rejected air into solution in preference to its extrusion as gas.

To briefly recapitulate the experimental results:—(1) In a thin ice-coating, the upper or surface half contains barely a trace of eliminated air, whilst its under or bottom half contained 0·08 cubic inch of air in each pound of ice. (2) A surface coating of ice $1\frac{1}{2}$ inch thick contained 0·15 cubic inch of air in each pound weight, whilst an entirely frozen mass contained 0·59 cubic inch of air in each pound weight. (3) The freezing of a limited body of water which had been first frozen over and the surface ice removed points still more strikingly to the concentration of air in solution; for this contained 0·89 cubic inch of air in each pound weight, compared with 0·15 cubic inch in surface ice, and 0·59 cubic inch in an entirely frozen mass.

The water employed in these experiments was from the East Surrey Waterworks. George Maw

NOTES

The following notice of motion has been given by Mr. Howell, M.P.:—"To call the attention of the House to the subject of technical education, and to move the following resolution:—'That, in the opinion of this House, it is essential to the maintenance and development of our manufacturing and agricultural industries, in view of the rapidly increasing competition of other nations, both in home markets and abroad; and in consequence of the almost universal abandonment of the system of apprenticeship; that our national scheme of education should be so widened as to bring technical instruction, the teaching of the natural sciences, and manual training, within the reach of the working classes throughout the country.'"

It is stated that in consequence of the financial difficulties of the Bristol College, and lack of endowments, the salaries of all the Professors will be reduced by the Council, and some Chairs are to be abolished. The course pursued by the Council has given rise to much correspondence in the local papers during the past month. It is earnestly to be hoped that circumstances may yet be found to cause the Council to reconsider their position, and that a course so diastrous to the College—an institution which, in spite of its insecure position, has done excellent educational work—and to the town itself, may yet be averted. Is Bristol so flourishing that the citizens can afford to neglect the only true foundation for prosperous trade and commerce at the present time, when we are trying to compete in the markets of the world with men more highly trained than ourselves?

THE Guthrie Memorial Fund, which will shortly be closed, has now nearly reached the sum of 1400*l*. As we explained some time ago, Prof. Guthrie was too exclusively devoted to teaching and scientific research to be able to make adequate provision for his family. The object of the fund is to place his children as nearly as possible in the position they would have occupied but for his untimely death; and subscribers have been glad to have this opportunity of expressing their appreciation of his personal character and scientific labours.

WE are glad to learn that the University Extension Scheme, which has led to such excellent results in England, is likely to be tried in Scotland. The question has been for some time under the consideration of the University Court of Glasgow, and now the matter has been taken in hand by some energetic University men in Edinburgh. The proposal is that the available lecturing power of the Scottish Universities shall be united, so that while any town would naturally in the first place be supplied as far as possible from the nearest University, any desired course might be drawn from a more distant one. It is hoped that in the larger towns Extension Colleges may be established. These institutions might be made permanent by means of small endowments, or towns might secure them as centres of regular teaching for a certain number of years by subscribing a few hundred pounds to make up the deficit from fees.

DR. LEUTHNER, of Vienna, author of a remarkable memoir on the Odontolabini, a subdivision of the Coleopterous family Lucanidæ, published in the Zoological Society's Transactions in 1885, will shortly leave Europe on a collecting expedition to South Arabia and Socotra, where much work remains to be done, notwithstanding several recent excursions to the same district. Dr. Leuthner's expedition is of a private nature, but he has the full support of the Austro-Hungarian Government, and a free passage in their ships.

PROF. G. SÉE has recently published a new book, concerning diet in disease ("Du Régime alimentaire: Traitement hygiénique des Malades"). M. Sée, although he has never studied physiological questions in a special manner, always writes useful books, being familiar with English and German, and very well posted in all foreign experiments and work. The most interesting part of his book, from a physiological point of view, is that in which he discusses the question of foods and their constituents. Criticising the food-ration of the French army, he says that too much bread is allowed, and too little meat.

THE volume of the *Indian Antiquary* for the past year contains a most interesting series of papers by Mr. H. G. M. Murray-Aynsley, under the modest title, "Discursive Contributions towards the Comparative Study of Asiatic Symbolism." They commence in the March number, and, with the exception of the issues for June and July, are, continued consecutively down to, and including, the November number, and are not yet completed. One feature of special value to the European student is the method of illustration adopted. The plates are numerous, and beautifully executed, and a large number describe objects collected by the writer himself in Northern India, which have probably never before been seen by the majority of Western scholars. It is to be hoped that Mr. Murray-Aynsley will ultimately collect these papers into a volume; at present we can do no more than barely indicate the outlines of their contents. His chief object is to make a collection of facts bearing upon the subject of customs and symbols, and, after a general introduction, a chapter is devoted to each of the following divisions:—(1) Sun and cup (or moon) symbols; (2) sun-worship; (3) the *Svastika*, or emblem of fire; (4) stones worshipped in India, and their counterparts in Scandinavia and other parts of Europe; (5) the land of departed souls; (6) the trees which have been held sacred in the East and in Europe; (7) snake-worship; (8) amulets and charms; (9) the evil eye; (10) the wild huntsman of Northern Europe and his possible Asiatic origin; (11) Eastern architecture compared with certain old churches and houses in Norway; (12) Asiatic symbolism in Spain. While this may give a notion of the general contents of these papers, it gives none whatever of the mass of facts collected from different sources, principally by the author himself in India and Cashmere. The coloured illustrations of the *Svastika* symbol, showing the wide area over which it is employed, are very interesting. In addition to many others given, the author might well have added that it is almost universal in this country as a bordering to the commoner kinds of linoleum and other floor-cloths, the manufacturers having probably borrowed it from the designs on Central Asian carpets and rugs.

AN important addition has just been made to the Zoological Society's Collection in the Regent's Park, in the shape of three fine specimens of the sea-lion or eared seal of the Auckland Islands (*Otaria hookeri*). These animals, originally four in number, one having been lost during the transit home, were captured in the Auckland Islands, which lie in the Antarctic Ocean, some 900 miles south of Tasmania, by Capt. John Fairchild, master of the New Zealand Government steamer *Hinemoa*, and were sent to London in the steamship *Tongariro* by the Hon. W. J. M. Larnach, C.M.G., Minister of Marine of New Zealand, as a present to the Zoological Society. The Zoological Society's menagerie already contained specimens of the sea-lion of the Falkland Islands (*Otaria jubata*), and of the Cape sea-lion (*Otaria pusilla*), but no example of the present rarer species has been previously brought alive to Europe. There are, however, stuffed specimens of this animal in the Museum of Natural History in the Jardin des Plantes, Paris.

IN the Report of the Fish and Game Commissioners of Massachusetts for 1886, there is an interesting paper by Mr. George Dimmock on certain fish-destroying insects in the United States. The largest of them, and the most dangerous to fishes, are those which belong to the family called Belostomidæ. They are provided with powerful fore-legs, and strong, somewhat oar shaped hind-legs for swimming; and, when full-grown, they have vigorous wings, and are capable of long-sustained flight. In seizing upon fishes or other small animals, they grasp their prey with their fore-feet, holding it firmly in their claws. Then they pierce it with their beak or proboscis, and suck its blood. They are strongly attracted by the electric light, and Mr. Dimmock suggests that it might be used as a means of destroying them, as it would be easy to contrive a trap that would retain them when they fall after striking the glass. An illuminated trap beneath the surface of the water might, he thinks, be more effective than one above the surface, for the Belostomidæ do not often leave the water, apparently, except when they quit it for the purpose of migration.

THE United States Fish Commission print in one of their recent Bulletins an excellent report by Mrs. Emma Metcalf Beckley, Curator of the Hawaiian National Museum, on "Hawaiian Fishing Implements and Methods of Fishing." The writer gives some curious details about octopus-fishing. The smaller kinds of octopus, which live in shallow water, are caught by women, who do their work with remarkable skill. They can tell whether an octopus is in a hole whose entrance is no larger than a silver dollar, and, plunging their spears in, they invariably draw one out. The larger kinds of octopus, which are always found in deep water, are caught by men with cowries, generally of the Mauritiana, but sometimes of the tiger species. An octopus will not rise to a large-spotted or ugly cowry, so the fishermen have to take care that the spots on the back of the shell are very small and red, breaking through a reddish-brown ground. Cowries with suitable spots, but objectionable otherwise, are slightly steamed over a fire of sugar-cane husks, a process which gives them the desired hue. The fisherman, having arrived at his fishing-grounds, first chews and spits on the water a mouthful of candle-nut meat, which renders the water glassy and clear; he then drops the shell with hook and line into the water, and swings it over a place likely to be inhabited by an octopus. The moment an octopus perceives a cowry, it shoots an arm out and clasps the shell. If the shell is of the attractive kind, one arm after the other comes out, and finally the whole body of the octopus is withdrawn from the hole and attaches itself to the cowry, which it closely hugs, curling itself all around it. The creature remains very quiet while being rapidly drawn up through the water. Just as it reaches the surface, the fisherman pulls the string so as to bring its head against the edge of the canoe, and it is killed by a blow from a club which is struck between the eyes. This must be done rapidly, before the animal has time to become alarmed; for if it lets go the cowry, it becomes a dangerous antagonist, and there is risk of the fisherman being squeezed to death. The cutting off of one or more of its eight arms does not affect the rest in the least.

WE have received *Studies in Microscopical Science*, vol. iv. No. 6, Sections 1–4. The text of the first three sections relates to botanical, animal, and pathological histology; that of the fourth to marine Algæ. The plates are very delicately executed.

WE have also received the seventh, eighth, and ninth parts of the Transactions of the Yorkshire Naturalists' Union. Among the contents is an interesting presidential address on "The Fathers of Yorkshire Botany," delivered, in 1884, by Mr. J. G. Baker, F.R.S., President of the Yorkshire Naturalists' Union.

THE Selborne Society intend to issue letters, from time to time, on its objects and work. They will be written by members who have a special knowledge of the subjects discussed. The first of the series, which has just been published, is on the feeding and protection of wild birds in winter. The next will be on the Wild Birds Protection Acts of 1880 and 1881, and their bearing on bird-catching and bird-nesting during the close season. Other letters will follow on birds, trees, and plants, and it may be hoped that the scheme will be of considerable service in disseminating a knowledge of practical natural history.

THE French Government has purchased the hillock of Sansan (Département du Gers), which is famous for its richness in fossil animal remains. M. E. Lartet was the first discoverer of this palæontological treasure. M. Filhol, the naturalist, has recently examined the hillock; he was commissioned by the Professor of Palæontology at the Jardin des Plantes, Paris. This gentleman, supported by M. Cavaré, found fossil remains not only of Mastodons, Macrotheria, Chalicotheria, &c., but also of bears, stags, dogs, and cats. Noteworthy are some stags' horns, with two main branches, or so-called Dicroceri. All these fossils will be deposited in a museum to be built at Sansan, and will be described in a catalogue by M. Filhol.

PROF. W. J. TSINGER, at Moscow, is busily engaged in preparing his bulky work on the flora of Middle Russia, including the floras of the fifteen central provinces.

A LEARNED Society called the Società Italiana Asiatica has been formed in Italy for the investigation of Eastern languages and archæology. Prof. Amari has been elected Honorary President. The Society has obtained the collaboration of the best Italian Orientalists, and has nominated twenty-four foreign honorary members, among whom are Profs. Böhtlingk, Max Müller, Roth, Fleischer, Renan, Weber, Whitney, Rawlinson, Maspero, Legge, Brugsch, and Friedrich Müller.

THE Anthropological Society of Bombay, the establishment of which less than a year ago has been noticed in these columns, has already over 300 members, and has published the first number of its Transactions. Mr. Tyrrell Leith, the founder of the Society, has a paper on divination by Hazirat among the Indian Mussulmans; Dr. Dymock writes on the hairy man of Burmah, and Indian necromancy; Dr. Weir, on sacrifice in India as a means of preventing epidemics; and Dr. Basu, on embalming in Ancient India, and on Nisi, the night demon. There are other papers, but this list is sufficient to show the activity and utility of the new Society.

THE author of the paper on "Mexican Codices and Graven Inscriptions" inadvertently referred to in a Note last week as "Mr. Z. Nuttall," is "Mrs. Zelia Nuttall," one of two American ladies elected to the honorary position of "Special Assistant" of the Peabody Museum of Archæology, Cambridge, Mass. The paper in question was communicated to the American Association for the Advancement of Science in August last, when Mrs. Zelia Nuttall announced her discovery of "determinative signs," forming a key to Aztec phonetic manuscript records and graven inscriptions, and presented, in support of her statements, comparative tables of phonetic signs for inspection to the Section of Anthropology. Mrs. Zelia Nuttall has recently contributed to the *American Journal of Archæology* an account of the terra-cotta heads of Teotihuacan. These little clay heads, of most varied types, are frequently found in the vicinity of the great pyramids at San Juan Teotihuacan, about 30 miles north-east of the city of Mexico. They had been generally considered the work of different races of people, inhabitants of the valley of Mexico at successive periods, and were therefore held to be of considerable antiquity. Mrs. Zelia Nuttall's comparative researches prove them to be of Aztec workmanship, and thus of more modern date. She found that several of the most typical head-dresses modelled in clay were identical with those worn by Aztecs of different social grades, as depicted in Spanish chronicles at the time of the conquest of Mexico. Mrs. Nuttall adduces satisfactory proofs that these little clay heads were the portrait-models of dead persons adorned with the insignia of their rank. Attached to bodies of perishable materials, they served as effigies of the dead, and were placed on the coffers or jars containing the cremated remains, which were kept in the household dwellings of the relatives. Food and wine were offered before them, incense was burnt, and, at certain prescribed recurrent ceremonials, animals were sacrified in their honour.

WE notice, in the last *Bulletin* of the St. Petersburg Academy of Sciences, a valuable preliminary sketch of the avifauna of the western spurs of the Pamir plateau and its northern border-ridge, the Altai Mountains, by V. Bianchi. The birds were collected by M. Grum-Grzimailo, and the collection includes 136 species, which probably represent about one-third of the species inhabiting the region. With the exception of nine species, the same were found by Dr. Severtzoff in Bokhara, and described in the *Journal of Ornithology*, 1875; and only five species are not yet known in Russian Turkestan. It thus appears that the avifauna of the Western Pamir is very similar to that of the region situated on the other slope of the Kashgar-daban Mountains. Nearly a hundred species out of the above-mentioned 136 are also found in the Western Himalayas, but this last region has a number of endemic species which give it its special character. The poverty of the fauna of the Pamir plateau is obviously the consequence of its valleys being at a height of no less than 10,000 feet above the sea-level. The presence of the following species in the region will be interesting to zoo-geographers:—*Saxicola finschi*, *Cyanecula leucocyana*, *Herbivocula neglecta*, *Acanthopneuste nitida*, *Trochalopterum lineatum*, *Microcichla scouleri*, *Cyanistes flavipectus*, *Rhodopechys sanguinea*, and *Nisaëtus fasciatus*.

IN the *Zeitschrift für Instrumentenkunde* for September 1886 there is a paper entitled "Ueber eine Methode zur Messung kleiner Winkeldifferenzen," by Herr Hugo Langner, of Breslau. It describes a method of measuring the angle between two plane reflecting surfaces when it is nearly an aliquot part of two right angles, by measuring the difference between the required angle and the nearest aliquot part. It is known that in looking into the angle formed by two such surfaces the image of any small object lying between them will be seen repeated. If the angle be nearly $\frac{\pi}{n}$ $\left(\text{say } \frac{\pi}{n} - \delta\right)$, then when δ is positive, there will be a certain portion of the space between the two reflecting planes where both nth images can be seen, but if δ be negative, there will be a space where neither can be seen. If, again, for a small object a scale be substituted, then when δ is + two images will be seen, and a certain portion of the scale will be seen in both images; while if δ be − there will be a portion which is in neither image, and this superfluous or defective portion will be a measure of δ. Herr Langner proposes to place in front of the angle, and at a considerable distance from it, a scale bent to a cylinder whose axis is the intersection of the reflecting planes. Observing with a telescope looking into the angle, the position where a division of one image of the scale falls on the other image can be read, and, if the radius of the scale be known, the angle subtended by the relative displacement of the images, and thence the difference between the approximate and real values of the angle between the reflecting surfaces found. Herr Langner gives as an example the determination of the angle of a right angled prism of glass, of which a single determination would seem not to be liable to a greater error than 4″ or 5″. And he suggests that the method might be applied advantageously to determine the movements of a magnet by determining from time to time the changes of the angle between a mirror fixed to the needle, and one which is absolutely fixed, and to measure small variations of an angle in other cases.

THE little marine laboratory connected with the Johns Hopkins University is almost as old as the great laboratory at Naples. A sketch of its history is presented in a recent report by Dr. W. K. Brooks, Director of the Marine Laboratory, to the President of the Johns Hopkins University. In 1878 a small appropriation was made by the Trustees of the University to enable a party of biologists to spend a few weeks at the seashore in the study of marine zoology; and the scientific results of the season's work were printed in an illustrated volume, the cost of publishing which was borne by some citizens of Baltimore. The next year the appropriation was renewed, and in 1880 the Trustees voted that the laboratory should be continued for three years more, providing 4500 dollars for outfit and an annual sum of 1000 dollars for current expenses. The scheme worked so well that at the end of three years the institution was maintained. After an examination of all the available localities, the town of Beaufort, N.C., about 400 miles south of Baltimore, was selected as the site for the laboratory; and a vacant house, suitable for the accommodation of a small party, was found, and rented as a laboratory and lodgings. This house has been occupied during five seasons, and much good work has been done in it. During the season of 1886 a party of seven students went, under the direction of Dr. Brooks, to carry on zoological investigation in the Bahama Islands.

THE additions to the Zoological Society's Gardens during the past week include three Hooker's Sea Lions (*Otaria hookeri* ♂ ♂ ♀) from New Zealand, presented by the Government of New Zealand; a Blue Penguin (*Eudyptula minor*) from New Zealand, presented by Dr. Bernard Lawson; a Domestic Sheep (*Ovis aries* ♂, four-horned var.) from Cashmere, presented by Major Roland Poole; two Wood Hares (*Lepus sylvaticus*) from North America, presented by Mr. Walter Ingram, F.Z.S.; a Blotched Genet (*Genetta tigrina*) from South Africa, presented by Capt. J. Robinson; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Mr. Stanlake Batson; a Spotted-billed Duck (*Anas pœcilorhyncha*) from India, received in exchange; three Lions (*Felis leo*), an Axis Deer (*Cervus axis* ♂) born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE NEW ALGOL-TYPE VARIABLE.—Mr. Chandler has been able (Gould's *Astronomical Journal*, No. 150) to secure some further observations of this star, which, so far as they go, tend to confirm the hypothesis of a period of about three days. Minima were observed on January 2 and 11, but these were inconclusive as to the period. The star was, however, observed on January 12, between 17h. 15h. and 18h. 5m., to be apparently of its normal maximum brilliancy, whereas the first rough elements formed would have given a minimum at 17h. 50m., had the period been 1·4992d. or 0·7496d. Further observations are much desired. It unfortunately happens, from the star's period being very closely commensurable with the mean solar day, that further observations of minima will be scarcely possible in Northern Europe or Eastern North America for many months.

GORE'S VARIABLE NEAR χ^1 ORIONIS.—Dr. G. Müller, from a series of observations extending from 1886 November 9 to 1887 January 8, finds that the star attained its maximum on 1886 December 12. Assuming the light-curve the same at the preceding maximum, it will have been at its brightest on 1885 December 13, so that the period will be about 364 days.

THE SOUTHERN COMET.—The following telegram has been received from Cape Town, from which it appears that the new southern comet resembles that of 1880 I. in its orbit as well as in its physical appearance:—"Cape Town, January 26.—No condensation observable; riband of light 35° long, narrowing towards sun, position narrowest part near as can observe, January 22·317 G.M.T., R.A. = 322° 31′, N.P.D. = 135° 48′. The orbit presents a close resemblance to Comet 1880 I. Perihelion, January 11, noon." The comet is rapidly diminishing in brightness, and it is already invisible to the naked eye.

A SHORT METHOD FOR COMPUTING REFRACTIONS.—In the *Astronomische Nachrichten*, No. 2768, Mr. Schaeberle, of the Ann Arbor Observatory, explains a short and convenient method for computing astronomical refractions between 0° and 45° zenith distance. Let k and k_0 be respectively the true and mean refractions when $z = 45°$, then for any other zenith distance less than 45° the approximate true and mean refractions would be given respectively by

$$r = k \tan z, \qquad r_0 = k_0 \tan z,$$

from which is derived

$$r = r_0 - \frac{k_0 - k}{k_0} r_0,$$

an expression which, for the assigned limits of zenith distance, will give the true refraction within 0″·01, provided the true value of r_0 is used in the second member of the equation. The factor $\frac{k_0 - k}{k_0}$ will, however, be constant only so long as the barometer and thermometer readings remain unchanged. To allow for changes in these quantities, let F_1 and F_2 denote respectively the values of these factors at the times T_1 and T_2;

the value of the factor at any intermediate time T will be given by

$$F = F_1 + \frac{T - T_1}{T_2 - T_1} (F_2 - F_1),$$

which can be easily taken from a table of double entry with the arguments barometer reading and thermometer reading. Such a table, together with one giving the values of the mean refractions computed to hundredths of a second of arc for every ten minutes of zenith distance, and a convenient multiplication table, are all that is required for the practical application of Mr. Schaeberle's method.

COMET BROOKS (1887 *b*).—A Science Observer Circular (No. 19) gives the following elements and ephemeris for this object:—

T = 1887 March 28·63 G.M.T.

$$\left.\begin{array}{l} \pi = 121^\circ\ 20' \\ \Omega = 294\ \ 45 \\ i = 94\ \ 17 \end{array}\right\} \text{Mean Eq. } 1887{\cdot}0$$

$\log q = 0{\cdot}1016$

Ephemeris for Greenwich Midnight

1887	R.A.	Decl.	Brightness
	° ′	° ′	
Jan. 31	305 24	+ 79 5	1·41
Feb. 4	337 32	79 59	
8	8 39	77 41	
12	28 4	72 57	1·95

The brightness at discovery is taken as unity.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 FEBRUARY 6–12

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on February 6

Sun rises, 7h. 32m.; souths, 12h. 14m. 18·5s.; sets, 16h. 56m.; decl. on meridian, 15° 37′ S.: Sidereal Time at Sunset, 2h. 2m.

Moon (Full on February 8) rises, 14h. 54m.; souths, 22h. 49m.; sets, 6h. 37m.*; decl. on meridian, 18° 2′ N.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury	7 46	12 16	16 46	17 38 S.
Venus	8 14	13 17	18 20	11 47 S.
Mars	8 14	13 23	18 32	10 39 S.
Jupiter	0 10	5 11	10 12	12 8 S.
Saturn	13 58	22 6	6 14*	22 16 N.

* Indicates that the setting is that of the following morning.

Feb.	h.	
6	6	Saturn in conjunction with and 3° 21′ north of the Moon.
6	18	Mercury in superior conjunction with the Sun.
8	—	A partial eclipse of the Moon occurs in the morning, not visible in Europe.

Saturn, February 6.—Outer major axis of outer ring = 45″·8; outer minor axis of outer ring = 18″·8; southern surface visible.

† Occurs on the following morning.

GEOGRAPHICAL NOTES

VARIOUS rumours have been afloat during the past week as to difficulties having arisen between the Egyptian Government and Mr. Stanley and as to the escape of Emin Pasha. To these rumours Mr. Stanley has telegraphed a positive contradiction, and it should be remembered that there is a small party in Egypt opposed both to the expedition and to Emin Pasha. Mr. Stanley leaves Cairo this week for Zanzibar, and every preparation has been made for his taking the Congo route. Meantime important information has reached Europe from Dr. Junker as to his explorations in what is known as the Wellé-Makua region. Dr. Junker's furthest position on the River Wellé, according to the calculation of Dr. Schweinfurth, was the village of Bassanga, 22° 47′ 40″ E. of Greenwich, and 3° 13′ 10″ N. lat. This position, combined with what we already know of the course of the Wellé, leaves little doubt that it is an affluent of the Congo. But that it reaches the Congo through the recently-discovered Mobangi is by no means so certain. Taking into account the altitudes and the general lie of the country, it seems more probable that it reaches the Congo at some point between the Mobangi and the Aruwimi. However, this is one of the problems which it is hoped Mr. Stanley will be able to solve. And even if Emin Pasha has escaped, it is to be hoped that the expedition will proceed, if not to take possession of the Equatorial Province, at least to carry out the exploring work which Mr. Stanley has planned for himself. The attempt of the Balloon Society to get up a second expedition by the Congo it is impossible to treat seriously.

To the new number of the Proceedings of the Royal Geographical Society Dr. Edmund Naumann, late head of the Geological Survey of Japan, contributes a paper of great scientific value, on the physical geography of Japan, in which he gives the results of his own surveys. Considering the Japanese chain as one continuous mass, the lowest parts of which are submerged, this great wave of the earth's surface bears the same relation to the Pacific Basin, according to Dr. Naumann, as the Himalaya mass does to the Indian peninsula. The dimensions of the two colossal earth-waves are almost equal. The ocean-bed on the Pacific side of Japan really rises very gradually to the coast-line, making an angle of not more than 3°, while on the opposite side the inclination is very slight indeed. The general character of the Japanese earth-wave establishes its close relation to the Asiatic continent. In fact, it is nothing else than the advanced frontier of Asia, and not a chain of volcanic ejections accumulated over a fissure of the ocean-bed, as certain famous geographers of past periods conjectured. One of the most original and interesting parts of Dr. Naumann's paper is that in which he deals with the magnetic map of Japan, a reproduction of which is given in the Proceedings. On this map is perceived a most remarkable correspondence between the lines of equal declination (the trogones) and the leading lines of geological structure described by Dr. Naumann. In general, the magnetic lines exhibit very striking and quite unexpected irregularities, and these irregularities are found to be in most intimate connection with the abnormal curvature of the folds. No less than two hundred complete observations for magnetism, at a like number of stations, were made. The results seem extremely satisfactory. Across the centre of the main island is a great depression which Dr. Naumann calls the Fossa Magna, and the map shows that the magnetic lines are influenced in their course by this cleft, in the same manner as by the folds. He is even inclined to say that the deviations of the lines of equal declination and the fold lines coincide to a certain extent. Where one of the great lines of horizontal dislocation, separating two unequally advanced sections of the Japanese Archipelago, crosses the chain, the trogones describe bends and sinuosities of a most peculiar character. As Dr. Naumann states, these results seem to open up a new field of research quite worth investigating.

A PAPER of unusual scientific interest was read at Monday's meeting of the Royal Geographical Society by Mr. H. J. Mackinder, B.A. (Oxford), on the field and methods of geography. Mr. Mackinder aimed at showing how geography could be made more than a mere cultivation of dry facts, and become indeed a department of scientific inquiry. He takes man as the centre of the field and defines geography as the study of man in relation to so much of his environment as varies locally; Mr. Mackinder thus takes geography to be the physical basis of history. He insists on a clear separation being made between physical geography and both geology and physiography. The physical geographer has to deal with only so much of the past as will enable him to interpret the present, whereas the geologist deals with the present, only that he may be able to interpret the past. So with other departments of science, as meteorology; from the new stand-point only so much of them is to be included as is pertinent to the geographical line of investigation. Mr. Mackinder illustrated his position by two sets of three maps—one of South-Eastern England, physical, geological, political; and the other of India, showing physical features in relation to rainfall and population. He attempted to show, on the basis of physical conditions, why, among other things, London should have become the metropolis of the Empire and why the three south-eastern counties should have had their existing boundaries. With reference to India, again, he showed how geographical conditions determined that Delhi and Calcutta should have become the ancient and modern capitals of India. Geography, when studied in this way, Mr. Mackinder thinks, might become a bridge between the physical sciences on the one hand and classical and historical studies on the other. The lecture was illustrated by some very fine and instructive maps and lantern views.

PHYSICAL NOTES

THE inverse electromotive force of the voltaic arc has recently been investigated by Prof. C. R. Cross, of the Massachusetts Institute of Technology, and by Mr. W. E. Shepard. It appears that with currents varying from 3 to 10 amperes the inverse electromotive force is about 39 volts when the arc is silent, and about 15 volts when it is hissing; but both these values show a diminution as the currents employed are increased. The transition from one state to the other is abrupt. Addition of volatile metallic salts to the arc always decreases the inverse electromotive force. In rarefied air the inverse electromotive force is unaltered, but the true resistance of the arc is diminished.

SENSITIVE hygrometers have lately been constructed upon a principle resembling Bregnet's metallic thermometer. A spiral composed of two substances having different hygrometric coefficients of expansion tends to curl or uncurl according to changes in the hygrometric state of the air. Some of these have been made by Prof. W. Holtz out of thin brass spirals with a thin coating of gelatine on one side. Independently, M. Nodon, of Paris, has constructed some recording hygrometers having spirals made of Bristol board coated on one side with gelatine (with a little salicylic acid), and on the other with bitumen. The principle is not new: in various collections of physical apparatus similar arrangements have existed for at least a dozen years.

LENSES which magnify, and yet are perfectly flat on both sides, have been constructed by Schott and Co., of Jena, the manufacturers of Abbé's optical glass. These lenses are mere curiosities. They consist of single disks of glass, such that the refractive index decreases in a regular manner from the surface inwards. The properties of this arrangement have been investigated by Prof. K. Exner, of Vienna.

QUADRANT electrometers have been lately described by M. Ledeboer, in which the motion of the needle (often of very annoying duration) is damped so as to be aperiodic. This is achieved by making each of the four "quadrants" of steel highly magnetised. The needle is therefore damped by magnetic friction. The suspension is unifilar.

SEVERAL modifications have been lately introduced into the Leclanché battery. Mr. Sydney Walker proposes to substitute sulphur for the manganese: it is cheaper, and less of it is required. Mr. A. Pollak does away with the manganese, but employs a special, porous, coarse, annular block of carbon, which stands half out of the liquid and absorbs oxygen from the air to depolarise. M. Germain introduces a novel material to hold the liquid, an absorbent preparation, chiefly cellulose, made from cocoa-nut fibre, and which has received the curious name of "cofferdam." It has truly remarkable absorbent properties, as it will suck up and hold from twelve to fourteen times its own weight of water. A "cofferdam" cell does not spill the liquid.

DRY portable cells appear to be coming into favour, gelatine being the favourite medium. They are claimed as novelties both in Paris and in Frankfort. Joule's "glue-battery"—a Daniell's cell, having a gelatinous mass impregnated with sulphates of copper and zinc—is the parent of all these later forms.

ELECTRIC welding is the latest of the industrial applications of electricity, and it would seem to have already reached a thoroughly practical stage. Prof. Elihu Thomson, of Lynn, Massachusetts, has shown that bars of iron, steel, copper, and brass can be welded firmly together in a few seconds by passing through their junction a very powerful electric current. He has invented a special kind of transformer or induction-coil to enable him to accomplish this operation. It is possible thus to weld iron and brass together in a firm joint. Simultaneously, researches on the same subject have been made by two Russian gentlemen in the laboratory of M. Marcel Deprez in Paris, and they have announced their discovery under the name of "electrohephaest." If we are not mistaken, similar experiments were made before the Académie des Sciences some years ago by the late M. Ruhmkorff. Moreover, in Mr. J. P. Joule's papers he mentions the discovery of the practicability of electric welding by himself and Sir William Thomson.

ACCORDING to Olszewski, the critical temperatures of nitrogen and oxygen are respectively $-146°$, $-118·8°$, of the Centigrade scale.

ON THE MORPHOLOGY OF BIRDS [1]

THERE are several things that go to increase the interest in the morphology of these culminating Sauropsida at the present time.

(1) The discovery by Gegenbaur, Huxley, and others, of the close relationship of birds and reptiles, especially of the extraordinary fact that the hind-limb and pelvis of even the most minute bird pass through a stage in which they correspond almost exactly with the hind-limb and pelvis of the most gigantic kinds of extinct reptiles—the Dinosaurs or Ornithoscelida.

(2) The recent discoveries of biologists as to the composition of the cheiropterygium in the various types of air-breathing Vertebrata. It is now well known that the five-fingered hand and the foot with five toes are the specialised modern representatives of hands and feet that had at least seven rays in their composition.

And (3) the study of the development and general morphology of birds is at the present time of great interest, now that we are looking to the study of metamorphosis for some initial elucidation of the mystery as to the origin of the various types of Vertebrata.

The labour of each succeeding day at this culminating class makes it more and more impossible for me to conceive of birds as arising *direct* from the Dinosaurians, or indeed from any other order or group of reptiles.

Long attention to the metamorphosis of the Amphibia has intensified this difficulty to me; for the newly-transformed frog or newt appears to me to be the true counterpart of a newly-hatched reptile—snake, lizard, turtle, or crocodile.

Each of these young creatures, whether it has undergone a true metamorphosis or has been the subject of pre-natal transformation, is evidently an imago, although an imago that continues to grow.

Now each amphibian has its own larva, for the larvæ of the various species have their specific differences.

The thousand known species of existing Amphibia—Anurans, Urodeles, and Cæcilians—and all the fishes that undergo meta-

[1] Paper by Prof. W. K. Parker, F.R.S., read before the Royal Society on January 27, 1887.

morphosis, are as truly, if not as remarkably, distinct from each other in their larval as in their imago form; as much so as is the case in insects, or any other of those invertebrate types that are truly metamorphic.

If *many* of the existing Vertebrata are metamorphic *now*, is it not very probable that they were *all* metamorphic *once?*

The fact that we have even now such forms as the larval lamprey (or Ammocœte), the larvæ of Ganoids and Dipnoi, and the tadpoles of newts and frogs, suggests to me the possibility of the existence of huge swarms of low proto-Vertebrata in the early ages of the inhabited planet.

If such proto-vertebrate forms existed, then it is quite supposable that a metamorphosis may, from time to time, have taken place, of this and that *quasi*-larval form into archaic reptile, ancestral bird, or primitive mammal.

I am not afraid that anyone familiar with the development, structure, and habits of the existing Amphibia will see any difficulty in the passage of a metamorphic into a *so-called* non-metamorphic type, during time, and under the pressure of new outward conditions—when the dilemma offered to the supposed low vertebrate was *Transform or perish.*

To me it seems that the creature's necessity was Nature's opportunity; and that, during long ages, the morphological force had accumulated in those low forms an enormous surplusage of unused energy, which, in the ripeness of time, blossomed out into this and that new and noble type.

Of all the types of Vertebrata, there is none like the bird of high degree for illustrating what Prof. Huxley calls "the threefold law of evolution,"[1] namely, overgrowth of some parts, starvation and even death of others, and fusion of parts originally distinct.

No kind of vertebrate whatever presents to the osteologist so hopeless an enigma in the adult skeleton, as that of the bird; in the overgrowth of certain parts, the abortion or suppression of others, and the extensive fusion of large tracts of skeletal elements.

Hence this class has largely acted upon the morphological mind; the "comparative anatomist" has, of necessity, undergone evolution into the "morphologist," and the latter has had to be refined and developed into the "embryologist."

In the bird class we meet with this remarkable phenomenon, namely, that the swiftest creatures by far that inhabit the earth have had, for the purposes of their most consummate mechanism, the greatest loss of freedom of the individual parts of the skeletal framework.

Between the pigeon, on one hand, above, and the emu, on the other, below, there are several families of related birds; but there is no direct superposition—they are obliquely above or below each other.

Amongst the Carinatæ, which lie in the intermediate space, there is none better for the purposes of study than the common fowl; to this type I have devoted most attention, and have now worked out the limbs in as many stages as I formerly did the skull.

I can now give an account of the vertebral column with the ribs and sternum, the limb-girdles and limbs, from the end of the seventh day of incubation; by which time the hyaline cartilage is perfect, and certain even of the bony tracts are begun.

The fowl is an intermediate form between the emu and the pigeon, but most akin to the latter. I shall now confine myself to what is seen in the development of the skeleton (excluding the skull) in this medium type.

The vertebral column, at the end of a week's incubation, is formed of hyaline cartilage; up to the end of the true sacrals, the notochord is completely invested with cartilage; but, behind those four segments, only at the sides.

The notochord has its constrictions in the middle of each centrum, and is most dilated at the intercentra.

The neural arches do not nearly meet above; the atlas is in four pieces—a superficial and an inner piece to the centrum, and a pair of arch-rudiments; the inner segment of the centrum becomes the odontoid process of the axis.

Between the axis and the first true sacral, all the vertebræ have separate ribs; in the cervical region, except near the dorsal region, there are small styloid cartilages lying horizontally, which have their head, or thick end, wedged in between the upper and lower transverse processes. Near the dorsals they are transversely placed, and then begin to develop a descending process.

The first vertebra of this stage with complete ribs becomes, by absorption of the lower part of the arch, the last cervical in the adult. Behind the twenty pre-sacrals there are fifteen sacrals, and this series has its subdivisions.

The first develops ribs (it is dorso-sacral), the next three develop minute but distinct ribs, like those near the lower part of the neck; these are lumbo-sacral. Then come the four sacrals with no ribs, and then the seven uro-sacrals, the first two of which have rib-bars that ossify separately, below the upper transverse processes, which latter form a complete series from the third cervical to the last free caudal segment.

Of those there are five; then come five more paired imperfect rudiments, clinging to the terminal part of the notochord.

At the end of the eighth day there are six of these, with the last elongated, and the notochord projecting behind far enough for three or four more rudiments.

At the end of the tenth day the vertebral chain has undergone a great change. The atlas is still composed of four distinct pieces of cartilages, but the ribs have become fused above and below with the transverse processes, and the notochord is now most constricted at the intercentra.

Besides this, in the pre-sacrals, it is constricted in two places within each centrum; so that each centrum in the modern bird corresponds to three subdivisions of this axial chord.

For two or three days there is evidence of an archaic subdivision of the notochord into three times as many vertebral divisions as are made now in the modern bird.

In the sacral the constrictions are fewer; they are only at the intercentra, and in the middle of the centrum.

The only absolutely necessary part of the sternum is that where the sternal ribs are attached; that is a very small part, and the rest is for the attachment of the huge muscles that act upon the wings, and for the obliqui and recti abdominis.

The limb-girdles are each in three pairs of distinct cartilages. In front, the scapula, the minute pre-coracoid, the coracoid; behind, the ilium, pubis, and ischium; the pre-pubis is part of the ilium, and that has two regions, the pre-ilium and the post-ilium.

These parts in the bird are not continuous tracts of cartilages, ossified by several centres, but are distinct, first as cartilages, then as bony tracts; those of the shoulder keep distinct; those of the hip soon coalesce.

The wings at the end of the seventh day are three-toed webbed paws, with all the digits turned inwards. The rods that compose the main part of it are composed of solid cartilage: the humerus, radius, ulna, and first and second metacarpals have a bony sheath round their middle part; the ends of the digits and the carpals are but partly chondrified. Five carpal nuclei, however, can be made out, and the two proximal nuclei are known to be further subdivided, each into two, in other types; hence we can already account for seven carpals in the bird, which has only two in the adult, in a free state.

Moreover, the first digit has two, and the second three phalanges, the normal number, as in lizards; the third, which should have four, but in birds has as a rule only one, has now two, as in the ostrich, and a few other birds; there is no sign at the end of the seventh or even of the eighth day of incubation of any more than three digits, but we have in the wrist an intermedio-radiale, a centralo-ulnare, and three distal carpals, answering to the three developed metacarpals. The digits up to the end of the eighth day are rounded and flattish, and are quite like those of a young newt or frog. But in two days more, at the end of the tenth day, the wing has almost acquired the adult form; and one more bony centre, that of the first metacarpal, has appeared. The overgrowth of the second distal carpal and the second metacarpal, with its large and dilated digit, has arrested the distal carpal of the first or short digit, the "pollex." This is the last nucleus to chondrify. It is still a very small, limpet-like disk of cartilage, and is now only to be seen on the flexor face of the manus, inside the top of the second metacarpal; the distal carpal of the third ray is also small as compared with the large crescentic second distal nucleus. It is thrown on to the ulnar or outer side of the manus by the overgrowth of the middle rod and its carpal. The curve of the digits at their end is now, not inwards, or to the radial side, but outwards; and the two developed distal segments form now the core of two claws, that of the first, or pollex, being of considerable length.

[1] See his paper "On the Application of the Laws of Evolution to the Arrangement of the Vertebrata, and more especially of the Mammalia" (Zool. Soc. Proc., December 14, 1884, pp. 649-662).

Thus, by the end of the tenth day, the reptilian type or fore-foot has been attained, and the amphibian type lost, whilst the limb as a whole is now a fore-leg no longer, but a wing, thoroughly specialised by evolutional transformation.

The fore-limb has not simply become modified into a wing by the shortening of the pollex and third ray, the enlargement of the second, and the abortion of the fourth and fifth of a fore-paw, like that of the lizard; but we have now the historical representatives of three more rays which have cropped up since the end of the eighth day.

I have repeatedly noticed that aborted parts, like over-shadowed plants, are late to appear, and soon wither, or are arrested in their growth. This is the case here, for the new rays are late, small, and scarcely functional in the fullest development. They are not lost, however, but, like certain larval structures to be found in the skulls of the highest types of birds, they are built up into the finished wing, although they form an unimportant part of it as far as function goes.

The first of these additional rays is the "pre-pollex"; this is a lunate tract of fibro-cartilage attached to the inner face of the first metacarpal. The other two are composed of true hyaline cartilage, and appear, one on the ulnar side of the second, and the other on the ulnar side of the third developed metacarpal.

I have described them as intercalary metacarpals, for they seem to be the starved twins of the second and third large rays; each distal carpal, very probably, in the archaic forms carried two rays. Thus there is supposed, for such a fore-limb, a digit inside the pollex of the modern bird, and then two pairs of rays, of which only the inner in each case has been retained.

The paddle of Ichthyosaurus shows this kind of primitive cheiropterygium admirably.

Thus we can account for seven carpals and six digits in the wing of the modern bird; in the legs the specialisation is not so intense, but is very great; the study of the embryonic stages shows in it many parts that the adult bird gives no signs of whatever.

Instead of there being even two tarsals, free and functional, there is only one, and that has merely the function of a "sesamoid," and has been mistaken continually for a bone of that sort, that nucleus answers to our naviculare, morphologically termed the "centrale."

Notwithstanding the extreme diversity in the habits of existing birds, and the great difference seen in their shank bone, this part is always single, although composed of three metatarsals. As in reptiles, the joint at this part is not between the astragalus and tibia, as in mammals, but through the tarsal series; no sign of this structure is seen in the adult bird. That which appears to be the condyloid end of the tibia is a row of tarsal bones, the tibiale, fibulare, and intermedium: these have long been known as separate bones in young birds, but their distinctness in the early embryo as cartilaginous nuclei has only lately been made out.

I have been able, however, to demonstrate this repeatedly in different kinds of birds. The centrale also, although seen in the embryo as one of the tarsal series, was not properly identified; it is a constant element, but becomes degraded.

The distal series of tarsals exists as a single tract of cartilage, and then as a single plate of bone. But it is related to three metatarsals, and the middle or thick part is the first to chondrify in the embryo, and to ossify in the chicken or young bird; there are here three connate nuclei, with very slight signs of distinctness. The whole mass answers to our middle and external "cuneiform bones," and to the inner half of the "os magnum." Thus five tarsals can be always made out clearly, and two more accounted for.

The first metatarsal, which has been known, for some time, through the valuable researches of Morse, to have occasionally a proximal as well as a distal rudiment, has, I find, always a proximal rudiment as well.

Then, as Dr. G. Baur and Miss A. Johnson have shown, there is a fifth metatarsal; it is a small pisiform cartilage, which soon coalesces with the fourth, and with the great distal tarsal. I can only find a "pre-hallux" by turning to teratology, and this is not the lawful method.

There may, however, be some "reversion" or "atavism" in the polydactyle foot of the Dorking fowl, which has a well-developed "pre-hallux" and a double "hallux"; the twin digits of that part have a very ichthyosaurian appearance.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, xxix., No. 11.—B. Dessau, on metal films arising from the disruption of a kathode. Discusses the production of mirror-like films such as obtained by Plücker, Crookes, and Wright from the disgregation of the metal kathode in Geissler-tubes. With a pointed kathode and a flat glass surface as recipient, the film forms a flat conical deposit, showing interference-rings in reflected light, and proving also the presence of optical dispersive power in the metal. The dispersion in films of platinum, iron, nickel, and silver. It is anomalous in the case of gold and copper. The films are double-refracting, and, in the case of oxidisable metals, disappear on oxidation.—Ed. Hagenbach, propagation of electricity in telegraph-wires. Experiments made with chronographic apparatus on Swiss lines, together with a discussion of the results of Wheatstone, Walker, Guillemin, and others. Arguing from theory, the author compares, not the apparent speed, but the ratio of the time to the square of the length of circuit.—B. von Kolenko, reply concerning the pyro-electricity of quartz. Maintains, against Prof. Hankel, that the poles of a warmed quartz crystal are not altered during cooling by passing through a flame.—E. Edlund, remarks on H. Hoppe's communication on the theory of unipolar induction.—S. von Wroblewski, on the representation of the rotation between the gaseous and liquid states of matter by isopyknal lines. The transition of state is represented by curves drawn on a diagram having, for given definite densities, pressures as ordinates and temperatures as abscissæ; such curves being termed *isopykns* or isopyknal lines. The result of examination of these curves shows that, though there is no such thing as an absolutely definite critical temperature or critical pressure *per se*, there is a critical density for every liquid.—K. Schmidt, on reflection at the surface of crystalline elliptically-polarising media. Experiments made with a crystal of cinnabar, and results compared with the formulæ of Voigt and that of Ketteler. The latter leads to closer correspondence than the former with the facts of observation.—H. Muraoka, on the deformation of metal plates by grinding. The radius of the curvature produced by grinding metal disks set in a bed of fusible alloy is proportional to the cube of their thickness.—K. Exner, validity of lens formulæ for non-homogeneous lenses.—E. Budde, a means of deciding between the electro-dynamic point-laws of Weber, Riemann, and Clausius. This gives the elementary theory of an experiment not yet made.—J. Kollert, on a new galvanometer. This is practically identical with Gray's form.

No. 12, 1886.—C. Fromme, on the galvanic polarisation evoked by small electromotive forces. This gives a first series of results with platinum electrodes in dilute sulphuric acid.—Edm. Hoppe, on the theory of unipolar induction; with a reply to Prof. Edlund.—F. Himstedt, on a determination of the quantity "v." The method was that of comparison of the two capacities of a condenser; the result $v = 3{\cdot}0074 \times 10^{10}$ cm./sec.—R. Lamprecht, on the action of the magnet upon electric discharges in rarefied gases, concludes that the law of Biot and Savart holds good as the calculated trajectories agree with curves observed by Hittorf in 1869.—A. Foeppl, the spread of the electric charge in conductors.—L. Boltzmann, remarks on the opinion of Herr Lorberg on a point in electro-dynamics.—W. Voigt, on the torsion of a rectangular prism of homogeneous crystalline substance; a mathematical investigation.—J. Kiewiet, on the elasticity of bending of pure zinc, copper, tin, and their alloys. The moduli of elasticity of alloys is not constant, but depends on the mode of preparation of the alloy as well as on its composition. Wertheim's rule for calculating the moduli of alloys from those of their components, according simply to the proportion of the constituents, appears to be inexact. The change of moduli of alloys with temperature is a simple linear function.—J. Stefan, on the relation between the theories of capillarity and evaporation.—A. Heritsch, on radiophony. The author combats Graham Bell's view that the condensed gases of a smoke deposit or carbon strip have something to do with its radiophonic properties. He finds that a coke plate heated to redness and then instantly placed in a tube and exposed to intermittent illumination from sunlight or electric light, emits tones. He further constructed a sort of flat glow-lamp, which, even when raised to brilliant incandescence, emitted tones when exposed to intermittent sunlight. No other source than sunlight was sufficient for this experiment.—G. Kobb, on the spectrum of germanium.—Greiner and Friedrichs, on a new mercury air-pump; a modification of Geissler's form.—A. Grosse, a wire-tape rheostat. Fine german-silver wires are spiralled around cotton threads, which are then woven into a sort of tape, the warps being thereby insulated from one another. A piece 2 cm. wide and 4 metres long has 1000 ohms resistance.—W. Holtz, a Wheatstone's bridge for air and water flow. An illustrative apparatus of tubes such as has often been used.

IN the *Scottish Geographical Magazine* for January there is an excellent bathy-orographical chart of the Clyde sea-area, constructed for Dr. H. R. Mill by Mr. J. G. Bartholomew. The colouring of the map is designed to show with special effect the area and depths of the Firth of Clyde and its inlets. For this purpose the land and sea have been treated separately, and coloured in strong contrast to each other. The system of colouring is, however, uniform, and in both cases the lowest or deepest areas are distinguished by the darkest tints, and graduated up to the lighter tints of the higher or shallower portions. The same number contains a paper on the configuration of the Clyde sea-area, which was read by Dr. Mill at the last meeting of the British Association.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 16 — "Note on Specific Inductive Capacity." By John Hopkinson, M.A., D.Sc., F.R.S.

Consider a condenser formed of two parallel plates at distance x from each other, their area A being so great, or the distance x so small, that the whole of the lines of force may be considered to be uniformly distributed perpendicular to the plates. The space between the plates is occupied by air, or by any insulating fluid. Let e be the charge of the condenser and V the difference of potential between the plates. If the dielectric be air, there is every reason to believe that $V \propto e$, that is, there is for air a constant of specific inductive capacity. My own experiments ([1880] Phil. Trans., vol. clxxii p. 355) show that in the case of flint-glass the ratio of V to e is sensibly constant over a range of values of V from 200 volts per cm. to 50,000 volts per cm. From experiments in which the dielectric is one or other of a number of fluids and values of V upwards of 30,000 volts per cm. are used, Prof. Quincke concludes (Wiedemann, *Annalen*, vol. xxviii., 1886, p. 549) that the value of e/V is somewhat less for great electric forces than for small. From the experiments described in that paper, and from his previous experiments (Wiedemann, *Annalen*, vol. xix., 1883, p. 705, *et seq.*) he also concludes that the specific inductive capacity determined from the mechanical force resisting separation of the plates is 10 per cent. to 50 per cent. greater than that determined by the actual charge of the condenser. The purpose of the present note is to examine the relations of these important conclusions, making as few assumptions as possible.

In words, the specific inductive capacity as determined by charge or discharge of a condenser at any given potential and distance between the plates is the arithmetic mean of the inductive capacities determined by the force resisting separation of the plates and that determined by lateral pressure, the potential and distance being the same. This is true whatever be the relation between charge and potential difference, but it is at variance with the experimental result that K_p and K_s are both greater than K.

The results obtained by Prof. Quincke are not easy to reconcile. For that reason it is the more desirable that their full significance should be ascertained. Full information is given of all the details of his experiments except on one point. It is not stated whether, in the experiments for determining K by direct discharge of the condenser, the capacity of the connection and key was ascertained. It would in most ordinary arrangements of key be very appreciable in comparison with the capacity of the condenser itself. If neglected, the effect would be to a certain extent to give too low a value of K, the effect being most marked when K is large.

The property of double refraction in liquids caused by electrification is sometimes cited as showing that electrification is not proportional to electromotive force. The fact that the double refraction in a liquid under powerful electromotive forces is very small would further show that there is a close approximation to proportionality, and that the deviation from proportionality would be insensible to any electro-static test. Such conclusions, however, cannot be safely drawn in the case of bodies such as castor-oil, in which $K \pm \mu^2$. In such bodies, assuming the electro-magnetic theory of light, the yielding to electromotive force is much greater if the force be applied for such time as 10^{-4} second than when applied for 10^{-14} second, and it is quite possible that the law of proportionality might be untrue in the former case, but very nearly or quite true in the latter.

"On the Dielectric Constants of Fluids." (Addendum to Dr. Hopkinson's "Note on Specific Inductive Capacity.") By Prof. G. Quincke, For. Mem. R.S.

In investigating the properties of dielectric fluids (*Wiedemann's Annalen*, vol. xix. 1883, p. 707; vol. xxviii., 1886, p. 529), I found the dielectric constants with the electric balance or by the hydrostatically measured pressure of an air-bladder greater than when measured by the capacity of a condenser surrounded by air or the insulating fluid, and discharged by turning a key through a ballistic galvanometer.

The capacity of the key and of the short thin junction-wire connecting the key with the condenser was, however, in that calculation left out of account as being evanescently small.

In consequence of a written communication from Dr. John Hopkinson, I quite recently compared the capacity of the key and the junction-wire with the capacity C of the condenser by observations with the ballistic galvanometer with the same difference of potential between the surfaces, and thereby found the relation—

$$\frac{x}{C} = 0{\cdot}1762;$$

greater, therefore, than I had conjectured.

Let there be subtracted from the observed galvanometer readings s_1 and s_{11} for the condenser in air and in the dielectric fluid, the deflection calculated for the electricity on the key and junction-wire, then there will actually be obtained from the ratio of the readings thus corrected (s_1) and (s_{11}) values of the dielectric constants (K) of the fluid almost exactly coinciding with the measurements of the electric balance. The agreement is indeed as perfect as might be expected, considering the difference in the methods of observation employed.

Thus, for example, it was found:

	Dielectric constants with Ballistic galvanometer (K)	Weighing K_p
Ether	4·211	4·394
Carbon disulphide ...	2·508	2·623
,, ,, ...	2·640	2·541
Benzole	2·359	2·360
Petroleum	2·025	2·073

[Note added by Dr. Hopkinson.—Prof. Quincke's explanation sets the questions I have raised at rest. There can be little doubt that K, K_s, and K_p are sensibly equal and sensibly constant. The question what will happen to K_p and K_s if K is not constant has for the present a purely hypothetical interest.

Physical Society, January 22.—Prof. McLeod, Vice-President, in the chair.—Dr. F. Wormack was elected a Member of the Society.—The following papers were then read:—The permanent and temporary effects on some of the physical properties of iron produced by raising the temperature to 100° C., by Mr. Herbert Tomlinson, B.A.—On some new measuring-instruments used in testing materials, by Prof. W. C. Unwin, F.R.S. In most measuring-instruments previously used, it has been considered sufficient to make the measurement of elongation from one side of the bar, but this, the Professor showed, was liable to serious errors owing to the fact that test-bars are not always perfectly straight, and to the possibility of originally straight bars being bent by improper fixing in the testing-machine. In such cases the modulus of elasticity calculated from the apparent elongations are subject to considerable error. In endeavouring to overcome these difficulties the author has devised several new forms of measuring-apparatus, which are attached to two sides of the bar by steel points, and the mean elongation of the two sides determined. The first apparatus described consists essentially of sliding calipers read by microscopes to 1/10,000 of an inch. Another form has two clamps provided with sensitive levels. Each is attached to the bar by two steel points, the line joining which is perpendicular to the direction of the stress, and the clamp can rotate in a vertical plane about this line as an axis. The lower clamp is levelled by a screw pressing against the surface of the bar, and the upper one by means of a micrometer-screw parallel to the axis of the bar, the nut of which is secured to the bottom clamp. By this means the elongation can be measured to 1/10,000 of an inch. In a third form two similar clamps without levels are kept apart by a steel rod ending in knife-edges. One of the clamps carries a small roller, which turns about an axis parallel to the line joining the steel points above mentioned, and the axis carries a small plane mirror. The other clamp supports a projecting arm parallel with the axis of the test-piece, and which presses on the surface of the roller. When the bar is elongated the mirror is turned through a small angle and the elongation is determined by a reading-telescope and vertical scale to 1/100,000 of an inch. A similar apparatus is used for testing the compression of stone, but in this the compression is multiplied by a lever and measured by a micrometer microscope to 1/100,000 of an inch.—At the conclusion of the meeting Prof. Unwin invited the members to visit the Engineering Laboratory of the City and Guilds of London Central Institution, where he broke a bar of Staffordshire iron in the 100-ton testing-machine, the force and elongation being automatically recorded.

Royal Meteorological Society, January 19.—Mr. W. Ellis, President, in the chair.—Mr. J. Willis Bund was elected a Fellow of the Society.—The following papers by the Hon. R. Abercromby, F.R.Met.Soc., were read:—(1) On the identity of cloud-forms all over the world, and on the general principles by which their indications must be read; (2) On the cloud to which the name "Roll-Cumulus" has been applied.—After the reading of these papers the annual general meeting was held, when the Report of the Council was read by Dr. Tripe, which showed the Society to be in a satisfactory condition. The number of Fellows is 524.—The President, Mr. W. Ellis, then delivered his address.—The Officers and Council for the ensuing year were elected:—President: William Ellis; Vice-Presidents: George Chatterton, Charles Harding, Cuthbert Edgar Peek, George Mathews Whipple; Treasurer: Henry Perigal; Trustees: Hon. Francis Albert Rollo Russell, Stephen William Silver; Secretaries: George James Symons, F.R.S., John William Tripe, M.D.; Foreign Secretary: Robert Henry Scott, F.R.S.; Council: Hon. Ralph Abercromby, Edmund Douglas Archibald, Francis Campbell Bayard, William Morris Beaufort, Arthur Brewin, Frederic William Cory, Henry Storks Eaton, Richard Inwards, Baldwin Latham, William Marcet, M.D., F.R.S., Edward Mawley, Charles Theodore Williams, M.D.

Entomological Society, January 19.—Mr. R. McLachlan, F.R.S., President, in the chair.—This was the fifty-fourth anniversary meeting.—An abstract of the Treasurer's accounts was read by Mr. Stainton, one of the auditors; and the Secretary read the Report of the Council.—The following gentlemen were elected as Officers and Council for 1887:—President: Dr. David Sharp; Treasurer: Mr. Edward Saunders; Secretaries, Mr. Herbert Goss and the Rev. W. W. Fowler; Librarian: Mr. Ferdinand Grut; and as other Members of the Council: Messrs. Robert McLachlan, Gervase Mathew, R.N., George T. Porritt, Edward B. Poulton, Osbert Salvin, F.R.S., Henry T. Stainton, F.R.S., Samuel Stevens, and J. Jenner Weir.—The retiring President delivered an address, and a vote of thanks to him was moved by Mr. E. B. Poulton, and seconded by Prof. Meldola, F.R.S.—A vote of thanks to the Treasurer, Secretaries, and Librarian was moved by Mr. McLachlan and seconded by Mr. Stainton; and Mr. Goss and Mr. Grut replied.

Middlesex Natural History and Science Society, January 18.—Dr. Archibald Geikie, F.R.S., in the chair.—Mr. Robert B. Hayward, F.R.S., read a paper on the water in the Chalk, beneath the London Clay, of the London Basin. The geology of the area in question was described, and the water in the beds above the Chalk briefly referred to. Mr. Hayward then drew attention to the great extent of the Chalk area, to the rainfall, and other atmospheric conditions affecting the water-supply, and gave detailed chemical analyses of the waters of a large number of wells in and near London, which draw their supplies from the Chalk. Those of Harrow and the north of London, being well known to the lecturer, received special attention. The water-levels were described and elucidated by Joseph Lucas's hydro-geological maps, and the movements of the underground waters fully treated of. A table of the above-mentioned chemical analyses was distributed to the members present. In the discussion which ensued, Dr. Geikie gave some interesting observations upon the probable origin of Harrow Hill, and the other hills of London Clay to the north of London, and was followed by Mr. Clement Reid, Mr. Mattieu Williams, and Mr. Klein.

Paris

Academy of Sciences, January 24.—M. Gosselin, President, in the chair.—Fresh statistics of persons that have been treated at the Pasteur Institute after having been bitten by animals either mad or suspected of madness, by M. Vulpian. This report covers the whole period from October 1885 to December 31, 1886, the tabulated results showing 2682 subjects treated in the Institute, of whom only 31, or 1·15 per cent., succumbed.—On the direct fixation of the gaseous nitrogen of the atmosphere by vegetable soils, by M. Berthelot. The experiments are here described which the author carried on during the year 1886 at the Meudon establishment for agricultural chemistry. As a general result it appears that vegetable soil is incessantly fixing free atmospheric nitrogen, apart even from any vegetation properly so called. Nor can the phenomena be attributed to the exclusive action of rain-water, for it was shown that in some cases the rain carried off under the form of nitrates alone more nitrogen than it had contributed under the combined forms of ammonia and nitric acid. In a future paper the experiments will be described that have been carried on simultaneously on the same soil with the co-operation of plant life.—The mechanism of the flight of birds studied by chrono-photography, by M. Marey. This is a further application of the author's new chrono-photographic method, already so successfully applied by him to the study of human motion. The paper is provided with four illustrations, one of which shows fifty images per second of a bird on the wing. Measured by the metric scale, the distance traversed during one complete revolution of the wing was 1·37 metre, or 6·85 metres per second, and 24,660 metres per hour.—Solar observations for the second half of the year 1886, by M. P. Tacchini. The results, as here tabulated, show a progressive diminution of spots and faculæ, with a very marked minimum in November. The phenomenon of protuberances also shows a falling off, although not to the same extent as that of the spots. This result appears to be in harmony with the fact that the maximum of protuberances always occurs after the maximum of spots.—On surfaces whose isothermal lines are constituted by a family of circles, by M. Demartres.—On the theory of algebraic forms with p variables, by M. R. Perrin. It is shown that a form of order m with p variables possesses a pure covariant, distinct or reducible, of $2p - 3$ degree and order $(2p - 3) m - 2p$.—On the action of the tetrachloride of carbon on chlorochromic acid and the phosphates of sesquioxide, by M. H. Quantin. To the reactions of the tetrachloride of carbon already described by M. Demarçay, the authors here add two others, dealing fully with that produced by making this substance act on the oxygenated salts. They describe the action that it exercises, without previous decomposition, on the neutral phosphate of the sesquioxide of iron. They hope by the dry method to be able to apply this reaction to the separation of minute quantities of phosphoric acid.—Preparation, properties, and constitution of inosite, by M. Maquenne. This substance, hitherto unavailable in sufficient quantities for the purpose of experiments, the author has succeeded in producing by a process here described, very rapidly and easily. The analysis of anhydrous inosite yields carbon 40·00, and hydrogen 6·66, and its formula, $C_6H_{12}O_6 + 2H_2O$, is shown to be correct.—On the separation of mono- and di-isobutylamine by means of oxalic acid, by M. H. Malbot.—On the preparation of a silicostannate of lime corresponding to sphene, by M. L. Bourgeois. The object of this paper is to show the possibility of preparing a silicostannate of lime, CaO,SiO_2,SnO_2, isomorphous with sphene, CaO,SiO_2,TiO_2. In solving the question, the author has employed the same method by which Hautefeuille obtained some fine specimens of the latter mineral.—Description of a lamellary thomsonite from Bishopton, Renfrewshire, by M. A. Lacroix. This specimen, picked up by the author in 1884, shows the same optical properties as the substance known as Stirlingshire gyrolite, and contains a considerable proportion of aluminium. At 13° C. the density is 2·34.—Note on a white epidote from Beagle Channel, Tierra del Fuego, by M. A. Lacroix. This specimen, brought back by

Prof. Domenico Lovisato, of the Cagliari University, is remarkable for its richness in aluminium, and the highly oxidised state of the iron contained in it. Outwardly it strongly resembles zoïsite, although its crystalline system and optical properties leave no doubt as to its true character.—On some peculiarities in the organisation of the Schizonemertians, by M. Remy Saint-Loup. The exact disposition of the cephalic fossettes is here determined by a comparative study of three types of these organisms.—On the colonial vascular system of the Tunicata, by M. F. Lahille. A careful study of this system leads the author to the conclusion that there is no valid reason for separating the Monascidians and Synacidians into two distinct orders of Tunicata.—On the cranial nerves of a human embryo thirty-two days old, by M. C. Phisalix. Balfour's theory, based on negative grounds, that the cranial nerves are disposed on a type absolutely different from the spinal nerves, seems disproved by the anatomical study of this subject.—Researches on the physiological action of methylal, by MM. A. Mairet and Combemale. These researches show that, in whatever way introduced into the system, methylal always produces the same hypnotic effects, but more rapidly by hypodermic than by pulmonary injection.—On the existence of submerged valleys in the Gulf of Genoa, by M. A. Issel. From the recent hydrographic surveys of Capt. J. B. Magnaghi, it appears that the valleys of the Bisagno, Polcevera, Quiliano, and other Ligurian streams are continued seawards by submarine valleys, which retain the same fluvial direction, and are perfectly distinct to a depth of at least 900 metres.—On the Artesian wells and new oases created in the Wed Rir', South Algeria, by M. G. Rolland. Since 1859, the French have sunk 117 wells in this region, creating five new oases, and increasing fivefold the value of the land. In the same period the population has been doubled, and many thousands of date-palms planted.

BERLIN

Physical Society, December 3, 1886.—Prof. von Helmholtz in the chair.—Dr. König exhibited a von Kries colour-mixing apparatus, the third specimen of the kind hitherto turned out in the factory of Schmidt and Hänsch, and discussed in a searching manner the construction of this instrument. The instrument contained essentially two displaceable slits, the light of which was by a prism decomposed into two spectra falling on each other and producing the mixture of the colours. A second double slit, and a simple fifth slit allowed a comparison of the mixed colours and an admixture at pleasure of white light.—Dr. Weinstein reported on his deductions from observations of the earth's current in the telegraph lines of the German Empire. Among the results already elsewhere published of his calculations (*vide* NATURE, vol. xxxiii. p. 624) it may here be brought out that, apart from its disturbances, the earth's current showed a daily period with eight fluctuations, which, however, did not occur throughout the whole year, nor always in a similar direction. These fluctuations were least in the morning between five and seven o'clock. They were the cause that the statements respecting the daily maxima and minima differed so considerably among the different authors. The earth's current showed an intimate relation to the earth's magnetism, and especially to the declination. The speaker failed, however, to discover a relation in the earth's current to the period of the sun's rotation, although such a relation was asserted for the earth's magnetism. The latter, too, was a point which the speaker doubted, and that because he had been unable to confirm the relation, which was likewise affirmed, between the aurora and the sun's rotation. It was true he obtained an average period of about twenty-five days, but the minima amounted to twelve and the maxima to thirty-seven days, and between such extremes a mean was not allowable. For the earth's current likewise he found minima of twelve days and maxima of thirty-seven days, and this result appeared to him to conflict with the assumption of a connection between the earth's current and the sun's rotation. He conjectured that in the case of the earth's magnetism single values deviating too strongly from one another had been united into a mean. Be it further related that the intensity of the earth-current proved itself to be nearly proportional to the length of the lines. In the discussion following this address, Dr. Brix spoke of the earth plates which had been introduced in the lines used for measurements of the earth-currents, and which had hitherto proved so little disturbing that for the present the introduction of unpolarisable plates was desisted from.

CHRISTIANIA

Society of Science, October 15, 1886.—Herr Schöyen announced that through experiments carried out during the summer he had succeeded in demonstrating that the parasite *Tylenchus hordei*, described by him, which in the district of Lom causes the remarkable disease on rye termed "krok," also attacks *Elymus arenarius*, whereby his opinion that the parasite was transmitted from the latter to the rye-fields has been confirmed. He further stated that he had received samples of rye affected with the same disease from Heligoland; here, too, it extended along the coast in the proximity of *Elymus arenarius*.

THURSDAY, FEBRUARY 10, 1887

THE HISTORY OF HOWIETOUN

The History of Howietoun. Part I. By Sir J. Ramsay Gibson Maitland, Bart. (Stirling, N.B.: J. R. Guy, Secretary Howietoun Fishery, 1887.)

PROBABLY every one at all interested in fish-breeding has heard the name of Howietoun, and a great many people, especially in Scotland, have some knowledge of the character of the establishment and the operations there carried on. Occasional paragraphs in scientific periodicals, as well as in daily papers, announce some experiment in the artificial stocking of home waters with some kinds of trout or with salmon fry, or some successful exportation of salmonoid ova to America or to the colonies at the Antipodes. The name of Sir James Maitland or of Howietoun very often occurs in such announcements. Those who have given attention to the subject will find much to interest them in the account of the development of his fish-farm, and in the description of its present condition, which Sir James Maitland is now placing before the public. At present we have only the first part of the work, in which the history is brought down to the spring of 1879. A note on the fly-leaf informs us that the remaining part will be issued shortly. The present volume is of large quarto size, printed in large type, and liberally illustrated with excellent woodcuts.

The author states in the preface that the culture of Salmonidæ is now an achieved success, and he describes the gradual progress of the efforts which have culminated in this result at Howietoun, with the hope that his experience may prove of use to those who are working on the still larger question of our sea-fisheries. The first seven chapters contain a general description of the regular operations which are now carried on after thirteen years of practice and experimental ingenuity at the Howietoun farm. Sir James Maitland asserts emphatically that Great Britain is pre-eminent among all nations in matters pertaining to fisheries. He does not argue at any length in support of this patriotic claim, which he seems to found chiefly on the perfection of the Howietoun establishment, and the success of the system of Government supervision under which the Scottish herring trade is carried on. His eulogy of these two institutions is quite justified by facts, and there can be little doubt that the value of the fisheries of Great Britain, in proportion to the total population and total wealth, is greater than in many other countries. But there are other matters pertaining to fisheries in which the pre-eminence of Great Britain may well be disputed, and has been disputed very frequently of late years. The scientific study of the sea-fisheries, and the application of the results of such study, have undoubtedly been carried out to an enormously greater extent in other countries than with us. The reproduction of the cod was first investigated in Norway; oyster-culture as understood in Holland and in France is still unknown in Britain; and the organised scientific investigation of fishery matters, which has been commenced by the Scottish Fishery Board and is about to be instituted by the Marine Biological Association in England, has been, as it were, forced upon us by the example of the United States. Perhaps no American salmon-hatchery is quite as efficient as the Howietoun farm, but the extent of piscicultural operations applied to Salmonidæ in the United States is certainly greater on the whole than in Britain. This is not the occasion, however, for a complete comparison of Great Britain with other countries with regard to pisciculture. The history of Howietoun shows how greatly Sir James Maitland, by his individual energy and enterprise, has advanced the art of breeding Salmonidæ, and we have to notice shortly some of the most interesting parts of his book.

Before considering particular points, we may remark that the "History of Howietoun" is a book that can not only be referred to with profit, but read with pleasure. The author's genial individuality has an interest of its own, and his pages are full of suggestions of healthy, cheerful, energetic out-door life which make them picturesque and refreshing. The use of the plural "ova" as a singular seems to be common among pisciculturists, and it is a pity that this small blemish was not remedied in the proofs.

The greater number of the ova hatched at Howietoun are from Loch Leven trout kept in ponds at the farm. Ova are collected from wild *Salmo salar* taken from differen Scottish rivers, and small numbers of ova of *S. fario* and *S. fontinalis* are dealt with, but the greatest amount of space and attention seems to be devoted to *S. levenensis*. In the account of the "egg harvest" some interesting discoveries are mentioned which show a constant relation between feeding and breeding. If the fish are highly fed at an early date in the year, they begin to spawn earlier; the food used for this purpose is Pecten, and if this is given early in February, maturity is reached early in November. To obtain the eggs for the hatchery the females are stripped over large earthenware milk-plates, into which the ova fall. About 10,000 ova are stripped into one pan, and these can usually be impregnated by the milt of one male. After the milt has been added, only a tumblerful of water is poured into the pan; the eggs are then left to impregnate for 30 to 45 minutes. The ova, when first shed, are soft to the touch and inclined to adhere together; after impregnation they feel hard, and separate easily. The next process is to pour the ova into large pails full of water, which are held immersed in one of the inlets to the ponds, so that the milt is washed away; the ova are then carried in the pails to the hatching-house.

Collecting ova from fish in the wild state is a much more laborious process than from the fish in the ponds, and Sir James advocates strongly the advisability of Fishery Boards building proper ponds in which to retain the gravid fish until ripe. At Howietoun 20,000,000 trout (presumably *levenensis*) ova can be produced at a cost of little over 1000*l*. a year.

The account of work in the hatching-house would naturally follow that of the egg-harvest, but the chapter on packing has been inserted between them. The work in the hatchery is described in detail. The eggs are poured with a glass measure over the centres of the glass tubes forming the *grilles*, and afterwards dressed into regular rows by "feathering," an operation performed by girls, as the eggs at this stage are easily killed by too much handling, and a trained girl can give the slight motion which is required to the eggs without actually touching them with the feather at all. Each box is entered by a number in a book, and a record of the number of dead eggs daily taken from it is kept on a printed form, and afterwards entered in the same book. Two girls only are employed in attending to all the hatcheries at Howietoun. The stage in the development of the ova between the formation of the blastoderm and the appearance of the eyes is called the "spectacle" stage, and the health of the embryo can be estimated by certain signs at this period; but the description given of these signs is not easy to follow. Up to the eye stage the ova are very delicate, but as soon as the eyes appear the eggs can be handled, and this is the best age for packing for the Antipodes. Eggs for America or Europe are packed at a later period, when red blood has appeared. When the eggs are ready to hatch, the *grilles* are taken out, the boxes cleaned, and the eggs are emptied off the *grilles* on to the bottom of the box. The depth of water in the boxes containing the alevins is only 3 inches. The alevins congregate in dense masses in the corners and against the sides of the hatching-box, and the motion of the pectoral fins causes a continuous current to descend downwards through the mass. When the yolk-sac is nearly absorbed, the fry are fed with food prepared from fillet of beef or of horse, and yolks of hard-boiled eggs. The food is made into paste in a mortar, and rubbed through "feeding-spoons" of perforated zinc into the hatching-box.

Next follows an account of the method of despatching living fry. These cannot travel for more than twenty-four hours, and they are sent in tanks quite full of water, as motion of the water exhausts the fish at this stage. The greater number of the fry, after a short time in the hatching-house, are placed in ponds constructed of wood, 100 feet in length, where they remain throughout the summer, and where they are fed daily by hand for the whole time. It is stated that 100,000 trout eleven months old would consume between two and three horses a week.

A considerable amount of stocking is effected with yearling trout, which are carried in conical tanks. The fish must be starved some days before being despatched, as, if placed in travelling-tanks when fully fed, they rapidly make the water foul. In the bottom of the lid of the tank is an inverted cone perforated with holes and filled with ice; this keeps a constant temperature, and promotes aëration of the water. Two-year-old, and even larger, trout are also sent out; these are placed in larger tanks, provided with small wheels, but constructed on the same principle.

In Chapter III. an elaborate account is given of the methods of packing ova. The first operation is to transfer the ova which are to be packed from the *grilles* to peach netting stretched on square wooden frames. This step is carried out in a specially constructed sink, through which water is kept running. The ova are emptied from the *grille* into a wooden box, from which they pass into a leaden basin with a narrow bottom. One of the frames is then floated in the sink, and a glass measure containing 1100 eggs is used to measure the eggs from the basin on to the frame. The frames are placed in the packing-room in piles, one pile for each box. Next morning the frames are examined, so that any egg with an ill-developed embryo may be picked out. Then, a square of swan's-down, contained in a special tray, is placed over the eggs on the frame, and, the two being suddenly reversed, the eggs rest on the swan's-down without altering their relative position; thus each egg lies separately on the swan's-down. The frame is removed, and the square of swan's-down with its burden placed in one of the travelling-trays. Above the eggs is next placed a square of felted moss (*Sphagnum*). Above the moss is placed another layer of swan's-down carrying a layer of eggs, and then another layer of moss, and so on, till the travelling-tray is filled. The bottom of the travelling-tray is made of perforated zinc, and before any eggs are placed in it, the bottom is covered with a thin layer of moss. The eggs thus rest on swan's-down, and are covered with felted moss, a layer of which also forms the lowest and uppermost layer of the tray when full. For journeys to the Continent or America, unbleached lino is substituted for the swan's-down, because swan's-down retains so much carbonic acid that advanced embryos are asphyxiated. For the Antipodes, an extra precaution has to be taken: a thin layer of moss is inserted between the layer of unbleached lino and the eggs, so that the latter are in contact with the moss above and below. The travelling-tray is 10 inches square and $2\frac{1}{2}$ inches deep. The trays are packed in an inner box only $\frac{3}{8}$ inch larger than themselves, and this is placed in an outer box 4 inches deeper and 3 inches wider than the inner. Between the two is a layer of sawdust. The outer box or case measures 1 foot 4 inches square, by 1 foot 10 inches deep. This is the method of packing for short journeys within the United Kingdom. The boxes for foreign consignments are larger, and oblong in shape; there is a sawdust space as in the boxes already described, but the trays are separated by means of charred fillets, so that an air-space surrounds each tray: above the pile of trays is a large ice-tray, which occupies the whole of the top of the box. Ova can be safely kept in one of these boxes during a period of sixty days.

In the chapter on "breeders" we have an account of the most unique feature of the Howietoun establishment,—the feature which entitles the place to be called a fish-*farm*, and not merely a hatchery. Salmon and trout eggs have been artificially fertilised and kept in hatching-houses by a great many pisciculturists, but never before the institution of the Howietoun system has a species of Salmo been treated after the same method which is applied by agriculturists to domestic cattle. Sir James Maitland may be said to have domesticated the Loch Leven trout. He keeps them in a system of ponds, where they are placed under more favourable conditions than they meet with in the wild state, where they are supplied with a constant abundance of food, and are protected from enemies. The Howietoun trout have been rescued from the battle of life and subjected to the influences of cultivation and artificial selection. A flow of 5,000,000 gallons of water per diem is made to support a stock which produces 20,000,000 ova annually. The original stock of breeding-fish was raised from eggs taken at Loch Leven in 1874. As the fish grew older the size of their eggs increased, the fry from these ova were bigger and stronger each season, and it became evident that the ova of old trout were much the most valuable.

Time has not yet shown whether the new generation of breeders raised from selected ova of the largest trout, in their turn produce still finer ova and fry, but there can be little doubt that this will be the case.

The history of the gradual improvement of the piscicultural apparatus given in Chapters VIII. to XVII. is extremely interesting. A detailed account is contained in these chapters of the increasing amount of stock, and of the hatching operations in succeeding seasons. But enough has been said to show the character and value of the first part of the work. The second part will contain descriptions of the experiments which have been made at Howietoun since the establishment reached its present complete and efficient condition. J. T. C.

HARMONY AND COUNTERPOINT

Elements of Harmony and Counterpoint. By F. Davenport, Professor of Harmony, &c., Royal Academy of Music. (London: Longmans, 1887.)

YEARS ago, when the laws of musical sounds, like the laws of Nature before Newton, lay hid in night, it was not unusual for clever and ingenious writers on music to invent what they called "systems of harmony." They found certain combinations and progressions in use by by the best composers, and they conceived it to be their duty to explain, or account for, or justify these by some kind of imaginary natural principles, more or less fanciful, which they conjured up out of their inner consciousness, to fit the case. But, unfortunately, these writers widely disagreed among themselves as to the principles on which their theories should be based, and the result was such a mass of contradiction and confusion that the very name of theoretical harmony became a by-word and a scandal, until the Newton of musical acoustics, Helmholtz, arose, and, by explaining the real nature of musical sensations, swept away these fanciful inventions into deserved oblivion.

Among these systems, however, was one, published in 1845, by a Dr. Alfred Day, which had the great good luck to be admired and patronised by no less a personage than Sir George Macfarren, the Principal of the Royal Academy of Music. So far as we know, this admiration has not been widely shared by musicians in general; but it would be idle to ignore the great weight that such an opinion must carry, and it is this, no doubt, that has preserved for Dr. Day's work an existence which might otherwise have terminated long ago.

It is natural that Prof. Macfarren should wish this system followed at the famed institution over which he presides, and the little book before us appears to be intended as a cheap manual for the purpose. No one need object to this, for, when it comes to the practical teaching of harmony, it matters little whose system is followed so that the orthodox forms of writing are taught and recommended. That system is the best which renders this knowledge easiest to acquire. It is a feature of Dr. Day's book, that he lays down strict laws, pretty copiously and peremptorily, as to what ought or ought not to be done, and Mr. Davenport has conscientiously carried out this plan. His work bristles throughout with such rules, and we may safely say that if any student can succeed, either with or without the professor's help, in mastering them, he ought to be competent to write very good harmony. If he is of an inquiring mind, and wants to know *why* he is strictly enjoined to do so and so, or strictly forbidden to do so and so, he should postpone his curiosity till he has finished his academical course, and in the meantime be content with the Dicta of Doctor Day.

We must do Mr. Davenport the justice to remark that he has added to the work an original feature of his own which is worthy of all praise, namely, the combination of *counterpoint* with harmony-teaching. It is the general custom to give the harmony examples in the form of pianoforte chords, and this produces the anomaly that when rules have to be stated affecting the motion of certain notes, an idea of part-writing must enter which is somewhat foreign to the general system. Our author has taken the bull by the horns, by requiring the student *ab initio* to write his harmony in separate parts, putting each part on a separate line with its proper clefs. This is an excellent idea. Counterpoint is the highest and most perfect style of musical writing, but it has been much neglected in late days, and Mr. Davenport has hit upon a happy mode of encouraging its cultivation, which cannot fail to benefit his pupils.

PEARLS AND PEARLING LIFE

Pearls and Pearling Life. By Edwin W. Streeter, F.R.G.S. (London: George Bell and Sons, 1886.)

THE book before us, according to the preface, and as far as we are aware, is the only work in the English language which is entirely devoted to the history of pearls. The introductory chapter is immediately followed by one which gives a brief historical account of pearls in connection with India, China, Persia, Palestine, Egypt, Ancient Greece and Italy, and Europe in the Middle Ages. This is succeeded by a *résumé* of the ancient ideas respecting the origin and supposed medicinal qualities of pearls, and by a few words on "breeding" pearls. The next chapter treats of the different kinds of pearl-forming mollusks, both marine and fluviatile. The writer then gives an account of the true mother-of-pearl shell, describing its geographical distribution, the different varieties, its structure, the parasites found within the shells, and their external enemies, their method of getting rid of extraneous substances (stones, small shells, &c.) accidentally introduced within the valves of the shell, and the uses to which the mother-of-pearl is put. The sixth chapter, although headed "The Origin and Formation of Pearls," also refers to the different kinds, such as *bouton* pearls, *baroque* pearls, and *coq de perle*, the mode of life of the oyster, the positions in which pearls are found, &c. It also treats of the qualities which regulate the value of pearls. The next chapter gives a short account of the Sooloo Archipelago, the natives as pearl-divers, and their method of dredging. Then follows a good description of the fisheries of North-West Australia and Torres Strait, and this is succeeded by an interesting chapter entitled "Pearling Life at the Present Day," which is practically descriptive of pearling expeditions made by Mr. Streeter's vessel, the *Sree Pas Sair*, from Singapore to the North-West Australian coast and the Sooloo Archipelago.

Chapter XI. is devoted to a condensed account of the pearl-fisheries of Ceylon and Southern India, and this is followed by a *résumé* of what is known respecting the fisheries in the Persian Gulf, the Red Sea, on the west coast of North America, and at the West Indies. Pearls produced by shells which inhabit the rivers and lakes of Great Britain and foreign countries are described in Chapter XIV., and the artificial production of pearls by the Chinese is also here referred to. The different kinds of coloured pearls, and the mollusks which produce them, are then treated of. In the succeeding chapter the most famous pearls of both ancient and modern times are recounted, and the immense sums at which some of them were valued are stated. Chapter XVII. gives the history of the remarkable cluster of pearls known as "the great Southern Cross pearl," which was exhibited in the West Australian Court of the Colonial and Indian Exhibition, and valued by the owners at 10,000*l.* The next and concluding chapter is devoted to the value of pearls, and shows how their worth has varied in this country at different periods from 1671 to the present time.

A map is then introduced showing the principal pearling regions. In an appendix, the works bearing on the subject which have been consulted by the author are enumerated, and a full index completes the volume.

Mr. Streeter has brought together a large amount of information which will be of interest to the general reader, for whom especially, and not for the scientific, the work has been written. The most original material is comprised in the part extending from the seventh to the tenth chapter. The chapter devoted to the Sooloo Archipelago contains some details which, although interesting in themselves, are rather foreign to the subject of the work. The same observation applies to the account of the constellation *Crux Australis*, or Southern Cross, introduced in the seventeenth chapter.

As far as we have noticed, the various opinions and statements set forth in the work are mostly accurate. It may, however, be questioned whether "there is perhaps no instinct implanted in the human breast more powerful than the love of admiration," for is not that of self-preservation supposed to reign supreme? We would point out that the term *Lamellibranchiata* is now superseded by that of *Pelecypoda*, and with good and sufficient reasons is adopted in the latest and best manuals on conchology. The bathymetrical range of bivalves far exceeds the stated limit—200 fathoms—specimens having been obtained by the *Challenger* and other deep-sea exploring expeditions in depths ranging as low down as 2900 fathoms.

The book is printed in good legible type upon toned paper, but the pictorial portion mars the rest. The plates illustrating the *Malleus*, the *Meleagrina*, the *Unio*, the *Pinna*, the *Strombus*, and the *Turbinella* are simply execrable. They are printed upon a fearful black ground (one almost expects to see "Sacred to the memory of," &c.), inclosed by a thin white line with ornamental corners, and seem to us to have a most common appearance. We cannot see one redeeming feature in them, the drawing and colouring of the shells being equally bad. If another edition is called for, fresh and accurate illustrations should be provided. E. A. S.

OUR BOOK SHELF

The Definitions of Euclid, with Explanations and Exercises, and an Appendix of Exercises on the First Book. By R. Webb, M.A. Pp. 48. (London: G. Bell and Sons, 1886.)

THERE are some good points in this little book which will make it a useful help in many cases, especially with backward and dull pupils. The explanations are clear and precise; the exercises are very simple, and aim chiefly at insuring that the pupil really masters the idea involved in the definition illustrated; and good diagrams are supplied. We are sceptical, however, as to the advisability of representing "each of two or more lines which are parallel to one another by two straight lines close together." This is put forward as an assistance to the memory, but the assistance, such as it is, may be very dearly purchased.

The deductions at the end of the volume—three or four on each proposition of Euclid, Book I.—are nearly all very easy; they do not require any knowledge of propositions subsequent to the ones to which they are attached.

Berättelse om en Resa til Grönland. ("Narrative of an Expedition to Greenland.") By Nils O. Holst. (Stockholm: Norstedt und Söner, 1886.)

DR. HOLST'S object in visiting Greenland was to investigate the phenomena of glacial action as they are manifested in the varied geological formations of the Arctic regions, and to secure materials which might help to elucidate many of the questions still needing solution in regard to the Ice Age in Europe.

Having obtained permission from the Swedish King to absent himself from his labours in connection with the Swedish Geological Surveys, and having been allowed by the Royal Danish Greenland Trading Company—generally very chary of granting similar favours—to make the voyage in one of their ships, he embarked at Copenhagen on April 8, 1881, in the *Peru*, which after thirty-nine days sighted the west coast of Greenland. Here he found himself suddenly brought into immediate contact with the ice-formations which he had come so far to study, for the pack-ice, which is annually brought by the Arctic current to the coasts of Greenland between the months of March and September, was so unusually dense in that year that it required ten days' cautious navigation to penetrate the ice—which, with a depth of 10 feet and more, was in many parts from 8 to 10 miles in width—and to reach safe anchoring-ground. This was at length found at Smalle, in 61° 32′ N. lat., far to the north-west of Julianehåb, for which the *Peru* was bound, and there Dr. Holst left the ship and engaged a native boat to carry him to the mouth of Arsukfjord, and to the settlement of Tigssaluk, where he had the opportunity of examining several of the "horse-shoe" moraines described by Hornerup, and comparing the land and water ice-sheets with their respective crevasses, glaciers, packs, and floes, besides making as complete a geological survey of the coast which he visited as time and circumstances permitted. In the course of these expeditions he ascended several of the characteristic so-called "*nunatackor*," or bare fjeld-tops, some of which are between 3000 and 4000 feet in height. On these isolated hill-tops were found, amongst other plants, various Cladonias, Silenes, Cetrarias, and Luzulas, besides *Rhododendron lapponicum*, *Nephroma arcticum*, &c.

Dr. Holst was disappointed in his expectation of examining the kryolite mines of Ivigtut, orders having been received from headquarters in Copenhagen that strangers should not be allowed to see the works, but he was able to determine the geological character of the district, and the conditions under which the mineral is found. According to him, the predominant rock is a grey, finelygranulated gneiss, in some places impacted together with green sandstone into a tolerably dense granitic breccia. At some points the kryolite is found in direct contact with the granite, at others pegmatite is interposed between the two, while here and there this mineral is embedded in a granitic ivigtite.

Great interest attaches to Dr. Holst's observations on the nature and appearance of the so-called "kryokonite," in regard to whose origin the most opposite views have been maintained. According to the writer, who mainly agrees with the opinions held by Danish geologists, this substance is nothing more nor less than moraine mud; in support of which view he gives the result of the careful analyses made, independently of one another, by Profs. Lassaulx, Zirkel, and Svedmark, who agree in maintaining that kryokonite contains nothing but the ordinary constituents of the native rocks. The evidence supplied by these and other carefully-conducted microscopical investigations is, it would appear, so conclusive as to the true constituents of all kryokonites, that it has considerably modified the views once held by Baron Nordenskjöld and others, who at one time maintained the cosmic origin of these bodies. In point of fact, Dr. Holst's observations of this substance, of which he collected various specimens between Kipissako, in 61° N. lat., and Illuliakik, 65° 25′ N. lat., seem to show that the kryokonite of Greenland differs in no way in its nature from the loess of Europe, of which it may be considered as the Arctic analogue.

During his four months' stay in Greenland Dr. Holst visited various native settlements, and his descriptions of the numerous difficulties he encountered in securing boats and guides in the face of the Greenlander's habitual slowness and vacillation are not without interest, but the great value of his narrative depends upon the care and clearness with which he has recorded the results of his scientific investigations. In these particulars, indeed, geologists will find that he has ably fulfilled the purposes of his expedition, and there can be no doubt that the results of his diligent study of the various processes by which glacial action is manifested, and the effects which it produces, will prove of the greatest use in contributing new materials towards the interpretation of various problems connected with the Ice Age in Europe.

A chart of South Greenland, drawn by C. J. Kjellström, on which the inland ice-beds are marked in green and the habitable land in white, enables the reader to follow the track of coast explored by the writer between Holstenborg, in 66° 50′, and Kipissako, in 61° N. lat.

The Handy Natural History. By J. G. Wood, Author of "Homes without Hands." With 226 Engravings. (London: Religious Tract Society, 1886.)

Mr. Wood is so well and so widely known for his many popular books on natural history, that the present one is sure to be welcomed by a large number of readers. The illustrations as a rule are most excellent, and care has been taken to make the text as simple as possible for even juvenile readers. The chapter on the monkey tribe is one of the longest and most interesting in the book. Mr. Wood is very careful to state in his first page that between the lower animals and man there is a great gulf fixed which neither can pass. Mr. Wood does not seem to see that the question which has been widely ventilated of late years is not whether there is a great gulf now, but whether there was originally any gulf at all. It is not necessary that this question should be discussed in a book intended chiefly for juvenile readers; but in the absence of a discussion, the statement to which we refer is one which had better not have been made.

There is no index to the book, but at the beginning of it an alphabetical list of animals mentioned is given, which practically serves the purpose of an index. The number of animals mentioned may be gathered from the fact that the list occupies seven pages of closely-printed type in three columns.

Hand-book of the British Flora. By George Bentham, F.R.S. Fifth Edition. Revised by Sir J. D. Hooker, F.R.S. (London: L. Reeve and Co., 1887.)

In the preface to the first edition of this book the author explained that he had often been asked to recommend a work which should enable persons having no previous knowledge of botany to name the wild flowers they might gather in their country rambles. His object in writing his "Hand-book" was simply to meet this demand, and experience has shown that it is well adapted for its purpose. Sir Joseph Hooker, we need hardly say, has revised his late friend's work with perfect tact and judgment, adding considerably to its value by bringing it into accordance with the latest knowledge, without making any essential changes. Mr. Bentham held that previous writers on our indigenous flora had exaggerated the number of distinct species. His opinions on this subject, Sir Joseph Hooker thinks, should not be dismissed hastily, since they were the views "of a great master of systematic and descriptive botany who had collected and studied a large proportion of the prevalent forms of British plants in a living state, not only in our three kingdoms, but in France, Scandinavia, Russia, Germany, Switzerland, and Turkey."

The Zoological Record for 1885. Being Vol. XXII. of the Record of Zoological Literature. Edited by Jeffrey Bell, M.A., &c. (London: John Van Voorst, 1886.)

Before the close of 1886 the record of zoological literature for the year 1885 was in the hands of those interested in zoology, and the editor is to be warmly congratulated on this result. The difficulties in the way of such a result are very great; on the present occasion they have been overcome, and we confidently trust the same may be the case for the future. The recorders have accomplished much, but they would be able to do more if the writers of scientific memoirs would assist in so desirable a cause and promptly send to the editor copies of their writings when first issued from the press. All of the recorders seem to have done their share of the work with care and discretion, though to some the lion's share has fallen; the largest contributor being Dr. Sharp, who records all the Insecta with the exception of the Neuroptera and the Orthoptera, which latter groups are recorded by Mr. McLachlan. The large group for so many years recorded by Dr. von Martens is now divided between Prof. W. A. Herdman and Messrs. W. E. Hoyle and G. R. Vine. Dr. P. Bertkau records the Arachnida, including the new species and genera for 1883 and 1884. Numerous corrections and additions have been made in the list of works consulted, and this list now forms a very useful work of reference to the scientific publications of the world. To the records of the Mammalia and the Birds short introductory paragraphs are added, a practice which we would suggest to the other recorders. It is very expedient that they should follow this example, for, short though these paragraphs are, yet in them the reader gets some hint of what has been done in the group for the year. The Zoological Record Association is again able to record grants of 100*l.* each from the Government Grant Fund and the British Association, and one of 10*l.* from the Royal Irish Academy. Although these money grants are extremely well disposed of, we very much regret that so valuable and essential a publication should be to a large extent dependent upon them, and we would fain hope to see the list of subscribers greatly increased.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Lightning-Flashes

THE brief note (NATURE, vol. xxxv. p. 85) giving the results of the observations of Herr Leyst, of the Pawlowsk Observatory, on the anomalous forms of lightning-flashes, suggests several considerations relating to this class of phenomena.

Leaving out of view the exceptional and anomalous phenomena of slow-moving (ball or globular) lightning—which are very difficult to correlate with any purely electrical manifestation—it is questionable whether it is possible for the observer to determine the direction in which the electrical current moves. In ordinary cases the velocity of the electrical discharge is so great, and the duration of the luminous flash is so brief, that it is impossible for the unassisted eye to determine the direction of motion.

According to the experiments of Prof. Rood (*American Journal of Science*, third series, vol. i. p. 15, 1871; also *idem*, vol. v. p. 163, 1873), the duration of lightning-flashes varies from 1/1600 to 1/20 of a second. Even the maximum duration of 1/20 of a second is probably too small to be recognised by the unaided human eye. Hence simple observation by means of the eye cannot determine the direction in which the electrical current moves.

It is nevertheless true that the eye seems to perceive the direction of motion of the luminous tract from one point of the cloud-covered sky to another. But this seeming recognition of direction must be an illusion of judgment based upon our interpretation of the phenomena presented to the sight. In these cases, our judgment of direction of motion seems to be dependent upon two considerations:—

(1) When the flash bifurcates or forks, we imagine (probably from the analogy of a ruptured projectile) that the electrical discharge passes in the direction of the diverging branches.

(2) But the more common cause of illusion of judgment in relation to the apparent direction of motion of the electrical discharge arises from the difference of brightness of different portions of the luminous path; this gives rise to a difference of duration of the lingering visual impression on the retina. Thus, in the case of a flash several kilometres in length, one extremity will probably be much nearer to the observer than the other; and hence the light emanating from one end will traverse a greater thickness of absorbing atmosphere than that emanating from the other end. This would necessarily render one extremity of the luminous path brighter than the other; and consequently the duration of the impression on the retina would be greater for one end than for the other: hence the flash would seem to reach the end where the visual effect lingered longer at a later period than the other extremity. In other terms, the light produced in the luminous path is really generated sensibly at the same instant of time along its entire length, and the apparent direction of discharge is an illusion of judgment arising from the varying duration of the visual impression, due to differences of brightness in different portions of the flash. It is evident that the refinements of modern methods of measuring indefinitely small intervals of time might render the actual direction of motion of the electrical discharge appreciable to our senses.

With regard to the zigzag and irregular branching forms of lightning-flashes, these are the natural results of electrical discharges through an interrupted and non-homogeneous medium. The enormous length of some flashes (eight or ten kilometres) indicates that the intervening non-homogeneous dielectric acts as an interrupted conductor. In such a medium the path of electrical discharge is along the line of least resistance, which is the line of best induction, which is likewise the line of best conduction. In the atmosphere these lines are irregular and are perpetually shifting, hence the path of discharge may be nearly rectilinear at one time, branching at another time, and even quadrilateral at another time.

JOHN LE CONTE

Berkeley, California

THE quotation from M. Hirn in your issue of January 27 (p. 303) suggests a few remarks. What may be the greatest length of a flash of lightning? In the year 1843 I attempted to answer this question by the following observations.

My Inarya hut had far-projecting eaves supported by rough posts, some black, others white, and thus easy to distinguish. On the first appearance of a storm in a brick-red cloud I took my seat near the threshold, leaning my head against the door-post, and holding to my ear a pocket-chronometer. Among several flashes I noticed one nearly horizontal. It travelled northwards, and its thunder followed 54·4 seconds later. The thermometer being then at 19° C., I took that degree of heat, from want of better information, as mean heat of the whole trajectory, and got thus 343·7 metres for the velocity of a sound per second. This gave a distance of 18·7 kilometres for the commencement of the flash. It had begun before post A and ended beyond post D. As they were near me, I took care not to move my head before measuring with a small sextant the horizontal angle between A and D. I found it = 20° 30′, and obtained thus 6760 metres for the length of flash, supposing it horizontal and perpendicular to my line of sight. This result was a minimum, because the angle was evidently too small, and because moreover the flash, not quite horizontal, had travelled obliquely towards me. I drew the latter conclusion also from what appeared to me a fact on this and on other occasions, viz. my ear referred the thunder successively to different parts of the preceding flash. If an amanuensis had been at hand, I could have dictated to him at what beats of the watch the sound came from the direction of each post. It would then have been easy to get at least a rough estimate of the azimuth in which the flash travelled, and consequently its real length. In a similar way I measured on another day a flash more than ten times longer. I have not put down its particulars, because such an enormous result made me fear some mistake in time or angle. On my return to Europe, I mentioned these observations to the late F. Petit, then astronomer at Toulouse. He subsequently informed me that he had measured two flashes of lightning, one 13 and another 17 kilometres long. Should you publish the foregoing note you may induce other observers to follow this line of inquiry with improved appliances.

ANTOINE D'ABBADIE

Abbadia, Hendaye, February 2

Dr. Modigliani's Exploration of Nias

YOU have on two occasions given news of Dr. Elio Modigliani's recent exploration of this remarkable and interesting island. I believe it will therefore interest your readers if I endeavour to complete such information. Dr. Modigliani returned to Florence from Nias a short time ago, and at the last meeting of our Anthropological Society gave an able and graphic account of his visit to the island, and especially of his experience of the people; he illustrated his communication with an exhibition of the rich and very complete ethnological and anthropological collections he has made.

The natives of Pulo Nias are evidently Malesoid, judging from the numerous interesting photographs taken by Dr. Modigliani, and yet they have peculiarities of their own; and looking at the fine series of crania exhibited, one would say that on a Malayan face a Papuan skull had been fastened. Dr. Modigliani found also some resemblance between the Nias people and some of the hill tribes of Southern India. No traces of stone or shell implements are found in use at Nias. The natives get their iron, brass, and gold from traders, principally Chinese, but work the metals themselves with a primitive forge, making axes (hafted in wooden, club-like handles, as those of some African tribes), lance-heads, and swords: the former, usually barbed, recall the Celebean ones; the latter are very like the *parangs* of the Bornean Dyaks. Their shields are often heavy and cumbrous, coated with buffalo-hide, very Bornean in shape; they make besides curious iron helmets of a common Asiatic pattern. The swords are sheathed in wood, and have in front a globular wicker or rotang basket, the size of a big orange, which contains curious and very various amulets, with which they never part willingly; the handle is often carved so as to represent a grotesque human face. The Nias people are inveterate head-hunters, and Dr. Modigliani showed one of their ghastly trophies procured whilst he was there, and preserved in spirits. The head is buried, and when the flesh has fallen off, the skull is hung up under the council-house. Every young fellow to be considered a man must have cut off at least one head—no distinction is made of sex or age; after that, he wears as special badge a collar made of a polished section of the cocoa-nut palm stem with ends of brass.

The women go about with a curious staff ornamented with brass; the usual ornaments are armlets of brass wire, bracelets cut out of Tridacna-shell, and ear-rings of the same material or of metal, and beads. The clothes used to be, and in the southern districts are still, entirely made of beaten bark.

Their idols are roughly carved wooden figures, and both they and the still more primitive carvings representing dead relations vividly recall the idols and the *Karwars* of the Western Papuans. Each village has its chief, and usually war to the knife is waging between one village and the other. This renders a thorough exploration of Nias far from easy.

Dr. Modigliani certainly lost no time, and did his very best; and although quite new to such explorations, in a very short time, with rare energy and perseverance, surmounting many difficulties and not slight dangers, he has succeeded in bringing home most interesting and ample information on the people, extensive ethnological and anthropological collections, important zoological series, and a most interesting sample of the local flora, amongst which are some new species of the singular ant-plants (*Myrmecodiæ*) now being illustrated by Dr. Beccari.

I must say in conclusion that I do not know of any traveller so young and inexperienced who in so short a time (Dr. Modigliani was absent from Florence altogether just eleven months) has succeeded in doing so much and so well.

HENRY H. GIGLIOLI

Royal Museum, Florence, January 22

"Lepidosiren paradoxa"

ZOOLOGISTS will be interested to hear of the capture of a fine specimen of this the rarest of the Dipnoi. Only a few weeks ago I received from my friend Dr. J. Barbosa Rodriguez, the learned and energetic Director of the Museu Botanico do Amazonas, at Manaós, a very fine specimen of the *Lepidosiren*, captured some time last August in that neighbourhood. This specimen is well preserved in alcohol; it measures 85 centimetres in length, with a girth behind the pectorals of 28 centimetres. On opening it I found that it is a female, the ovaries being well laden with well-developed ova; unfortunately the alcohol had not been let into the visceral cavity, and none of the internal organs were in a condition to be successfully investigated. I found the pericardium singularly large and thick. The body is cylindrical, but quite flat along the abdominal surface, where the scales are also bigger, thicker, and of a lighter colour. The short caudal region is much compressed. There are no true median fins except the irregularly rounded caudal, which extends merely as a slightly marked keel to about the middle of the back. The fin-rays on the caudal portion are close together, cartilaginous, and quite hidden by the skin; pectorals and ventrals without traces of membranous edging and rays; the former are slender and compressed, the latter conical and considerably stouter. The entire body, except the head in front of the eyes and the paired fins, is covered with moderate cycloid scales—thicker, as I observed, on the *abdominal cuirasse*, extending from the chin to the anus and composed of about ten longitudinal rows of scales. Except along this ventral stripe, which is of a whitish colour, the animal is generally of a dark brownish purple, with darker indistinct blotches. The double lateral line is dark; it reticulates on the cheeks and around the eyes. These are quite rudimentary, and show under the skin as a whitish spot; they remind me of the eyes of the two *Gymnotus* which I saw alive in the Insect House at the London Zoological Gardens last October. The branchial openings are very narrow, protected by a thick fleshy flap: there are no traces of external branchial appendages, indeed, even the internal branchiæ cannot be seen through the deep, narrow, branchial slit. The mouth is terminal, with well-developed fleshy lips; there are two small conical vomerine teeth; the maxillary and mandibular dental plates are very similar in size and shape; fleshy pads fit into the spaces between the dental ridges. The tongue is thick, smooth, and fleshy, with a rounded point. Four branchial clefts can be made out on each side in the pharynx, the fourth is much reduced; the three free branchial arches are fringed with conical papillæ. The palate and mucous membrane of the mouth is white and quite smooth; the pads along the dental plates are papillous. The anus is exactly 10 millimetres on the left of the mesial line; it is 8 millimetres in diameter, and surrounded with a border in deep folds. I had forgotten to mention the nostrils: both pairs are *inside* the mouth; the anterior ones, just within the upper lip, are ovoid, transverse, without flap or valve; the posterior pair are situated just outside the hinder ridge of the maxillary dental plate, they are ovoid and longitudinal.

I need hardly insist on the importance of the capture of this new specimen of *Lepidosiren*. As far as I am aware, this is the *fourth* known; there are, besides, Natterer's two preserved at Vienna, and Castelnau's one in the Paris Museum. More recent explorers have utterly failed to find any, although an active search was made by several. Only recently I heard from a high authority the expression of a doubt as to the existence of such a creature as the South American *Lepidosiren*!

I may finally state that, evidently prompted by his friendship for me, Dr. Barbosa Rodriguez, seeing, as he believed, distinctions in his specimen, sent a brief description to a Rio scientific periodical, naming it *Lepidosiren gigliolina;* this before forwarding the specimen to me. I have not yet seen his description, nor am I in a position to decide as to any distinction existing between this and the other three existing specimens. I can only say that I consider such a difference very unlikely. I suppose that, like *Ceratodus*, *Lepidosiren* is liable to considerable individual variation. Lastly, I believe it not unlikely that *Lepidosiren* may be on the verge of extinction; that would account for its rarity.

Royal Museum, Florence, January 22

The Coal-Dust Theory

SOME of the facts elicited at the adjourned inquest on the bodies of the twenty-eight persons who lost their lives in an explosion at Elemore pit on December 2 last, appear to have a direct bearing upon the coal-dust theory, and are therefore worthy of being recorded. It will be remembered that the inquest was adjourned until January 18, when it was re-opened; it was concluded on the following day. The verdict of the jury was as follows:—

"That Ralph Fishburn and others met their deaths by an explosion in the George Low Main seam, Elemore Colliery, on the morning of December 2, 1886; that the said explosion occurred between the Daleway end and the greaser; but what caused the ignition there is not sufficient evidence to show."

One of the victims, named Luke, who afterwards died from his injuries, made a statement to the effect that a shot was fired in one of the main intake airways not far from the bottom of the down-cast shaft, at the instant the explosion took place. The person who, according to Luke's statement, ignited the shot, still survives, and denies having done so, although he admits having fired a shot near the same place a short time previously. Some of the experts, including the two inspectors of mines, came to the conclusion that Luke's statement was the more probable; others were unable to concur with them in this. The evidences of violence point to the place indicated by Luke as having been the origin of the explosion. A good deal of discussion took place between some of the examining counsel and solicitors and some of the witnesses, as to whether coal-dust alone in the absence of fire-damp could originate and carry on an explosion, but nothing new was elicited in this respect. All agreed that there could not have been any gas present at the point where the shot was said to have been fired. Mr. G. Baker Foster was "quite of opinion that there had been no gas; . . . he could not imagine that in such an intake, with such ventilation, and such a position, gas could accumulate for a minute." Mr. Bell, the Inspector of Mines for the district, said:—"The ventilation throughout the pit was good. It was a well-managed pit, and the last in which he would have expected an explosion to take place." Mr. W. M. Atkinson, the Assistant-Inspector, said:—"The explosion was confined to those parts of the pit least likely to contain gas, and where there was the most coal-dust. It was highly improbable that there was any fire-damp where the explosion originated. He once examined the place when the barometer was as low as 27·5 inches, and no trace of fire-damp could be detected." (The barometer stood at 29·55 inches at 1 a.m., two hours before the explosion.) "He believed the explosion was entirely due to the combustion of coal-dust in pure air, and that its ignition was caused by a shot fired by Johnson. A blown-out shot would not be necessary. Wherever there had been coal-dust in the mine the explosion had gone; but wherever there was an absence of coal-dust, there the explosion ceased." The last statement was not called in question by anyone, and stands unimpeached.

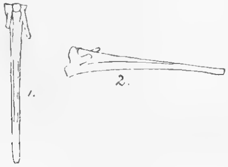
Those witnesses who would not go the length of saying that coal-dust alone in the absence of fire-damp had caused the explosion, had no explanation of their own to offer. The "outburst of gas," the cry which used to be so often adopted in similar cases, was not entertained by anyone in this case. Some of the witnesses were unable to accept the coal-dust theory on account of preconceived notions regarding it; others had read in books and papers certain statements which prevented them from adopting it; and one (Mr. Lishman, the manager of Elemore Colliery) had made experiments, with an apparatus similar to one of mine, which did not lead to conclusive results. With these conflicting opinions before them, the jury arrived at the conclusion that the men had been killed by *an explosion*, but, with the characteristic caution of men of the North, they refrained from stating what it was that had exploded.

Cardiff, February 3 W. GALLOWAY

Abnormality in the Urostyle of the Common Frog

ATTENTION has recently been drawn to abnormalities in the vertebral column of Rana. (See Bourne, *Quarterly Journal of Microscopical Science*, January 1884; Howes, *Anatomischer Anzeiger*, 1 Jahrgang, 1886, Nr. 11; Lloyd Morgan, NATURE, November 1886.) One form of such abnormality is the addition of a supernumerary (tenth) vertebra.

I wish here to record the occurrence, in the skeleton of a large *Rana temporaria*, of an abnormal urostyle, bearing at its anterior end a larger (right) and a smaller (left) transverse process. These are shown in the accompanying figures. Fig. 2 shows a tendency,



in the dorsal moiety, towards a segmentation of the urostyle and and the separation of a supernumerary vertebra. The coccygeal foramina lie just behind the transverse processes.

This case is interesting as showing an incompletely separated tenth vertebra, and as bringing an abnormal Rana into relation with a normal Discoglossus. C. LLOYD MORGAN

University College, Bristol

The Cambridge Cholera Fungus

I HAVE read with much interest the correspondence on the above subject in your issue of January 27 (p. 295). In the new edition of my work on bacteriology, to be issued, I hope, before many days, will be found the following statement:—

"At a meeting of the Physiological Society, held May 15, 1886, at Cambridge, a preliminary communication was made upon the investigations in Spain, referred to in the first edition of this work. The observations made by Roy, Brown, and Sherrington rather tend, in the opinion of the author, to confirm Koch's views. Comma-bacilli were found to be present in some cases in enormous numbers, and the frequency of their occurrence led these observers to believe that they must bear some relation to the disease. At the same time, as they failed to find them in all cases, they regarded the existence of a causal relation as not proven. They failed to find the Naples bacterium or the small straight bacillus noted by Klein, but they drew attention to certain peculiar mycelium-like threads in the mucous membrane of the intestines. These organisms, however, judging from a preparation stained with methylene-blue which was exhibited at the meeting, appeared to the author to much more closely resemble some of the involution-forms of comma-bacilli, *filaments à masses globuleuses*, figured by Van Ermengem, than anything else he had seen. Yet assuming these peculiar structures to belong, as described, to some species of Chytridiaceæ, it is very doubtful whether they can be considered to be of any significance. Methylene-blue has been employed by Koch and others, including the author, for staining sections of the intestine from cholera cases, and had they been constantly present, it is hardly possible that such striking objects could have been overlooked. Again, we must bear in mind that hyphomycetous fungi have been found occasionally to occur saprophytically in the intestinal canal, as well as in the lungs, external auditory meatus, and elsewhere. We must, however, wait before expressing a more definite opinion, until the Report of these observers is published in full."

This, I think, may explain Mr. Gardiner's difficulty. Very probably the same preparation was shown to him, as his second opinion coincides with the conclusion I arrived at last May. I have now before me the Proceedings of the Royal Society, No. 247, and I am greatly puzzled by the illustrations, for they certainly appear to represent a branching mycelium, and do not in the least recall to my mind the preparation which I had an opportunity of examining. EDGAR CROOKSHANK

Eastbourne, January 31

Low Barometric Readings

IN a Note in NATURE of December 16 (p. 157) you observe that the barometric reading of 27·333 inches (reduced to sea-level) recorded at Ochtertyre, Perthshire, on January 26, 1884, is the lowest observed by man anywhere on the land surface of the globe. This, however, is not the case. The cyclone which on the morning of September 22, 1885, swept over False Point, on the coast of Orissa, gave the lower readings 27·135 at the beginning of the central calm, and 27·154 half an hour later (both readings reduced to 32° and sea-level). These readings are perfectly authentic, the instrument being a Casella's observatory standard (on Fortin's principle) that has been verified with the Calcutta standard and is corrected to that standard, which is 0·011″ higher than the Kew standard. Its elevation above the sea, 20·6 feet, has been determined by spirit-level; and the observer, Mr. Workman, is one of the best of those who keep a regular meteorological register for this department. The above are the lowest of a series of readings, taken at intervals throughout the storm, which was then travelling at the rate of thirteen miles an hour.

The storm will be long remembered as that in which the settlement of Hookeytollah, six miles to the north of False Point lighthouse, together with its inhabitants, was swept away by the storm-wave accompanying the cyclone. At False Point station the water rose 22 feet above mean sea-level directly after the passage of the storm centre. The country inundated lay to the north of the lighthouse, and is a low-lying alluvial tract from 4 to 5 feet above mean sea-level, intersected by a network of salt-water tidal creeks.

The destruction that ensued was very great. Including the small settlement of Hookeytollah, some two thousand households were swept away, representing a loss of from six to ten thousand souls. Crops valued at ten lakhs of rupees (100,000*l.*) were irretrievably damaged and lost; the wells and tanks of drinking-water were rendered unfit for use; and about 60,000 acres of land rendered unfit for cultivation for two or three years to come. But even this is very small in comparison with the destructive effects of the Calcutta cyclone of October 5, 1864, and those of the Backerganj cyclone of November 1, 1876.

Magnetic Theory

MR. WATSON asks, What is the physical evidence in favour of the existence of A, B, C, and α, β, γ? With regard to the former the evidence, derived from the permanence of the magnetisation in a small piece of a hard steel magnet, seems to me almost conclusive; while the following consideration tells very strongly in favour of α, β, γ.

To determine the mechanical force and couple acting on a magnetic element placed in a magnetic field in air, we treat it as consisting of two equal and opposite poles very near together, and find the resultant of the forces on these two poles. It may be proved without difficulty that the same process may be used to find the mechanical force and couple, arising from magnetic causes, acting on an element within the mass of a magnet. In the first case we may, of course, employ either α, β, γ, or a, b, c, as the forces acting on a unit pole. But in the second case we must employ α, β, γ, as defined in Mr. Watson's letter in your issue of January 27 (p. 296). These mechanical forces cannot, I believe, be expressed in terms of the values of a, b, c, u, v, w, and their differential coefficients at the point. This is a definite physical argument in favour of the existence of α, β, γ, within a magnet.

"Phantasms of the Living"

NOTHING in your last week's notice of "Phantasms of the Living" gratified me more than the attention paid to our experimental results. The grounds of our own confidence in them are (1) that the conditions were in many cases such as completely to exclude unconscious physical signs, and (2) that, if the success was due to fraud, it was not fraud which the investigators failed to detect, but fraud in which they must actively have shared. But, where the scientific presumption against new phenomena is so strong, it is best to recognise that no line can be drawn at which the evidence for them *ought* to be found convincing, and that, till it actually *is* found convincing, it is incomplete. Meanwhile it *ought* to be sceptically approached—not with the impatient scepticism which denies that such facts can ever be proved, but with the cautious scepticism which perceives that they require a very great deal of proving. The object of this letter, then, is to urge the paramount importance of extending the area of experiment. This cannot be done without an amount of public spirit which it is very hard to evoke. The "percipient" faculty, even though possessed in a high degree, is very unlikely to reveal itself spontaneously: our only hope of discovering it is that trials in thought transference shall be very widely made—which means that a large number of persons shall spend some time and trouble in a manner which will often appear to have been fruitless. It is difficult to press this on anyone as a duty; but it is at any rate worth while to point out how simple and rapid the process of experimentation may be made. Especially anxious am I that a great many pairs of persons should carry out experiments of the very simple type described in "Phantasms," vol. i. pp. 32, 33. If any of your readers are willing to do this, will they kindly, *before beginning*, send me their names and the number of the trials that they propose to make, to guard against any *selection* of results? EDMUND GURNEY

14 Dean's Yard, S.W., February 3

University College, Bristol

MY attention has been called to a paragraph in your issue of the 3rd inst. (p. 326), referring to this College. Will you kindly grant me space to correct the statement made therein, which is inaccurate in some important points, and is calculated, as it stands, to injure our reputation?

No general reduction of the salaries of the Professors has been made, nor is it contemplated. Notice to terminate our engagement with two Professors has been given them, as it was believed that more advantageous arrangements could be made in their departments without affecting the quality of the instruction given. It is too true that the College greatly needs more liberal pecuniary support than it has hitherto received, but efforts are being made to procure it; and as yet the Council have no intention of limiting the subjects hitherto taught, or of requiring a lower standard of attainment than that which has distinguished so many of their Professors. ALBERT FRY,

Chairman of the Council

A Rule for escaping a Danger

SUPPOSE a weir, AB, across a river, and first let it be at right angles to the direction of the current. Suppose a man in the stream above the weir, nearer to B than to A. Let O be his position, and OX a perpendicular on AB. Then he cannot escape if his velocity, v, is $< \frac{\text{BX}}{\text{OB}} . u$, where u is that of the stream. If his full speed has this critical value, or if there is any uncertainty about his safety, he must swim at right angles to OB.

The rule is obviously correct, for to escape he must clear the nearer end of the weir, and must therefore exert his strength in the direction mentioned. Geometry puts it clearly: Reduce the stream to rest so that the weir is advancing on the man with velocity u. Let P be the point at which the man is overtaken, then, if PN be perpendicular to AB,

$$\frac{\text{OP}}{v} = \frac{\text{PN}}{u},$$

so that P is on a conic for any given velocity. Varying v, he will escape if the conic reaches the bank. The first to do so touches at the end C of the minor axis, and since CB is a tangent, the angle COB is right. Also now

$$v : u = \text{OC} : \text{CB} = \text{BX} : \text{OB}.$$

If the weir slants across the river, the direction of safety is still at right angles to the line joining O to A or B. The swimmer must decide, by looking in both directions, to which bank to direct his efforts. The locus of points for which both directions give the same distance is, to axes through the middle of the weir up and at right angles to the current, of the form

$$(y^2x - 2aby + b^2x)(y^2a - 2bxy + ab^2) = by(x^2 - a^2)^2,$$

a quintic having cusps at A, B.

The rule fails if the change of velocity as one approaches the bank be considerable. One would then strike more across.

If one were being charged by any insensate object, the rule would of course apply. FRANK MORLEY

Bath College

Abnormal Cats' Paws

IN reference to the recent articles in NATURE on six-toed cats, allow me to remark that the experiment about to be tried on one of the small islands off the English coast has *apparently* been anticipated at the village of Morriches Centre, on Long Island, where nearly all the cats have at least one supernumerary digit on all feet, and are currently called, in the place, "double-footed." I have a specimen showing the abnormality distinctly. I say "apparently," because there can be little doubt that at some time a single individual was introduced, which has become the ancestor of all the "six-toed" cats in the village.

E. W. CLAYPOLE

ABNORMITIES in cats' paws occur rather frequently in Massachusetts. They are called mitten cats, and are much in demand because they are considered to be good mousers. The first I ever saw was a male yellow tiger, whose four paws had two extra toes strongly developed. A little stray female kitten which was brought up at my house had two abnormal fore-paws with four extra toes on each. As there are no male cats in our neighbourhood with any abnormity I was very anxious to see whether her young ones would inherit the shape of their paws from the father or mother cat, and whether some abnormity would also appear in the hind-paws. She had eight, and only one of them with four normal paws; all the others inherited from the mother the abnormal fore-paws, some even having five to seven extra toes, with perfectly developed claws and pads. I did not pay attention to the sex, but brought one up on account of its strong build, which turned out to be a male, and another for its beautiful stripes, which was a female. The old cat rested nearly a year, and then again had eight three times in succession, in April, June, and October, and every time only one with normal paws. The mother is a pale grey tiger, and each one of the young ones was differently spotted, and, as I believe, had a different father, as I recognised the marked resemblance to the various visitors to our garden. I paid no attention to the sex, but brought up from the last litter the strongest looking, which turned out to be a male, and two others—the one selected by a child, the other because it had seven extra toes. Both these were females.

The Cross as a Sun Symbol

THE use of the cross as a sacred symbol dates from the earliest times, and is almost universal. It occurs upon the monuments and utensils of every primitive people from China to Yucatan. In many, perhaps in a majority of, instances it is used as a symbol of the sun. One of the oldest and most widely occurring forms is the cross with *crampons* turned to the right or left, the *svastika* and *sauvastika* of India, the "Thor's hammer" of Western Europe. Prof. Max Müller thinks that the *svastika* represents the vernal sun, and is hence an emblem of life, health, and creative energy (Schliemann's "Ilios," p. 348). Mr. Edward Thomas (*ibid.*) believes it to have arisen from the conception of the sun as a rolling wheel. The Chaldean sun symbol was first a circle, then a circle with an inscribed cross. The symbol of the sun-god at Sippara is a small circle with four triangular rays, the four angles between being occupied by radiating lines, and the whole circumscribed by a larger circle. The same symbol occurs repeatedly upon the shell gorgets of the mound-builders (Second Annual Report of the U.S. Bureau of Ethnology, plates liii., lviii., and lix.). The peculiar figure repeated upon the *façade* of the "House of the Nuns" at Uxmal seems to be a conventionalised circle and cross with rays. The Moqui symbol for the sun is a Greek cross with a small circle at the centre, in which are three marks to indicate the eyes and mouth of a face (First Annual Report of the U.S. Bureau of Ethnology, p. 371). It is needless to multiply examples: the important question is, How has the cross come to be a symbol of the sun? If anyone will observe carefully a lamp, or other bright light, with partially closed eyes, the answer will be obvious. The rays which appear to proceed from the luminous point always form a cross of some kind. A little experimenting will show that this appearance is due to reflection from the eyelashes and edges of the eyelids. The same experiment may be tried with the sun itself: if observed when considerably above the horizon, squinting will be unavoidable. If the head is erect, the downward arm of the cross will be much the strongest, and the upward arm may be obsolete; but if the head is thrown back, the arms will be nearly equal. The evolution of the sun symbol seems to have been as follows: He was first represented by a circle or disk as he appears when near the horizon; observations made when he was shining brightly revealed the crossed rays. This led to a combination of the circle and cross. If this hypothesis be correct, the *swastika* was originally neither a rolling wheel, nor, as Burnouf supposes, the crossed sticks from which our ancestors elicited fire; but it is a modification of the circle and inscribed cross.

It is not claimed that the cross has in every case originated in this way; but since sun-worship is known to have been an almost universal form of primitive religion, and since the unscientific observer would be sure to regard the crossed rays as an essential part of the sun, this hypothesis furnishes a reasonable explanation of the universality of the symbol. Anything bearing the cross would be regarded as sacred; hence the Egyptian worship of the scarab, as noticed by Mr. R. G. Haliburton (NATURE, vol. xxxiv. p. 610), and the spider-gorgets of the mound-builders (Second Annual Report of the U.S. Bureau of Ethnology, plate lxi.). Not the least remarkable feature of the subject is the fact that the most ancient and universal symbol of the physical sun should, for entirely independent reasons, continue in use as the sign of "the Sun of righteousness" and "the Light of the world."

Fort Wayne, Ind., U.S.A., January 12

Clausius's Formula

IN the report of our preliminary communication to the Royal Society, reported in your issue of the 13th inst. (p. 262), we give Clausius's formula intended to express the relation between the gaseous and liquid states of matter as

$$p = \frac{RT}{v - \alpha} - \frac{c}{T(v+\beta)^2}.$$

We should have mentioned that this formula has been amended by Clausius to

$$p = \frac{RT}{v - \alpha} - \frac{c}{\Theta(v+\beta)^2},$$

where $\Theta = aT^n b$. As Θ is a function of T, it is evident that this latest form also is not in agreement with the simple relation pointed out by us for ethyl ether,

$$p = bT - a.$$

Notes on Certain Traits of Infant Navajos

AS we know, the Navajos are an American tribe of Indians, scattered for the most part over the Territories of New Mexico and Arizona. Quite a number of them live with their families, in the curious little habitations they erect, about the frontier military station of Fort Wingate, New Mexico. It is in this latter place that I have had the opportunity, for over two years past, of studying many of their ways and customs. And it was here, too, that, a few days ago, I went out among them with a photographic camera, armed with an English instantaneous shutter, with the view of taking a few pictures of them while they were actively engaged in some of their very interesting games.

After having obtained four or five more or less satisfactory plates, the Indians became quite restive, as they rather object to that sort of a thing; and, as if by common consent, they gradually disappeared, a few at a time making for one of their low, conical-shaped mud huts, where they entered through the single small door at its side. In less than half an hour there were none of them to be seen outside at all, and, knowing full well that they would not appear again so long as I remained upon the ground, I shouldered my instrument and prepared to come away. At the time, I was standing between two of their huts, situated some three hundred yards apart, with a well-beaten, though narrow footpath passing from one to the other. There were no trees within a quarter of a mile, the plain being sparsely covered with sage-brush, the plants being from 2 to 3 feet high. Just then one of their babies toddled out of the doorway of the upper hut; the child could not have been over ten months old, and wore only a very dirty little shirt, which came about half way down to its knees. It looked more like an infant Eskimo than any child, not white, that I know anything about; and it started right down the path with a very unsteady baby-waddle, making for the lower hut, where I imagine its mother had taken refuge from my merciless camera. I had often longed for a good picture of a Navajo baby in its native plains, and here was an opportunity not to be lost. So, stepping a few feet out of the way, in an instant I had my instrument in position, focused on the path, and, with instantaneous snap ready, I stood quietly for my subject to pass. On he toddled, until he came within about 30 feet of me, where he suddenly stopped, and, to my surprise, seemed to fully take in the situation.

At this stage, I feel quite sure that one of our babies, especially at this tender age, would have begun to cry, and more than likely retraced its steps to the hut from whence it had issued. Not so, however, this infant Navajo; and, mark the difference. He steadily watched my every movement, and was evidently determined to reach the lower hut. Very cautiously leaving the path on the side furthest from me, he was, in the next instant, behind one of the sage-brushes, which was something over a foot taller than the baby. From this position he peered through the leafless twigs at me, to see what I would do about it. A little annoyed at this turn in affairs, I threw the focusing-cloth over my head, and turned the instrument on him. Taking advantage of this temporary concealment of my head, he ran, thoroughly baby-fashion, to the next *lower* brush, a distance of some 10 feet, where, hiding as before, he crouched down, and stared at me like a young lynx through the twigs. He now looked, for all the world, the young Indian cub at bay, with all the native instincts of his ancestors on the alert, and making use of all the strategy his baby mind could muster. It was a wonderfully interesting picture to study; but, fearing that I would lose a permanent memento of it, I turned to lift my instrument, with the view of taking a much nearer position, when, again facing the brush where I had last seen the baby, it was, to my great surprise, not there, but had scampered to the next lower one, in the direction of the hut for which it was bound. A full-grown buck of the tribe could not have possibly managed this last movement any better. As it ran to the still next lower brush, I was astonished beyond measure (for, I take it, I am a good stalker myself) how it took advantage of everything that lay in the short intervening distance, and how, after it arrived at the brush, it immediately took a position on the opposite side of it, from where it could make another quick start, and yet not lose sight of my movements. And, mind you, all this from a baby only ten months old at the most. As it was rapidly gaining its point and approaching the lower hut, in sheer desperation I ran up on its last place of concealment, holding my camera in such a way that I could immediately place the tripod in position, which I succeeded in doing, with the lens levelled directly at its head, and not 3 feet from it. It now stood up to the full extent of its baby height, and, giving vent to a genuine infantile bawl, it made a break for the final point of its destination, for there was nothing else left for it to do. It is almost needless to add that, before I could focus and insert a plate, my Navajo baby was out of range. And, fearing that its angered mother might appear at any point, at the cry of alarm of her child, I immediately forsook the ground.

My object in making a record of such an interesting case as this is to simply draw attention to the fact that the native instincts of these American Indians are exhibited in their young at a wonderfully tender age; and in this particular they differ vastly from our own children at a corresponding time of life, and reared, as they have been for ages, in a civilised environment.

R. W. SHUFELDT

Fort Wingate, New Mexico, January 11

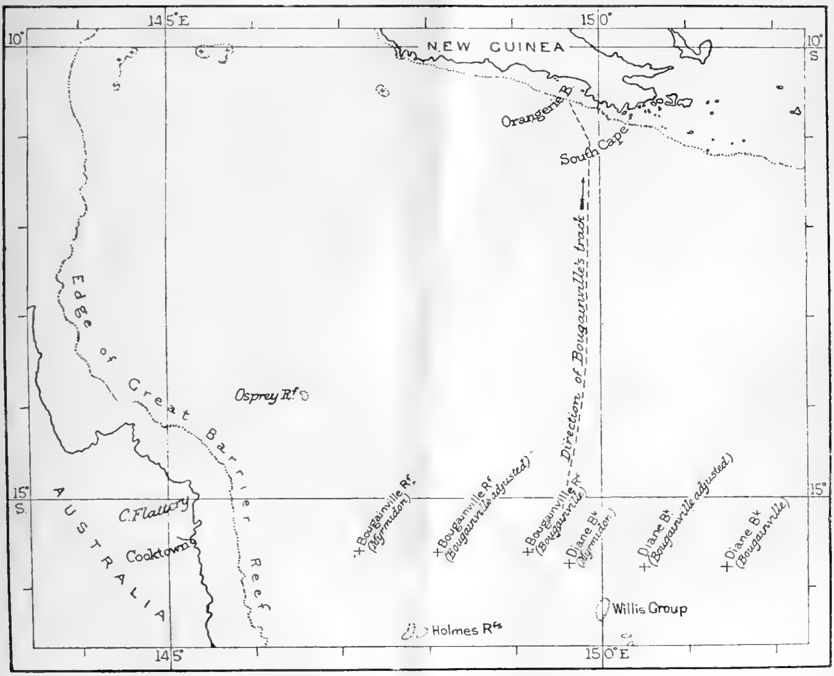
LONG-LOST REEFS

A REMARKABLE instance of the manner in which small reefs in the ocean may elude search has recently been brought to light, and may be of interest to some readers of NATURE.

In June 1768 M. de Bougainville, in the frigate *La Boudeuse*, having left Espiritu Santo, in the New Hebrides, was sailing west over the Coral Sea, south of New Guinea, near the parallel of 15° S. At midnight of the 4th he sighted a sand-bank, and waited till daylight to examine it, when it proved to be a very small patch of sand only just out of water, with apparently no reef around it. This he called Bâture de Diane.

Resuming his course west, he, on the 6th, having run by his reckoning 137 miles from the sand-bank, sighted a reef on which the sea broke heavily, and closing it, at noon obtained its position. After a zig-zag course of five hours, another reef was seen ahead, and as this might be but the prelude to more, the project of exploring further westward was given up, and *La Boudeuse* steered northward, making New Guinea at a bay to which the name of Cul de Sac de l'Orangerie was given. Bougainville thus lost the honour of discovering the eastern coast of Australia, which the celebrated Cook explored two years later. On the last reefs seen no name was bestowed, but they have always been known as the Bougainville Reefs.

Time passed, but these dangers were not again seen.



The subject of their existence was much discussed, and on the longitude of Espiritu Santo being revised, it was recognised that M. de Bougainville's discoveries should be also moved to the westward about sixty miles—the amount of error in longitude of Espiritu Santo in his time. The Diane was therefore placed in longitude 150° 28′ E., and the reefs in 148° 6′. In this position they were searched for by Capt. Denham in H.M.S. *Herald*, who spent fifteen days in traversing in every direction an area of forty miles radius round each danger, but without success. As a result of this search, seeing that Bougainville's description was so circumstantial that the existence of the dangers could scarcely be doubted, they were removed back to their original positions on the charts. These positions, though manifestly too near to Espiritu Santo, agreed better with the land-fall made in New Guinea by *La Boudeuse* after leaving the last reef, as it seemed impossible that the bay generally supposed to be the Cul de Sac de l'Orangerie could have been reached on the course steered by M. de Bougainville from any position westward of longitude 149° 8′ E., Bougainville's own position of the reef.

Many ships passed in fear and trembling over the long line in which it was thought these dangers might yet exist, and the records are full of remarks as to their non-existence, especially with regard to the Diane, which lay near the main track to Torres Strait from Sydney. They were, however, retained on the charts, with notations as to the doubt in their positions.

At length, in 1884, two reports were made by small trading-vessels from Queensland to New Guinea, one of a small bank in lat. 15° 41′, and long. 149° 43′, the other of a submerged reef in lat. 15° 28′, long. 147° 6′. It was at once observed that the latitudes of these, and their distance apart, agreed with those of Bougainville's discoveries, though they were far to the westward, and it seemed as if the long-lost reefs were at length again found, since it was not at all improbable that the westerly current had caused the reckoning in longitude, uncorrected by chronometers, to be over-run by *La Boudeuse*. Capt. Denham's searches, minute and painstaking, and apparently sufficiently extended as they had been, just fell short of the positions of these new reports, the limit of his examinations passing within ten miles of both of them.

One link, however, was missing to insure certainty in the identification, viz. the second reef of Bougainville.

During the past year H.M.S. *Myrmidon* has been scouring the Coral Sea, and in the course of her cruise made this one object of search. It was, however, unavailing; clear sea was alone seen in the direction of the second reef. But her description both of sand-bank and reef reported in 1884 tallied precisely with Bougainville's detailed accounts. More accurate observations, moreover, showed that the latitudes were in each case almost exactly identical with his, and that the distances apart, as before stated, agreed.

But what of the reef still missing?

A closer examination of Bougainville's journal revealed that the second reef was sighted from aloft at 5.30 p.m., at an estimated distance of five miles. The sun set at 5.35, behind the reef; twilight is short in those latitudes, and it seems improbable that *La Boudeuse* could have been near enough to see the reef clearly before night closed in. It is therefore believed that the delusive appearance of reflection misled the voyagers, and that Bougainville, so accurate in his other reports, was in this instance mistaken.

A further difficulty remains. How could *La Boudeuse* steering the course reported have made the land 100 miles to windward of her direct track? Here, again, the explanation seems to be that later voyagers re-bestowed the name of Orangerie on that one of the numerous bays on the New Guinea coast which corresponded to Bougainville's longitude. These are assumptions; but the other evidence is so complete that it is believed that the mystery of 120 years is cleared up, and that the dangers which have so long been a source of anxiety to the navigator have at length found their true places on the charts.

The three positions these reefs have occupied are as follows:—

	By Bougainville S.	By Bougainville E.	Bougainville corrected for the position of Espiritu Santo S.	Bougainville corrected for the position of Espiritu Santo E.	By *Myrmidon* S.	By *Myrmidon* E.
Diane	15° 46′	151° 26′	15° 46′	150° 28′	15° 43′	149° 37′
Bougainville Reefs	15° 35′	149° 8′	15° 35′	148° 6′	15° 33′	147° 12′

W. J. L. WHARTON

THE CROCUS[1]

MANY splendidly printed and illustrated monographs of special genera of flowering plants have been published, but few surpass in merit or interest Mr. Maw's monograph of the species of the genus Crocus. This work, the author tells us, has pleasantly occupied his spare hours for the last eight years. In collecting the material for it, he has travelled far and wide over the crocus region; he has enlisted the services of a whole host of friends, who, on the borders of the Mediterranean, of the great Basin of the Black Sea, and along the shores of the Caspian, have collected the species peculiar to these localities, and forwarded them for culture and description to Mr. Maw. Perhaps never before has a monograph been written so entirely from the study of living plants. At the same time, no information that was to be gleaned from the dried specimens in herbaria has been neglected.

The monograph opens with a chapter on the life-history and physiology of the forms belonging to the genus. As the minute structure of the various parts of the plants has not been made a special study by the author, this portion of the subject leaves a good deal to be done by future workers. The strange phenomenon of dissepiments on the pollen-tube is figured as existing, on the authority of Prof. Martin Duncan. In the chapter on classification and sequence, we find that the author adopts the division of the species indicated by Dean Herbert, into those with, and those without, a basal spathe. These larger divisions are, again, subdivided into sections, characterised by the form assumed by the bundle tissue or the corm tissues, and these, again, into groups arranged according to the period of flowering. The third chapter is a most interesting one, on the geographical distribution of the species. Confined to the Old World, the species of crocus are therein only to be met with in the northern hemisphere, where they reach a northern limit at about 50° N. latitude. Westwards, they reach their limit at the coast of Portugal; southwards, the limit extends to Morocco, though no species appear to be endemic to Africa, and none have been found in the region between Tetuan and the Nile Delta. In Asia, on the borders of Syria, *Crocus hyemalis* has the most southern range of all the species. The eastern limit of the species is at present uncertain, for it seems pretty certain that one or more species have been found in Afghan Turkestan. Of the sixty-nine known species, thirty occur in 40° N. latitude, which is far in advance of any other district as a line of growth, but the metropolis of the genus is a district including Greece, the Greek Archipelago, and Asia Minor, for in these regions it forms a more important feature in the flora than in the outlying countries to which it extends. The genus is also remarkable for the wide range in altitude of the majority of the species, those that are essentially alpine or lowland being comparatively few in number; and Mr. Maw does not know of a single species which is not perfectly hardy, that is to say, capable of enduring any of the extremes of cold or heat to be met with in our climate. There do not appear to be distinct areas for the spring and autumn flowering forms, and Mr. Maw has been unable to detect any instances of wild hybrid forms, notwithstanding the close relationship of some of the species, and the fact that their areas of distribution constantly overlap.

In a fourth chapter the history and literature of the genus are treated of. Two centuries before the days of Linnæus the crocus was known in England as a garden plant, and in Gerarde's "Herball" (1597) eleven forms are figured and described. Most of the famous pre-Linnean writers on plants have added to our knowledge of the species, such as Parkinson in his "Paradisus" (1629), and Ewart in his "Florilegium" (1612); but Linnæus contented himself with making but two species, one *C. vernus*, and the other *C.* (*Bulbocodium*) *bulbocodium*. The first important attempt to classify the genus was made by A. H. Haworth in 1809, followed by Goldbach's monograph in 1817, Gay's in 1827, and Sabine's in 1830. Dean Herbert in 1847 and Baker in 1873 added much to our scientific knowledge of the group, and now in this beautiful monograph

[1] "A Monograph of the Genus Crocus." By George Maw F.L.S., &c. With an Appendix on the etymology of the words "Crocus" and "Saffron," by C. C. Lacaita, M.A., M.P., F.L.S. (London: Dulau and Co., 1886.)

we have the history of the genus, written in a manner that, except for the anatomical student, will not for very long indeed be surpassed.

Hints on cultivation and on species not yet introduced to cultivation, and remarks on saffron, its cultivation and uses, form Chapters V. and VI. Saffron would appear to have been cultivated in England prior to 1582, and from its importance as an article of commerce gave its name to Saffron Walden. It is very strange that after having been grown as an economic plant in England for three or four centuries its production has died out, and that it is an extremely difficult thing to get the saffron crocus to flower in this country. The author says that saffron was used as a royal dye in the olden time in Ireland, but this is a very doubtful statement.

Into the descriptive portion of this work it is needless that we should enter in detail. All the species and their chief varieties are most carefully described, full synonymic lists are given, and ample details as to the geographical distribution of each and its period of flowering. The description of each species is accompanied by a plate illustrating the corm, flower, leaves, fruit, and structural details; and, as if to add to the attractiveness of this splendid volume, there is a series of very exquisite woodcuts, introduced as head-pieces, of some of the more remarkable districts where the rarer species are found. Some of these are from original sketches, by Mr. Danford, of the remote mountain region of the Taurus and of other parts of Asia Minor, where, with Mrs. Danford, journeys were made in quest of crocuses. The volume is dedicated to Mr. and Mrs. Danford.

The appendix, by Mr. Lacaita, on the etymology of the words crocus and saffron, is of great interest, and tells of the almost world-wide use of the terms.

NOTES

LAST week, Sir William Armstrong paid to the bankers of the Royal Society a cheque for 780*l.* for the Scientific Relief Fund.

THE Council of the Geological Society have awarded the medals to be given at the anniversary meeting of the Society on February 18, as follows:—The Wollaston Gold Medal to Mr J. W. Hulke, F.R.S., the Murchison Medal to the Rev. P. B. Brodie, the Lyell Medal to Mr. S. Allport, and the Bigsby Gold Medal to Prof. C. Lapworth. The balances of the Funds at the disposal of the Society are awarded as follows:—The Wollaston Fund to Mr. B. N. Peach, the Murchison Fund to Mr. R. Kidston, and the Lyell Fund to the Rev. Osmond Fisher. We believe that the President's address at the anniversary meeting will deal mainly with the relations between geology and the mineralogical sciences.

THE Geographical Society of Australasia has been authorised by the Queen to prefix the word "Royal" to its title.

THE recent death of General Hazen, the chief of the Army Signal Service in the United States, which is responsible for the meteorology of that country, has raised the question whether or not meteorology should be dealt with by a civil rather than a military bureau. It will be remembered that when the present meteorological system was established in the United States it was connected with the Signal Service, in order to utilise the time of the officers and men during peace. There is no doubt that the work done by the American Signal Service has been done with a thoroughness and vigour which have not been equalled elsewhere; and the eminent men of science who have been associated with the Chief Signal Officer have taken care that the mere forwarding of weather information should not be the whole of their duties. A Committee of the National Academy of Science has already been appointed to consider the matter, and has recommended separation of the work from the War Office. Whatever decision is arrived at, it is to be hoped that the service in its new form (if it is to have one) may not be less efficient than it has been in the past. This question is of course part of the general question now being seriously discussed in the United States, as to whether a purely scientific service should be controlled and directed by scientific men. In the abstract there can be of course but one answer to this question, but it must at the same time be pointed out that to make a man of science responsible for large administrative and executive work is to destroy him utterly as a man of science. This is a good reason for having some one other than a man of science for the carrying out of such work. It is, however, no argument for placing the man of science in a subordinate position to any mere administrator, and it would perhaps be best to intrust such inquiries on a very large scale to a small Committee, one of whom should be the man responsible for the science and the other the man responsible for the administration.

VERY enlightened ideas prevail among the influential classes of India with regard to the manner in which the Queen's Jubilee should be celebrated. On the motion of Dr. Hunter, the Vice-Chancellor of Calcutta University, the Jubilee Committee at Calcutta decided some days ago that the fund which is to be raised in India for a permanent memorial, shall be devoted partly to the Imperial Institute in London, partly to a scheme for the placing of technical education in India on a sound and lasting basis. It is said that the provincial cities are resolved not to be outstripped by the capital. The people of Patna propose to found an industrial school, and the Calcutta Correspondent of the *Times* says their example is likely to be followed in many places. The native princes have also begun to see the importance of technical education, and the Maharajah of Mysore has determined not only to contribute largely to the Imperial Institute in London, but to form an Institute of a similar kind in his own dominions. All this promises well for the material progress of our great dependency, and it should tend to strengthen the movement among ourselves for the establishment of closer relations between science and industry.

NEARLY four years ago we were able to announce that a vote had been passed at Oxford authorising the Curators of the University Chest to spend a sum of 7500*l.* in building an annex to the east side of the University Museum, to contain the splendid anthropological collection which General Pitt-Rivers had most munificently offered to the University, and in providing the requisite cases and fittings. The collection has now been partially arranged in the hall built for it, and is thrown open to visitors. It has been enriched by objects transferred from other University Museums, such as the Ashmolean, and by numerous donations from other sources. The opening of the collection ought to mark an epoch in the history of anthropological study at Oxford. Its importance arises less from the value of the objects (although that, of course, is very great) than from the manner in which they are grouped. The arrangement brings out with astonishing clearness the working of the law of evolution in the development of all kinds of implements and weapons.

IT is proposed that a Medical School shall be formed in connection with University College, Dundee. There can be little doubt that the scheme will be successful, for not only has Dundee an important hospital, but medical students at the new school would have the advantage of being able to take the degrees of the University of St. Andrews. Some time ago Mr. T. H. Cox offered 12,000*l.* as an endowment for a Chair of Anatomy, and now the sons and daughters of the late Mr. J. F. White, of Balruddery, have given 6000*l.* to found a Lectureship or Chair to be associated with their father's name.

About 2000 delegates, including about 300 from Europe, are expected to be present at the ninth triennial meeting of the International Medical Congress at Washington in September next. An effort is being made to secure the hall of the House of Representatives for the opening meeting. After this meeting the Congress will be divided into seventeen sections, assembling in the different halls of the city.

Mr. G. T. Ryves, F.R.Met.Soc., wrote the other day to the *Times*, from Stoke-on-Trent, presenting the results of an independent comparison of the daily forecast issued by the Meteorological Office for the Midland District with the actual weather experienced in 1886. The number of forecasts sent out by the Office during the year was 310. Of these, 309 were tested, and Mr. Ryves found that there were 247 absolute successes, 26 absolute failures, and 36 partial or doubtful successes. That is to say, omitting small fractions, there were 80 per cent of successes, 8½ per cent. of failures, and 11½ per cent. of doubtful cases. Mr. Ryves understands that a similar result has been arrived at in other places where the forecasts have been submitted to an examination extending over a period of sufficient length to make it possible to strike a fair average.

The French Minister for Public Instruction has nominated a Commission, under the presidency of M. Bertrand, the Secretary of the Académie des Sciences, which will award a prize of 50,000 francs (2000*l.*) to the inventor of a cheap method for the application of electricity to the purposes either of heating and lighting, chemical or mechanical force, telegraphy, or the treatment of the sick.

The Royal Scientific Society of Göttingen offers a prize of 500 marks (25*l.*), in 1889, for a complete review of the literature of the Arabs and the Arabian-speaking tribes of the Islam and Christian kingdoms up to the time of the conquest of Egypt by Turkey. Further particulars can be obtained of the Society.

Mr. Maclean, the official assistant to the Professor of Natural Philosophy in the University of Glasgow, has just published a little book containing examples of exercises given in the natural philosophy class during recent years, with indications how to answer them The exercises deal largely with dynamics and properties of matter, and include sound, light, magnetism, electricity, and heat. The exercises, especially those on dynamics, are very interesting, and indicate distinctly the thoroughness of the instruction given. Several of the hints for solution will be found also of great value to students.

We have frequently had to refer to the scientific *renaissance* now going on in Italy. Another indication of this has just reached us, in the shape of a volume of some 500 pages, on "Geological Evolution: Inorganic, Animal, and Human," by Signor Enrico del Pozzo di Mombello. The book is published by Sgariglia, of Foligno. It exhibits a wide philosophical grasp of the subject. The first chapter is almost confined to an analysis of Herbert Spencer's "Principles of Evolution." The writer then discusses the nebular hypothesis, and the new views as to the inorganic evolution now going on in the sun. Geological climates, with full references to the works of Lyell and Croll, follow; and after a chapter on vulcanism are chapters on practical geology. The rest of the work deals with life, including a full statement of Darwinism and human evolution, while the last chapters are devoted to prehistoric man. Such a book as this will be of the greatest service to science in Italy.

We have received the fifth edition of "Celestial Motions," a handy book of astronomy, by Mr. W. T. Lynn, formerly of the Royal Observatory, Greenwich In this last edition a chapter has been added on the refraction, propagation, and aberration of light. The treatment, however, is necessarily so limited, that the chapter is practically useless for educational purposes.

We have received also the fifth edition of Prof. Bentley's "Manual of Botany." The physiological part of the subject has been largely revised, with the assistance of Mr. J. D. Groves, Demonstrator of Practical Biology at King's College, London. Many alterations have been made in the part treating of the properties and uses of plants; but the most marked change is in those chapters relating to the classification of plants. The book is now adapted in all essentials to the arrangement adopted in the "Genera Plantarum."

A strong shock of earthquake was felt in Venice on the night of January 24. No damage seems to have been done. At Aquila, in Lower Italy, seven shocks of earthquake were noticed on January 26, three of which were rather strong. They occurred between 2.30 p.m. and 7.45 a.m. of the next day.

On the night of January 31 a shock of earthquake was felt in Zurich and the neighbourhood, and in the cantons of Zug and Schwyz. The district affected was about 80 kilometres in diameter.

Under the auspices of the Geological and Natural History Survey of Canada, Prof. J. Macoun, of Ottawa, has now completed the first volume of his "Catalogue of Canadian Plants." The third part, just published, comprises the Apetalæ, Coniferæ, and a long list of additions and corrections to parts 1 and 2, carrying the work down to the end of Exogens.

A consignment of German carp has been forwarded to Portugal by the National Fish-Culture Association, for the purpose of acclimatisation in the waters of that country. The experiment is being made by Messrs. Broughton and Frietas, who have also made arrangements to import a quantity of salmon and trout ova, and hatch them out for a similar purpose. The National Fish-Culture Association have intimated their intention of supplying Salmonidæ fry this year gratuitously to public bodies desirous of repopulating depleted waters. One million and a half of whitefish ova (*Coregonus albus*) arrived from the American Government at the hatchery of the Association on January 31.

The National Fish-Culture Association have just issued the first number of their quarterly Journal, edited by Mr. J. W. Willis-Bund. The objects of this publication are not only to chronicle the operations of the Association, but to collect information concerning the fish, fish-culture, and fisheries both of the United Kingdom and abroad. The present number includes articles by Dr. Francis Day, Mr. J. W. Willis-Bund, Mr. W. Oldham Chambers, and Mr. Anderson Smith.

Herr Richard Andree, of Leipzig, who has for some years past made a special study of cannibalism and its prevalence in ancient and modern times, has recently published (Beit: Leipzig) a pamphlet on the subject, which is full of interest to others besides the ethnologists for whom it is, of course, mainly intended. He treats first of the practice of anthropophagy in prehistoric times, discussing traces of it in popular tales, legends, and superstitions. To this section also belong the investigations into the remains found in caves and ancient burial-places in Europe, which Herr Andree thinks prove beyond doubt that cannibalism existed at this remote epoch in countries which are now the most highly civilised on the globe. The next part deals with the geographical distribution of the practice at the present day. The mass of information brought together is drawn from the literature of many countries, ancient and modern, and is enormous in amount. The writer attributes the origin of cannibalism to hunger and want in the first instance, until it developed into a settled practice, from which the step to human sacrifice, whether of single individuals, such as prisoners, or of holocausts of victims, as in ancient Mexico, is not a long one.

The death is announced of Dr. Philip Fischer, the well-known mathematician and Professor at the Polytechnic Institution at Darmstadt. He died on January 22.

IN a recent issue, *Science* comments on the fact that the number of lectures delivered by professors at Oxford and Cambridge falls considerably below that which it is usual for a professor to give in the United States. *Science* is by no means of opinion that the American plan is best. American professors are, it says, compelled to teach and lecture so much that few of them have an opportunity of doing justice to their abilities as investigators and writers. Our American contemporary counsels governing Boards in the United States to take this fact into serious consideration. "They value a professor according to the number of lectures he delivers and the number of students he attracts. They fail to perceive that scientific research is the peculiar duty, and should be the peculiar privilege, of the University professor. Oxford and Cambridge professors do more original work than our professors, simply because they are given the time for it."

CAPT. DUTTON, of the U.S. Geological Survey, is making rapid progress with the preparations for his Report on the Charleston earthquake. With regard to the velocity of the propagation of the earth-wave, the final computations have not yet been made, but the evidence is said to indicate with certainty a velocity somewhat in excess of three miles per second.

WE have received the new number of the *Annuaire* of the Royal Observatory of Brussels, by M. Folie, Director of the Observatory. This periodical has appeared every year without interruption since 1834. The present number, like its predecessors, contains much useful astronomical information. The section on physical units and constants has been enlarged, and there are valuable notes on the geography and statistics of Belgium.

MESSRS. RIVINGTON will shortly have ready a "Text-book on Animal Biology," by Prof. C. Lloyd Morgan, of University College, Bristol. The first part of the volume deals with the anatomy and physiology of vertebrates, as exemplified by the frog, the pigeon and fowl, and the rabbit. In this part there are special chapters on histology, embryology, the genesis of tissues and organs, and animal metabolism. The second part is occupied with the structure and life-history of some invertebrate types, viz. the crayfish, cockroach, earthworm, liver-fluke and tapeworm, snail, freshwater mussel, hydra, vorticella, and amœba. Numerous outline woodcuts have been drawn specially for this work. It aims at satisfying the requirements of those who are preparing for the immediate science and preliminary scientific examinations of the London University, and for the Oxford and Cambridge Local Examinations.

IN a report on the working of his department during the past six years, which has just been laid before Parliament (C—4943), the Controller of the Stationery Office refers to the publication of the Report of the scientific results of the exploring voyage of the *Challenger*. This was much delayed, Mr. Pigott observes, by the long illness and death of Sir Wyville Thomson in 1882, but it now approaches completion. The original estimate of the bulk of the work has already been very largely exceeded, "owing," writes Mr. Murray, the present editor, "to the enormous wealth of the observations and collections made during the expedition not having been at first realised." Twenty-seven quarto volumes, illustrated by about 2000 full-sized lithographic plates (many of them exquisitely finished in colours), by some eighty charts and diagrams, and by many hundred photographs and woodcuts, either already have been, or in the course of a few weeks will be, published. The editor (continues Mr. Pigott) estimates that another seven volumes at least will be required to complete the work, but hopes that with perhaps the exception of the last, in which it is intended to show the bearing of facts stated in the previous volumes on theories hitherto accepted, all will be before the public before the end of the coming financial year (March 31, 1888). The Controller thinks that perhaps it is fortunate for science that the Lords of the Treasury, when considering whether the publication of the results of the voyage should be undertaken at the public expense, were necessarily imperfectly informed of the cost. The amount paid from Stationery Office votes alone has already reached nearly 25,000*l.*, of which about 12,000*l.* only has been recovered by sales. To the balance of this account in calculating the actual cost of the book must be added the sums granted annually by Parliament for the expenses of the commission since the return of the ship—something over 40,000*l.*, making the net cost of the publication up to the present time, roughly, 53,000*l.*—a larger sum perhaps than has ever been spent by any Government on a single work. On the other side, however, Mr. Controller Pigott is good enough to add that the value of the Report can scarcely be exaggerated, and in a few lines he gives his estimate of the work of the expedition.

LIEUTENANT W. H. EMORY, of the U.S. Navy, who commanded the *Bear* in the Greely Relief Expedition, has been ordered to the *Thetis*, and will shortly sail for Alaska. He is to investigate the seal-fisheries, and has received special instructions regarding the boundary-line between Alaska and British territory.

THERE seems to be some need for a scientific examination of medals granted in America for distinguished services. The "fine, large, gold medal," given to General Grant for the part he played in the Mexican war, is now in the National Museum, Washington, and, according to *Science*, it is "bogus," having a specific gravity of only 7 instead of 16.

IN a recent Report, Mr. J. R. Dodge, Statistician of the U.S. Agricultural Department, shows that the amount of beetroot-sugar produced last season exceeded the cane-sugar by 162,000 metric tons. The manufacture of beet-sugar is wholly a European industry, and Mr. Dodge says its success in Europe is largely due to the fact that each shareholder in the stock of a beet-sugar factory is required to furnish so many beets per share. The farmers are in reality the manufacturers, and, since they obtain the profits of the manufacture, it is their interest to raise good beets at a nominal price. Mr. Dodge states that the sugar consumed in the United States amounts to about one-fourth of all the sugar reported from the places of principal production, and that within twenty-five years the country will require as much as the whole of the present supply of the cane-sugar of commerce, and nearly as much as the present production of beet-sugar. Mr. Dodge expresses surprise that Americans "scour the world for food-products costing more than 200,000,000 dollars per annum, the larger portion of which should be produced in the United States." What is needed, he thinks, is "a more skilful, scientific, and inventive agriculture."

THE introduction of the electric light is not always, apparently, an unmixed benefit. Some time ago electric lights were placed in front of the Treasury and other public buildings in Washington, and a fine and striking effect is said to have been produced. Unfortunately, however, spiders discovered that game is plentiful in the vicinity of the new lights, and that they may there ply their craft successfully both day and night. In consequence, as Mr. G. Thompson writes to *Science*, their webs are so thick and numerous that portions of the architectural ornamentation are no longer visible, and when the webs are torn down by the wind, or fall from decay, the refuse gives a dingy and dirty appearance to everything it comes in contact with.

WE notice in one of the morning papers that considerable progress is being made at the great Lambeth factory of Messrs. Maudslay, Sons, and Field, with the large compound engines which are being prepared for the new Italian armour-clad *Il Re Umberto*. According to the contract, these engines are to be of 19,500 horse-power, which is about 7500 horse-power more than that of any vessel yet designed for the British Navy. It is stated that they will actually indicate 21,000 horse-power, or 9000 more than any vessel in the British Navy. These engines, completely made of steel, are expected to drive the *Il Re Umberto*, fully equipped, about 20 knots per hour.

MR. C. C. LACAITA is taking charge of the Sanitary Registration of Buildings Bill in the House of Commons. The Bill as introduced in 1886 consisted of ten sections, and, it will be remembered, made the sanitary registration of all buildings compulsory in towns of 50,000 inhabitants and upwards. The new Bill consists of seventeen sections, and is to apply to all towns or districts of 2000 inhabitants, but it is only to be compulsory in the case of schools, colleges, hospitals, asylums, hotels, and lodging-houses. An important feature of the new Bill is that the local authorities will have to keep a Sanitary Register, in which any building certified in accordance with the proposed Act may be registered, so that a stranger visiting any district would be able to ascertain at the office of the local authority whether any particular house was or was not certified as in a satisfactory sanitary condition. The new Bill will, no doubt, be more acceptable to sanitary experts, seeing that all persons entitled to certify must first obtain a license from the Local Government Board, and provision is made for the appointment of examining Boards. Persons entitled to sign certificates are designated Licentiates in Sanitary Practice.

THE town of Baku was recently threatened with destruction by the sudden outburst of a natural naphtha fountain. This was soon followed by a volcanic eruption from Lok Botan, close to the Ponta railway station, and about ten miles from Baku. The eruption began on the night of January 15, when the inhabitants of Baku were alarmed by a shock like that of an explosion, which made all their window-panes tremble violently, while towards the south-west the sky was illuminated by an intense light, as of some terrific conflagration. The following information, furnished by the railway officials of the Ponta station, appeared in a telegram from the St. Petersburg Correspondent of the *Times* on Monday last :—"Quite suddenly, at eleven o'clock at night, the noise of an explosion was heard, and the summit of Lok Botan shot up an enormous column of fire some 350 feet high. The whole country was instantly lit up brighter than day, and the heat could be felt at nearly a mile from the crater. There was scarcely any wind, so that the column continued to ascend quite vertically, carrying with it, as could be seen, large dark substances which appeared to fall again into the volcano. This lasted with short intervals of subsidence all through the night and the following twenty-four hours, but luckily the matters ejected did not reach the railway station." The *Times* Correspondent says that the volume of muddy liquid thrown out is estimated at half a million cubic *sajenes*—the Russian *sajene* equalling 7 feet—and has spread itself over more than a square mile to a depth of from 7 to 14 feet.

ON the night of January 26 a brilliant meteor was observed at Holmestrand, on the south-east coast of Norway. It went from south-west to north-east, at a rapid pace, and disappeared below the horizon. The light was an intense white, illuminating for a few seconds the whole town as in broad daylight.

A STATUE is to be erected at Christiania in honour of the celebrated mathematician Abel, subscriptions being raised towards it from all parts of Europe.

THE Council of the Royal Meteorological Society have arranged to hold, at 25 Great George Street, S.W. (by permission of the Council of the Institution of Civil Engineers), on March 15 to 18 next, an Exhibition of Marine Meteorological Instruments and Apparatus. The Exhibition Committee are anxious to obtain as large a collection as possible of such instruments; and they will be glad to show any *new* meteorological instruments or apparatus invented or first constructed since last March, as well as photographs and drawings possessing meteorological interest.

MR. JOHN MURRAY, of the *Challenger* Expedition Office, Edinburgh, writes to us that the passage placed within inverted commas in one of our Notes on Jan. 27 was not a quotation from his address to the Royal Society of Edinburgh. We may explain that the passage was quoted from what professes to be "a condensed report of the address" in the January number of the *Scottish Geographical Magazine*. In this "condensed report" Mr. Murray is represented as having said that "money grants of considerable annual value are devoted to the maintenance of learned Societies in London and Dublin." Our only object was to point out that so far as London is concerned this statement is misleading.

THE additions to the Zoological Society's Gardens during the past week include a Black-winged Peafowl (*Pavo nigripennis* ♀) from Cochin China, presented by Mr. John Marshall; a Cayenne Lapwing (*Vanellus cayennensis*) from South America, purchased; six Long-fronted Gerbilles (*Gerbillus longifrons*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

COMET BROOKS (1887 *b*).—This object was observed at Paris on January 27 as a circular nebulosity of about 1'·5 in diameter, with a small but fairly bright nucleus, almost stellar in appearance, and situated not quite in the centre of the coma. The comet was estimated as of the 12th magnitude.

Dr. Rud. Spitaler, Vienna Observatory, has computed the following elements and ephemeris :—

T = 1887 March 23·01985 Berlin M.T.

$$\left.\begin{array}{l}\pi = 89^\circ\ 26'\ 17''\\ \Omega = 283\ \ 0\ \ 15\\ \iota = 102\ \ 25\ \ 29\end{array}\right\}\text{Mean Eq. 1887·0}$$

$$\log q = 0·19021$$

Error of middle place $(O - C)$.

$$d\lambda \cos\beta = +9'', \qquad d\beta = -5''.$$

Ephemeris for Berlin Midnight

1887	R.A. h. m. s	Decl. ° '	log Δ	log *r*	Brightness
Feb. 12	1 59 34	+ 73 5·6	0·07734	0·21040	1·39
16	2 35 23	68 19·5	0·08193	0·20660	1·39
20	2 59 23	63 27·4	0·09016	0·20314	1·36
24	3 16 58	58 41·5	0·10154	0·20007	1·31
28	3 30 42	+ 54 9·1	0·11553	0·19744	1·25

The brightness on January 25 is taken as unity.

COMET BARNARD (1887 *c*).—Barnard's comet was observed at Paris on January 26, and seemed to be of much the same brightness and dimensions as Brooks's comet appeared on the following night, but it differed somewhat as to its nucleus, there being a central condensation forming a diffused nucleus about 4" or 5" in diameter. The comet is steadily diminishing in brightness. The following elements and ephemeris are by Prof. E. Weiss :—

T = 1886 November 23·6302 Berlin M.T.

$$\left.\begin{array}{l}\pi = 284^\circ\ 27'\ 58''\\ \Omega = 257\ \ 14\ \ 17\\ \iota = 85\ \ 22\ \ 5\end{array}\right\}\text{Mean Eq. 1887·0.}$$

$$\log q = 0·15454$$

Error of middle places $(O - C)$.

$$\Delta\lambda \cos\beta + 4'' - 3'', \qquad \Delta\beta - 1'' - 9'.$$

Ephemeris for Berlin Midnight

1887	R.A. h m s.	Decl. ° ′	log Δ	log *r*	Brightness
Feb. 12	20 4 1	+ 37 25·2	0·33827	0·26127	0·83

The brightness on January 24 is taken as unity.

THE ROUSDON OBSERVATORY.—We have received Mr. Peek's report on the astronomical work done at the Rousdon Observatory, Lyme Regis, in 1886. During the year, 146 nights were available for observation, the most cloudy month having been February, and the clearest December. Selected lists of long-period variable stars are under systematic observation with the 6·4-inch equatorial. The following comets have also been observed: 1885 *d* and *e*, 1886 *a*, *b*, *c*, *e*, and *f*. The great nebula in Andromeda is under regular observation. We would suggest to Mr. Peek the propriety of publishing the observations of cometary positions at as early a date as is possible; their value is much increased by speedy publication.

MINOR PLANET No. 264.—This asteroid has been named Libussa by Prof. Peters, of Clinton, U.S.A., the discoverer.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 FEBRUARY 13–19

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on February 13

Sun rises, 7h. 20m.; souths, 12h. 14m. 25·5s.; sets, 17h. 8m.; decl. on meridian, 13° 21′ S.: Sidereal Time at Sunset, 2h. 42m.

Moon (at Last Quarter February 15) rises, 22h. 48m.*; souths, 4h. 27m.; sets, 9h. 55m.; decl. on meridian, 7° 5′ S.

GEOGRAPHICAL NOTES

IN a private letter from Mr. H. M. Stanley, published yesterday, he says that when he reached Cairo he found that all the political authorities and experts there were opposed to the idea of his taking the Congo route. They thought that as the Expedition was to be armed with several hundred Remingtons and a machine-gun of the latest invention it was to be an offensive force, conducted after strict military rules, and that Mr. Stanley would therefore meet with no insuperable difficulties either by the Karagwé or by the Masai route. On this point he undeceived them, and he also showed that if serious fighting were necessary his men would be wholly unable to meet great masses of native warriors. Besides, the probable result of a struggle with Uganda would be that Mr. Mackay, the missionary, and the French Bishop and Père, now in Mwanga's power, would be murdered. The total length of each land journey is given by Mr. Stanley as follows:—Congo route: Mataddi to Stanley Pool, 235 English miles; Stanley Falls to Lake Albert, 360 English miles—total 595 English miles. Karagwé route: Zanzibar to Lake Albert, 950 English miles. Masai route: *viâ* Taveta, Kenia, and Turkan, 925 English miles. Mr. Stanley also calculates the length of the various routes by days, assuming that only an average of six miles could be made daily. Congo route: land journeys, 99 days; Zanzibar to Congo, by steamer, 20 days; Lower Congo, by steamer, 3 days; Upper Congo, by steamer, 35 days. Total, 157 days. Karagwé route: land journey, 156 days. Masai route: land journey, 154 days.

THE most important contribution to the new number of the *Bulletin* of the Paris Geographical Society is the series of maps of the River Ogové in West Africa, by Lieut. Mizon. These maps, which are on the scale of about 1 kilometre to an inch, and refer to the whole course of the river as surveyed by Lieut. Mizon, are executed with much care. In the brief text which accompanies the maps, the author describes his method of observation, and gives the positions of some of the more important points. M. Jamkowski contributes an article on Fernando Po, in which he gives some welcome information on the curious people known as Bubis, who inhabit the mountainous districts of the island. Other papers in this number are on the "Ksour" of Bouda (West Sahara), by M. Chatelier; two papers on Tonquin, by Lieut. Gouin; and a paper on the expedition of General de Bussy in the Deccan in the eighteenth century.

IN the Bulletin of the American Geographical Society, No. 2, 1886, Commander H. C. Taylor, U.S.N., describes the various projects which from time to time have been advanced for the construction of a canal across Nicaragua, and attempts to show that this is the most favourable route for a canal between the Atlantic and Pacific. Dr. G. E. Ellis gives an interesting *résumé* of the history of the Hudson's Bay Company, 1670–1870.

LAKE TAHOE, long regarded as the deepest fresh-water lake in the United States, must now take the second place. Capt. C. E. Dutton, of the U.S. Geological Survey, made, in July 1886, a series of soundings at Crater Lake, Oregon, with unexpected results. The mountain wall that surrounds the lake is 900 feet high; the average depth is 1500 feet, and the maximum 1996.

To the January number of *Petermann's Mitteilungen*, Dr. Theobald Fischer contributes the first part of a study of the coasts of North Africa, in which he attempts to account with precision, on geological and meteorological bases, as well as by the action of the sea, for the various features of the North African coast. The present instalment deals mainly with the Algerian and Tunisian coast, and the investigation forms part of a detailed study which Dr. Fischer is making of the whole Mediterranean coasts. The paper is accompanied by maps, while another map illustrates the distribution of languages in Germany and Austria, the accompanying text being by Prof. F. Held. Dr. Possewitz contributes a paper on the laterite outcrops in the Island of Banka.

THE new number of *Appalachia* contains, among other things, a series of useful data, by Prof. E. C. Pickering, on "The Heights of the White Mountains," and a valuable paper by Prof. W. Morris Davis, on "Mountain Meteorology."

IT may interest both geographers and ethnologists to know that in the current numbers of *Les Missions Catholiques* the Rev. Jules Brunetti describes his recent journey up the River Maroni, in French Guiana, giving many details concerning the Negro population which is settled on its banks.

THE Austro-Hungarian Expedition for the investigation of Central Africa, which was organised last year by Count Samuel Teleki, and reached Zanzibar last June, has left for the interior.

A GERMAN Expedition to Brazil sailed from Bremerhafen on January 25. The gentlemen are: Dr. Karl von den Steinen and his cousin Wilhelm, Dr. P. Vogel (Uelfeldt), and Dr. Ehrenreich (Berlin). Both Dr. K. von den Steinen and Dr. Vogel took part in the German Polar Expedition to South Georgia, and the former gentleman and Dr. Clauss were with the celebrated Expedition for the investigation of the Xingu River in Central Brazil, while Dr. Ehrenreich was on a journey in the Amazon district.

THE new number of the *Mittheilungen* of the Vienna Geographical Society contains Dr. Lenz's map of the Congo between Stanley Falls and Kasonge, to the journey up which we referred in a recent number of NATURE. The map gives much information as to the character of the country along the banks of the river, and the people who inhabit them. As it is only six months since Dr. Lenz arrived at Kasonge, one cannot but remark the rapidity with which the journey between the coast and the centre of Africa can now be made. As a matter of fact, the London Missionary Society has a monthly mail between Zanzibar and Lake Tanganyika, and letters from their missionaries on the west shore of that lake reach London in three months.

THE same number contains the conclusion of Herr Baumann's very valuable description of the country and people on the Middle and Lower Congo; a paper on the high lakes of the Eastern Alps, by Dr. August Böhm; and a collection of recent statistics on the population of Bosnia and Herzegovina.

HERR P. LANGHAUS has been endeavouring to form an estimate of the native population in the Cameroons territory recently acquired by Germany. He confines himself to the coast region between the Rio del Rey and the Rio Campo, and gives 480,500 as the population on 26,000 square kilometres, or only 18 per square kilometre. The people mostly belong to the north-west branch of the Bantu stock, and Herr Langhaus gives some useful details as to their distribution and subdivision in the *Deutsche Rundschau* for January.

A NEW exploration of the districts on the Upper Meikong, inhabited by the Laos tribes subject to Siam, has attracted considerable attention in Paris. Towards the end of 1885, the Siamese Government found it necessary to undertake an expedition against these tribes (the principal of them being the Ho). An Italian officer, Capt. Pinson, who was a military instructor in the Siamese service, accompanied the expedition, which ultimately arrived at Muen-Son, fourteen days' march to the north-east of Luang-Prabang, in the centre of a region wholly unknown to Europeans, for these Hos had prevented Dr. Neis from completing his famous exploration of the whole of the Laos States. The expedition, owing to frontier complications with Tonquin, was not a success, and now M. Pinson has determined to explore the country for himself, partly with the object of discovering commercial routes along the Meikong into Yunnan and into Tonquin, both starting from Luang-Prabang, and also for geographical purposes. He has arrived in Paris to lay the project before the President of the Council and the various mercantile bodies. To the former he has presented a memorial asking to be despatched on the mission by the French Government. In this document he describes briefly the divisions of the Siamese Laos, the nature of the soil, the commercial situation of Great Britain in Burmah in regard to the Laos States, the alternative trade routes for Upper Laos—which he describes as by the Meinam to Bangkok (which appears the natural route), by the Ho country into Tonquin, or by the Meikong—and other details. He expresses the determination to return without delay to Luang-Prabang, and, if aided by the French Government, (1) to penetrate into Yunnan in order to study the peoples on the route and their commercial wants, and (2) to explore and study in like manner the two routes from the same town into Tonquin and Annam. The projected exploration, it will be observed, is mainly through unknown territory, Dr. Neis not having been able to penetrate a large part of this region.

IN the last number of *La Gazette Géographique* M. Kaltbrunner publishes an interesting article entitled "L'Indicateur Géographique." He first gives statistics of the various Societies for geography and the allied sciences in the world. According to continents, the number of these is as follows:—Europe 91, Africa 5, America 9, Asia 9, Australia 2, giving a total of 115. France heads the list with 28, then comes Germany with 23, then Italy with 8, Switzerland with 7, Austria with 6, and Great Britain with 4. The total number of periodicals treating of geography as a principal or accessory subject is 263, of which 214 are published in Europe, 14 in Africa, 19 in America, 15 in Asia, and 1 in Australia. France again heads the list with 79, Germany has 42, Great Britain 18, Italy 13, Austria and the United States 11 each. Many other interesting details respecting membership, amount of subscriptions, of Government assistance, &c., are given. In Great Britain, Germany, and France the average subscriptions per member are 70, 35, and 15 francs respectively. The writer complains that, notwithstanding the great number of French Societies and publications, no one publication similar to *Petermann* in Germany and the Proceedings of the Royal Geographical Society in England exists. He proposes, therefore, that a geographical indicator should be published containing the title, place of publication, summary of contents, price, and, where desirable, a critical review of all the geographical journals, as well as of new books, maps, &c. The editor of *La Gazette Géographique* promises to carry out the idea as far as possible by giving these details respecting such of the publications as have reached his hands since the beginning of the New Year.

DR. VON KLÖDEN recently published a list of 374 rivers, with their lengths, and other data, in which he gave the Nile as the longest river, with a length of 6470 kilometres, the Missouri-Mississippi coming second with 5882 kilometres. General von Tillo revises these estimates, and from more exact measurements concludes that the Missouri-Mississippi is the longest river in the world, with 6750 kilometres, the Nile coming next, with 6470 kilometres as in Von Klöden's list. Other rivers given both by Von Klöden and Tillo with the same measurements are the Ta-Kiang, 5083 kilometres; the Amazons, 4929; the Yenisei-Selenga, 4750; the Amur, 4700; the Congo, 4640; and the Mackenzie, 4615. In connection with this subject *Petermann's Mitteilungen* states that a new curvimeter is being practically tested in Perthes's geographical establishment; if the results are satisfactory it will be of great service to those who have much to do with maps.

THE Geographical Society of Mexico is about to resume the publication of its proceedings, which has been interrupted since 1882.

Cosmos announces the forthcoming publication of an important work on the geography of the interior of Madagascar, by a French Jesuit, Père Roblet, who has explored the greater part of the island. It will be accompanied by various topographical maps, especially of the provinces of Imerina and Betsileo.

AT a recent meeting of the Geographical Society of Paris, a note was read from M. Cervera, who is charged by the Madrid Geographical Society with a journey in Eastern Africa, on his itinerary. M. Raffray, the Consul of France at Zanzibar, sent a report on the results of Dr. Junker's last journey. M. Chaffanjon, writing from San Fernando, announced his approaching departure for the exploration of the Orinoco; and Dr. Chervin read an interesting paper on the increase of the populations of France and the principal States of Europe during the present century. In France the urban population was only 24 per cent. of the total in 1843, while now it is 35 per cent. The writer referred to the very slow increase of the population in France, although the average mortality is less than in other European countries. In some of the departments the population is even less now than it was in 1801. He thought colonial extension was one of the most efficacious remedies for a state of things which threatened to place France in a position of numerical inferiority towards other States. New colonies, he says, open new fields to future generations. The process suggested, however, appears like that of putting the cart before the horse.

THE INSTITUTION OF MECHANICAL ENGINEERS

THE Institution of Mechanical Engineers held its meeting in the Theatre of the Institution of Civil Engineers on Thursday and Friday of last week. The paper on "Triple Expansion Engines," read at the last meeting, of which we then gave an abstract, was discussed. The remainder of the papers on the programme were read and discussed.

Mr. E. P. Rathbone's paper on "Copper-Mining in the Lake Superior District" comprised a general description of the district, the method pursued in mining, and the system of ore-dressing and machinery employed. The ore employed is what is known mineralogically as "native copper." It does not occur in true fissure veins, but rather in beds, or, as they are not inaptly termed in the district, "belts," dipping at the same inclination as the "country" or rock inclosing them.

From exhaustive scientific investigations into the origin and derivation of the copper in these deposits, it appears probable that it was infiltrated into them in the form of an aqueous solution of copper, which also appears to have had a strong chemical affinity for special constituents of the rocks, thereby giving rise to a series of chemical reactions, whence resulted the precipitation of native copper in a more or less concentrated state, according to the proportion and the even distribution or otherwise of the precipitating or displacing agent present in the original rocks. In the amygdaloidal trap-rocks the displacing agent appears generally to have been less evenly distributed than in the conglomerates; in certain places the concentration of the displacing agent has been so excessive as to give rise to the formation of large masses of copper. Whether or not the precipitating action was connected with some natural process of lixiviation, influenced by terrestrial electrical currents, it is impossible to decide. In the amygdaloidal trap-rocks the veinstone is frequently composed largely of epidote, a mineral whose presence is regarded as favourable or "kindly" to copper. Other minerals found in association with the hornblendic and augitic porphyries that constitute the veinstone proper, are quartz, calc-spar, and many varieties of the zeolite group. The commercial copper smelted from these ores being entirely free from deleterious matters, such as arsenic, bismuth, antimony, &c., is especially valuable for electrical purposes, as the conductivity of copper is reduced by the presence of foreign matter even in the minutest proportions, a trace of arsenic reducing the conductivity 20 per cent. In the manufacture of brass, again, the presence of antimony is most deleterious: one-tenth of 1 per cent. converts first-rate "best selected" into the worst possible; one-fortieth of 1 per cent. renders it unfit for anything but inferior brass; one-eightieth of 1 per cent. changes "best selected" into "tough ingot"; one-tenth of 1 per cent. of either bismuth, arsenic, phosphorus, nickel, or cobalt, is sufficient to turn "best selected" into tough metal.

There are two methods pursued: "mass mining," where copper is found concentrated into masses varying in weight from a few hundred pounds up to many tons; and "stamp-rock mining," where the copper occurs in a more or less divided state, and usually pretty evenly disseminated throughout the whole veinstone, so that its separation from the matrix or gangue can be economically effected only by stamping and by the subsequent processes ordinarily employed in mechanical ore-dressing. The more evenly the copper is distributed throughout the veinstone, the more valuable is the latter, and hence it is that veinstone producing only 0·75 per cent. can be worked profitably at the present low price of copper.

The object of ore-dressing is to separate as far as possible the small percentage of valuable metal occurring in the ore from the worthless matrix or gangue, and concentrating it to the highest degree of purity practicable. The main feature of the process may be said to consist in applying to copper ore the principles and the machinery already employed elsewhere in the dressing of tin and lead ores.

In the Lake Superior copper-mining the features which appear to the author most worthy of special attention are:—(1) The care with which the exploratory workings are kept in advance of the stoping. (2) The general use of machine drills, which admits of opening up the mines at a rate otherwise impracticable. This is one of the few localities where drills are employed for stoping, and it has been found that two or three times as much rock can be stoped in the same time by drill as by hand. (3) The care bestowed upon the separation of the copper from the gangue by dressing.

M. Marc Berrier-Fontaine's paper was descriptive of his portable hydraulic drilling-machine, by means of which holes are drilled in a single operation through all the superposed thicknesses of metal without stopping the drill, which insures that all the holes are quite true. By its use 25 per cent. more holes are drilled than can be drilled by stationary machines in the shops.

Mr. H. Teague's notes on the pumping-engines at the Lincoln Water-works, which the Institution visited at its summer meeting last year, are mainly of a technical character. It is interesting to learn that when in 1884 still further pumping power was required, the author, from experience gained at Grantham, Maidstone, and other places, decided to revert to the Cornish pumping-engine, as he had been convinced that the cost of coals and repairs had been reduced in some instances to as low as only one-sixth of the annual expenditure pertaining to rotatory pumping-engines previously in use there.

THE SCOTTISH METEOROLOGICAL SOCIETY[1]

THE Journal of the Scottish Meteorological Society, which has recently been published, contains, in addition to copious tables of the meteorology of 1885, several papers of more than usual interest. Prof. Piazzi Smyth leads with a suggestive paper on hygrometric observation, based chiefly on observations made by him in the neighbourhood of Malvern in the summer of 1885, on fifteen successive days, at 9 a.m., in June, at a height of 125 feet; and subsequently for twenty successive days at the same hour but at a height of 350 feet. Scrupulous care was taken to have the dry-bulb surrounded with air as nearly as possible of the same quality as that of the free atmosphere outside, by placing a large and tall black iron chimney on the top of the Stevenson screen, according to Mr. Aitken's idea of promoting a current inside the screen; and to have the wet-bulb as perfect as possible by enveloping it in thin muslin, tightly drawn over its surface, and by securing that it was always thoroughly wet for each observation. The results gave for the lower station a mean depression of 3°·4 of the wet- below the dry-bulb; and 6°·4 for the upper station. It is probable that these results would be found to be higher than what obtained at the three or four stations in Central England nearest to Prof. Smyth's at the same dates; and without a doubt the value of the inquiry would have been enhanced if such comparisons had been made and recorded in the paper.

An important point would be gained if such inquiries led meteorologists more earnestly to consider the necessity of improving the means and methods of observing and reducing the observations of this most important element of the atmosphere, it being by its aqueous vapour that the disturbing influences at work are called into play, giving rise to winds, storms, rain, snow, hail, electric displays, and other atmospheric phenomena.

Mr. Omond, in an interesting paper on the wind and rainfall of Ben Nevis in 1885, based on the hourly observations at the Observatory, shows that the direction of wind with which most rain fell was a little to the north of west, and that the quantity diminishes round the compass in both directions from this until the driest point is reached a little to the south of east: east winds having a very low value. As regards the rate of fall with each wind during the time it lasts, north-westerly winds are the wettest and easterly and south-easterly winds the driest. Since south-easterly winds mostly occur when an anticyclone is moving off and a cyclone approaching, the fact of their dryness at the Observatory, 4406 feet high, is a valuable contribution to our knowledge of storms, since the same winds under the same conditions at lower levels are notoriously wet.

A hopeful inquiry is being carried on at the Ben Nevis Observatory by Mr. Rankin, first assistant, on rainband observations; and from the results already obtained there can be little doubt that when a complete low-level observatory, with hourly observations, has been established at Fort William, much light will be thrown on the vertical distribution of vapour in this part of Great Britain, and its important bearing on forecasting the weather. The observations for seven months are discussed, and the means show that a heavier rainband indicates with steady regularity a larger rainfall as determined by the hourly observations.

But the most important contribution of new facts in the Journal are thirty-nine pages of temperature observations made on the Firth and Lochs of the Clyde from March to November 1886, by

[1] Journal of the Scottish Meteorological Society, Third Series, No. iii. (Edinburgh and London: William Blackwood and Sons.)

the staff of the Scottish Marine Station on board the *Medusa*; the trips having been made in April, June, August, September, and November. The observations were made at all depths of the sea, from the surface to 107 fathoms. The novelty and, in not a few cases, the unexpectedness of the results render it advisable to delay a full discussion till more observations have been made and the densities worked out. In the meantime a provisional report on the results of the April and June trips, by Dr. H. R. Mill, will be read with interest. Among the unexpected results was the discovery in June in Loch Fyne of a lenticular mass of water with temperature below 43° floating between two warmer strata, the cold area being most definite at its upper surface and more diffused below. The greatest thickness of the mass of water colder than 43° was 180 feet, off Inveraray. Its lower bounding plane ran along the bottom from the head of the loch to Dunderave; then where the water deepens it dipped down again at the same angle until off Inveraray, where it bent up again and met the upper bounding surface at Furnace, 120 feet under the surface of the loch.

In a paper by the secretary on the meteorology of Ben Nevis, it is shown from the three years' observations at the low-level station and the high-level observatory that the mean decrease of temperature with height is at the rate of 1° F. for every 270 feet of ascent, the lowest monthly rate being 1° for every 284 feet in winter and the most rapid rate 247 feet in spring. A table of the barometric corrections for height for the different sea-level pressures and air temperatures that occur has also been prepared directly from the observations themselves. The importance of the results of these two inquiries rests on the fact that the Ben Nevis pair of stations alone supply, owing to their great difference in height, close proximity horizontally, and the positions of their thermometers, the physical data of observation which satisfy with sufficient closeness the requirements of these fundamental problems of meteorology. The science has now passed that stage when Great St. Bernard with Geneva, Mount Washington with Portland and Burlington, Hochobir with a station in one of the neighbouring deep valleys, or brief continued observations with balloons or at different heights on the slopes of the Faulhorn, can be accepted as affording the data required for dealing seriously with these questions.

REPORT ON THE BOTANICAL GARDEN, SAHARUNPUR

MR. DUTHIE'S "Report on the Progress and Condition of the Government Botanical Gardens at Saharunpur and Mussoorie for the Year ending March 31, 1886," which has recently reached us, contains, besides the usual routine matter, inseparable from such Reports, on the state of the Garden itself, much that has a wider range of interest. As usual, the cultivation of new plants of economic value appears to have occupied a considerable amount of attention during the year. Where so many useful plants have been introduced and reported upon, it is not an easy matter to select one or two for an example of the work in which Mr. Duthie is engaged. The character of this work is now, however, pretty well known, though the following extracts will show that plants of very varied character and uses are yearly being experimented with in our Indian and colonial botanic gardens.

Under the head of New Zealand spinach, a quantity of the seed of this vegetable is reported to have been received and planted, germinating freely and yielding a continuous crop of leaves, which, when cooked, is said to much resemble in flavour that of English spinach. The plants, Mr. Duthie says, seed freely, and he has no doubt that it will readily acclimatise; though, as he says, the introduction is not one of much importance, except for variety, as it comes into season at the same time as English kinds, and it can hardly compete with them in popular estimation. This so-called New Zealand spinach many of our readers will remember as *Tetragonia expansa*.

The Oca-quina (*Ullucus tuberosus*) is another food-plant upon which experiments in cultivation have been made. It is a native of South America, and the tubers, which are about the size of a walnut, and similar in appearance to a potato, are eaten, when cooked, by the people. Its cultivation in this country as a substitute for the potato was at one time proposed and attempted. Mr. Duthie says that twenty-eight tubers were received by him from the Royal Gardens, Kew, four of which were sent to the Arnigardh Garden, and the remainder were planted at Saharunpur. Up to within a few weeks of the date of the Report, these latter plants had made good growth, but after the commencement of the hot weather they became sickly, so that it is evident it will not suit the plains of India, but may succeed very well in the climate of Arnigardh, where it was intended that the majority of the plants should be sent.

Of the Japanese varnish-tree (*Rhus vernicifera*) the seedlings are stated to be making rapid progress. The growth for the two years after germination did not average more than a foot, which, however, has been doubled since the commencement of the hot season, and there is now no reason to doubt that this useful tree will thrive in the climate of Saharunpur. Mr. Duthie further says a small plantation will be made next rainy season, and it will then be a question of time as to when the plants will be ready for tapping.

Mr. Duthie makes the following interesting report on the subject of spider silk, which had previously attracted some attention. He says:—"I arrived from British Garwhal just in time to superintend operations at the commencement. The men employed on this work were provided with small sticks about a foot long, and they were told to collect as many clean webs as possible during the day. There was not much to show at the end of the day, as the silk takes up very little space when wound round these sticks, and the weight is inappreciable. The total weight of webs collected during the season did not exceed 10 lbs., the bulk of which was despatched to Mr. Wardle, of Leek. The cost of collecting the above, and the carriage from Bhim Teel to Saharunpur, and from Saharunpur to Bombay, amounted to Rupees 33 - 7 - 0. At this rate the export of spider silk to England would, of course, never pay, but expenses might be reduced very considerably: for instance, this first consignment included the weight of the sticks round which the silk was wound. The silk is removable after immersion in hot water. During my stay at Indalpur, in the Sháhjahánpur district, I saw some fine clean webs of the same kind in a forest about eight miles to the north of Indalpur."

Judging from the remarks of Mr. Duthie, there seems but little chance of spider silk ever becoming an article of commercial value.

The Report includes some interesting notes on some official tours made by Mr. Duthie during the year, and a valuable list of plants collected, the names of which have been verified at the Royal Gardens, Kew.

SCIENTIFIC SERIALS

Bulletin de l'Académie des Sciences de St. Pétersbourg, tome xxxi. No. 3.—Corrections and additions to the Syrian-German and Votyak-German dictionaries, published in 1880, by F. J. Wiedemann. These emendations are based on the following recent works: "The Land and Language of the Syrians," by Lytkin; the publications on the Votyak language issued by the Kazan Mission; "Votyak Tales and Proverbs," collected by Dr. Aminoff, and published in the works of the recently instituted Finnish-Ugrian Society; Dr. Max Buch's ethnographical sketch of the Votyaks in the "Actæ Societatis Scient. Fennicæ," vol. xii.; and MM. Koshurnikoff and Miropolsky's monographs on the Votyaks.—On the Ornis of the western spurs of the Pamir and Alai, by V. Bianchi—On "Claudii Galeni Pergameni Scripta minora," by L. Nauck.

Nyt Magazin for Naturvidenskaberne, vol. xxx. Nos. 3 and 4, Christiania, 1886.—This number of the Norwegian *New Journal of Sciences* contains:—Continuation of Herr Brögger's paper on the geological history of the Christiania Fjord. According to the writer, it may be assumed that the bed of the fjord has been raised by eruption to the surface of an older bed, which consists of depressed strata of the earth's crust, whose depression had been connected with active processes of dislocation, crumpling, and folding in the post-Silurian period. The evidences of erosion and eruption are considered at length, with special reference to the action of glaciers in the formation of the fjord. —Dr. Lang concludes in an exhaustive paper his contributions to the study of the eruptive rocks of the Silurian beds of Christiania, and thus completes an important chapter in the geological history of South Scandinavia.—Notice of *Regalecus glesne ascanius*, by Herr J. Grieg. This specimen, a female, with well-developed ovarium, is the fourteenth that has been taken off the Norwegian coasts since 1740.—Report of the various attempts made within the last four years to introduce new plants into Iceland, by Dr. Schierbeck. The results of these efforts to enlarge the meagre flora of the island are scarcely encouraging. Thus, although hopes are entertained that some kinds of maples may thrive in sheltered spots, conifers, from whose introduction great expectations were entertained, have not given promise of success, while poplars, oaks, apple and pear trees have without exception died. Common red- and black-currant bushes thrive so far as to set fruit, but this does not ripen except in the warmer summers. Potatoes, which would be invaluable to the islanders, have not yet been successfully cultivated, but turnips, rhubarb plants, and several of the hardier cabbages, together with lettuce and chamomile, do well. The great question, whether cereals can be cultivated, as would appear to have been the case in the times of the Sagas, does not seem to admit of a satisfactory solution, and, according to the writer, the present regular supply of corn from the mother-country by means of rapid steamers, no longer makes the attempt necessary or desirable from an economic point of view. An interesting list of the various plants introduced, with the times of sprouting, budding, &c., adds to the value of Herr Schierbeck's paper.

Revue d'Anthropologie, troisième série, tome ii., Paris.—Recapitulation, by M. Topinard, of the Society's instructions for noting the colour of the eyes and hair in France, with *facsimiles* of the printed papers distributed to intending observers, and directions how they should be filled up.—On a quinary nomenclature for the nasal index in the living subject, by Dr. Collignon. The writer, who considers a correct and systematically determined nasal index as the most important anthropometric determination, not excepting even the cephalic index, proposes to divide the ordinarily accepted nasal groups into hyper-leptorhinian, leptorhinian, mesorhinian, platyrhinian, and hyper-platyrhinian, including under the platyrhinian section all the black races, under the mesorhinian the yellow races generally, and under the leptorhinian most of the white races. The paper gives a clear and concise description of the instruments in general use, and of those best adapted for making the required measurements, which he regards as of paramount value in determining racial characteristics.—Contributions to the sociology of the Australian races, by Elie Reclus. This paper, which is principally concerned with the system of clanships and cousinships existing among these peoples, has comparatively little interest for English readers, who have long been familiar with the curious questions involved in the principles of inter-tribal relationship. Indeed, M. Reclus has drawn so largely from the writings of Brough-Smyth, Eyre, Howitt, Taplin, Morgan, McLennan, and other British writers, that this first part of his paper is a mere *résumé* of some of the more sensational details of information contained in their several works.—Anthropological observations in Guiana and Venezuela, by Dr. Ten Kate. These observations chiefly refer to the differences between the native Caribs, the so called "wood Negroes," and half-castes. The first of these present two distinct types, reminding the anthropologist of the Red Indians in some respects, and of the Mongolian races in others; the second are a specially vigorous black tribe, the descendants of runaway slaves domiciled in the forests of Surinam. Most of these men are of herculean strength and stature. Numerous anthropometric and other tables illustrate the paper.—On the depopulation of France, by M. de Lapouge. This subject, which has lately been attracting renewed attention through the appearance of the second edition of M. de Nadaillac's interesting pamphlet "On the Decline of the Birth-Rate in France," is considered by the author from an anthropological as well as a social and moral point of view. After drawing attention to the fact that while between 1770 and 1780 there were 380 births for every 10,000 of the population, this number has gradually fallen to 235 for the present decade, and is thus lower than that of Switzerland, which had been assumed to have the lowest birth-rate in Europe, and less than half that of Russia. According to the writer, the population of France has reached a stationary point, its annual increase of 80,000 admitting of no comparison with the hundreds of thousands, and even millions, annually added to the populations of Germany, Russia, the United States, and the British Empire, while, moreover, this slight increase is solely to be referred to the constantly increased immigration into France of foreigners, who now constitute one million of the population, and who predominate so largely at some points as to have reduced the French language to a secondary place in such districts. The writer discusses the various causes, such as the adoption of Malthusian principles, alcoholism, Catholicism, immorality, want of patriotism, self-interest, &c., to which the present low birth-rate has been referred. And rejecting these as inadequate, he insists that the main source of the increasing depopulation in France is the gradual obliteration since the great revolution of the blond dolichocephalic type, to which he considers most of the distinguished Frenchmen of earlier times belonged, while the representatives of the brachycephalic races, who have never distinguished themselves in science, art, or letters, have been able to take the lead through superiority of numbers. By their cupidity, narrow range of interests, and indifference to the traditions of family and national glory, he holds them responsible for the anomalous condition of the country, in which an unprecedented accumulation of wealth and great prosperity are associated with physical degeneration and diminished births. In the re-introduction of the dolichocephalic element through immigration the author sees the surest means of effecting a substitution of national type and the best prospects of securing renewed vitality to the French race.

Rendiconti del Reale Istituto Lombardo, December 1886.—Obituary notice of the late honorary member of the Institute, Signor Marco Minghetti, by the Editor. Reference is made more especially to the illustrious statesman's great merits as a political economist and art critic.—On the liquors employed in the artificial cultivation of Bacteria and other minute organisms, by E. L. Maggi. The various gelatinous, albuminous, and other solutions now in general use are described, with remarks on the best means of preparing and rendering them sterile.—On the geometry of linear spaces in a space of n dimensions, by Prof. E. Bertini. The author's theorem for ordinary space of three dimensions—"A necessary and sufficient condition for three straight lines to exist in a plane is that all straight lines meeting two of them at arbitrary points shall also meet the third"—is here generalised for a linear space S of any number n dimensions.—Meteorological observations made at the Brera Observatory, Milan, during the months of October, November, and December, 1886.

Rivista Scientifico-Industriale, December 1886.—Determination of the weight of the mercury contained in a thermometer, by Dr. G. Gerosa. Clayden having recently determined the volume of the mercury contained in a thermometer (Proceedings of the Physical Society of London, vol. vii. p. 367, 1886), Dr. Gerosa here gives a determination of its weight, which he had already worked out in the Rendiconti of the R. Academia dei Lincei, vol. x., 1881.—On the electric transmission of force, by Dr. Gerosa. The paper gives a critical appreciation of the work done by M. Marcel Deprez at Creil and by M. Fontaine in the Atelier Gramme. He considers the latter experiments the more successful of the two, M. Fontaine showing that with more economic means the same results may be realised as were obtained in the experiments at Creil.—On the development of electricity in the condensation of aqueous vapour, by Dr. Franco Magrini. In reply to Prof. Costantino Rovelli the author again shows that there is no perceptible development of electricity during the condensation of the vapour of water. A description follows of M. A. Nodon's hygrometer, already reported in the *Journal de Physique* for October 1886.

SOCIETIES AND ACADEMIES

London

Royal Society, January 13.—"Supplementary Note on Remains of Polacanthus foxii." By J. W. Hulke, F.R.S.

In a paper published in the Phil. Trans. 1881 the author described some remains of a large Dinosaur, remarkable chiefly for its dermal armour, discovered some fifteen years previously in Brixton Bay by the late Rev. W. Fox, and then in his collection. These have since become national property; and the large shield, which, for facility of transport, had been broken up by its discoverer into innumerable small pieces, having been recently reconstructed in the workshop of the British Museum, the author now describes this singular armature, and also some parts of the pelvis formerly obscured by rock. The pieces, which, in their very fragmentary condition, had been thought scutes, are now seen to be parts of a continuous osseous shield which protected the rump and loins, having its anterior surface ornamented with closely-set tubercles, and in each lateral half four longitudinal rows of keeled eminences. The ischium has its long axis directed transversely to that of the trunk, and not roughly parallel to it as in the Iguanodonts.

January 20.—"A Study of the Thermal Properties of Methyl Alcohol." By William Ramsay, Ph.D., and Sydney Young, D.Sc.

The writers have investigated the properties of the above substance, and obtained numerical values for the expansion of the liquid, the vapour-pressure, and the compressibility of the vapour; and from these results the densities of the saturated vapour and the heats of vaporisation have been deduced. The range of temperature is from $-15°$ to $240°$ C., and of pressure from 11 mm. to 60,000 mm. The apparent critical temperature is $240°$, and the pressure 59,660 mm. The pressures were corrected by means of Amagat's results, and the temperatures are those of an air thermometer.

January 27.—"On a Perspective Microscope." By G. J. Burch.

In 1874, the author, while trying to devise means whereby the different planes of an object should be visible under the microscope without the adjustment of the focus to each, discovered that, when two lenses are separated by a distance equal to the sum of their focal lengths, the optical conditions are such that the magnitude of the image bears a constant ratio to that of the object, no matter where upon the optic axis it is situated—the ratio being that of the focal lengths of the two lenses; that a given displacement of the object along the axis causes a displacement of the image in the same direction, but in the square of the ratio.

Further, that a picture drawn with the camera lucida under these conditions has the perspective of an object magnified in the square of the ratio, when it is brought within the proper distance of the eye.

The field of view of the perspective microscope is small, but may be increased by using more than two lenses, and the author's researches gave him reason to believe that, with glasses of wide angle specially constructed, a high power, with sufficiently large field, might be obtained. Several uses, other than microscopic, were indicated, to which the instrument can be applied.

The paper was accompanied by diagrams showing, in two different ways, the changes of position of the principal foci and principal points, &c., of a system of two lenses as the distance between them is varied.

A piece of moss was shown under the instrument, in magnified perspective.

"On the Thermo-dynamic Properties of Substances whose Intrinsic Equation is a Linear Function of the Pressure and Temperature." By Geo. Fras. Fitzgerald, F.R.S.

Prof. Ramsay and Mr. Young have found that within wide limits several substances in the liquid and gaseous states have the following relation connecting their pressure (p), temperature (T), and specific volume (v),

$$p = a\mathrm{T} + b,$$

where a and b are functions of v only.

Now in this case the following are the forms that the thermodynamic equations assume: T is temperature, and ϕ is entropy, and I is the internal energy.

Then $$\mathrm{I} = \gamma + \lambda,$$

where γ is a function of temperature only, and λ a function of volume only.

Also $$\phi = \Gamma + \alpha,$$

where Γ is a function of temperature and α of volume only.

Also, the specific heat at a constant volume is a function of the temperature only.

It would be most important if by some method, König's for instance, or by inserting a small microphone into a tube, the velocity of sound in substances in various states could be accurately determined, as that would enable us to determine separately the specific heats at constant pressure and constant volume.

Linnean Society, January 20.—W. Carruthers, F.R.S., President, in the chair.—Mr. J. Benbow and Mr. F. S. J. Cornwallis were elected Fellows of the Society.—It was announced from the chair that H.R.H. the Prince of Wales had officially entered his name on the roll of the Society.—The President made the presentation of an oil-portrait of Francis Masson, F.L.S., elected 1796.—Prof. Bayley Balfour exhibited specimens and showed the microscopic structure of the "ginger-beer plant." He pointed out that, although well known and used by many people as a means of manufacturing an acid drink out of sugar solution and ginger, yet no scientific account of the organism had appeared except a short note by Worthington Smith in the *Gardener's Chronicle*. It has the appearance of a white No toc, and is composed of a Bacterium (passing through all forms of rods, coils, and filaments), which apparently constitutes its greater part; and associated with this is a sprouting fungus. Judging from descriptions and figures by Kern of the "Kephir," used in the Caucasus to induce fermentation in milk, the ginger-beer plant closely resembles this; but there are many points of difference. The plant is said to have been introduced into Britain by soldiers from the Crimea.—A letter was read from Mr. Benj. Lowne referring to an exhibition by him of photographs from microscopical specimens of the retina of insects. One section represented the retinal layer detached from the opticon; other sections showed the basilar layer: thus practically affording evidence that the nerves terminate in end organs, rods placed in groups beneath the opticon—a view promulgated by Mr. Lowne in his memoir published in the Society's Transactions.—Mr. J. W. Waller exhibited a block of wood, part of an oak grown in Sussex containing an excavated tunnel and live larva of the longicorn beetle *Prionus coriarius*.—Mr. Thiselton Dyer showed and made remarks on two sheets of Arctic Alpine plants from Corea.—Mr. F. Darwin and Miss A. Bateson read a paper on the effects of stimuli on turgescent vegetable tissues, of which we hope to give an abstract in an early issue.—Mr. J. R. Vaizey read a paper on the morphology of the sporophore in mosses. According to his researches, the seta of mosses consists of an outer sclerenchyma, within which is parenchymatous tissue, and in the middle the "central strand"; this latter being surrounded by a single layer of cells, forming the endoderm, derived from the outer meristem of the growing apex. It consists of two forms of tissue, one being of thin-walled prosenchymatous cells destitute of protoplasm, their function being to conduct water: this the author terms *proxylem*. Surrounding this is a second cylinder of elongated cells with thickened walls, containing granular protoplasm; this tissue he terms *prophloëm*. On tracing the proxylem downwards, it is found that it gradually encroaches on the other tissues by the "foot," until it takes on the character of conducting tissue. The stomata on the theca are confined to the hypophysis: the form of stomata in which the guard-cells communicate is internally typical only of Polytrichaceæ and *Funaria*. In the young sporagonium five distinct meristems occur with different laws of cell-division; one form with an axial solid cylinder he terms "endomeristem." It gives rise to the central strand in the seta, and in the theca to so much of the tissue of the columella as lies within the sporagenous zone, the cells round this being derived from the "epomeristem," whilst the sporagonium layer is itself derived from the endomeristem. The hypophysis is an absorbing and assimilating organ, and performs all the functions of a leaf, and should be classed as a phyllome. The water-conducting tissue of the sporagonium only differs from the xylem of Vasculares in the absence of spiral thickening and lignification of the cells. The prophloëm differs even less from the phloëm of some Vasculares, and though no sieve-like tubes have been made out, yet they are wanting also in some Vasculares, *e.g. Selaginella*. The author compares the development of the sporagonium in some respects to certain parasitic plants; and he draws the conclusion that the Muscineæ are descended from an ancestor common to them and Vasculars, similar to the Anthocerotheæ, finally hoping in a future paper to deal with their phylogeny, specially referring to the vascular system and its homologue, the central strand of the Musci.

Anthropological Institute, January 25.—Anniversary Meeting.—Mr. Francis Galton, F.R.S., President, in the chair.—The following were elected Officers and Council for the ensuing year:—President: Francis Galton, F.R.S. Vice-Presidents: Hyde Clarke, J. G. Garson, M.D., Prof. A. H. Keane. Secretary: F. W. Rudler. Treasurer: A. L. Lewis. Council: G. M. Atkinson, Sir W. Bowman, Bart., E. W. Brabrook, Sir George Campbell, M.P., C. H. E. Carmichael, A. W. Franks, F.R.S., Lieut.-Colonel H. H. Godwin-Austen, F.R.S., Colonel J. A. Grant, C.B., T. V. Holmes, Prof. A. Macalister, F.R.S., R. Biddulph Martin, Prof. Meldola, F.R.S., Prof. Moseley, F.R.S., C. Peek, F. G. H. Price, Charles H. Read, Lord Arthur Russell, H. Seebohm, Prof. G. D. Thane, M. J. Walhouse.

Chemical Society, December 16, 1886.—Dr. Hugo Müller, F.R.S., President, in the chair.—The following were duly elected Fellows of the Society:—Messrs. Horace Edward

Brothers, Francis J. H. Coutts, Tamemasa Haga, Henry John Hardy, Michitada Kawakita, Walter Leach, Stephen James Pentecost, Henry Joshua Phillips, P. Yeshwant Sheshadri, Tetsukichi Shimidzu, Joseph Stapleton, William Phillips Thomson, Hikorokuro Yoshida.—The following papers were read:—Researches on the constitution of azo- and diazo-derivatives; (1) Diazoamido-compounds, by R. Meldola, F.R.S., and F. W. Streatfeild.—The influence of silicon on the properties of iron and steel, part 1, by Thomas Turner.—The distribution of nitrifying organisms in the soil, by R. Warington, F.R.S.—Isomeric change in the phenol series; the action of bromine on the dibromonitrophenols, by A. R. Ling.—Some azines, by Francis R. Japp, F.R.S., and Cosmo Innes Burton.

January 20.—Dr. Hugo Müller, F.R.S., President, in the chair.—The following papers were read:—Some silicon compounds and their derivatives, by J. Emerson Reynolds, M.D., F.R.S.—Chromo-organic acids; part 1, certain chromoxalates, by Emil A. Werner.—Note on the constitution of the double chromic oxalates, by W. N. Hartley, F.R.S.—Remarks on recent papers by A. Baeyer and J. Thomsen on the constitution of benzene, by Alex. K. Miller, Ph.D.

Royal Microscopical Society, January 12.—Rev. Dr Dallinger, F.R.S., President, in the chair.—Mr. J. Mayall, Jun., directed the attention of the meeting to eleven photo-micrographs sent by Dr. van Heurck, and which the latter thought showed results of exceptional merit. The one of *A. pellucida* by transmitted light was rather striking; it showed apparently two series of lines which were resolved into dots, and, so far as he was aware, this was the best of the kind which he had yet seen. But Dr. van Heurck did not say whether it was taken from a specimen mounted in a dense medium or not, and he thought also that several important questions of technique were omitted which it would have been very useful to have had mentioned. In the pamphlet which accompanied the photographs, Dr. Royston-Pigott was quoted to the effect that they were quite free from what used to be called "diffraction-spectra," which now here have no existence whatever; but on examination, unless he was much mistaken, they had been painted out, or otherwise blotted out, from the negative, so that Dr. Royston-Pigott, in his remarks upon this supposed fact, had made what the French called a *boulette*. If it was desired to give each photograph a real value, the background should not be interfered with, and each impression should have the particulars as to magnification, mounting, and other data for identifying the object, the possession of which was essential in order to form any reliable opinion. As regards the longitudinal lines of *A. pellucida*, as shown in the untouched negatives of these photographs, Dr. van Heurck said he had submitted them to Prof. Abbe, who replied that, as they appeared closer than the diffraction-lines, that was a satisfactory demonstration of their existence in the object. As to the photograph of *P. angulatum*, in which a central spot was shown, all who were familiar with the object were aware that they could get the appearance of a central spot or not, according to how they looked at it: it was a question of change of focus. *Surirella gemma*, he thought, was not better shown than in Dr. Woodward's photographs. Then there were photographs of Nobert's lines, which were said to be of the 18th and 19th bands; but here again there was nothing to enable one to identify them or to say that they were not the 14th and 15th bands.—Mr. M. Pillischer exhibited his new "Kosmos" microscope.—Mr. T. Charters White read a note on tartar from teeth of the Stone Age.—Mr. Crisp exhibited a cylinder of glass, which, though it had plane ends, acted as a concave lens, and solved some of the questions which had been raised as to the images formed in insects' eyes. He also explained Prof. Exner's method of preparing similar cylinders from celloidin and gelatine, when the effect of convex lenses was obtained.—Mr. Crisp directed the attention of the meeting to the figures of enormous microscopes in Schott's "Magia Naturalis," 1657. These had long puzzled microscopists, who were at a loss to understand what could be the object in making microscopes of the large size which was indicated by the comparison with the observers as looking through them. In Traber's "Nervus Opticus," what was undoubtedly meant for drawings of the same microscopes, the mystery was solved, for if Schott's figures were rubbed out, and single eyes were substituted for them, as Traber did in his drawings, the scale of the microscope represented was, of course, strikingly altered, and it was seen that they were small hand microscopes after all.—Mr. J. Medland exhibited and described his portable cabinet for microscopic slides.—Mr. Crisp exhibited Stein's electric microscope.—Mr. A. W. Bennett gave a *résumé* of his paper on freshwater Algæ (including chlorophyllaceous Protophyta of North Cornwall), with descriptions of six new species, illustrated by coloured diagrams.—Mr. J. Mayall, Jun., gave a very interesting account of a recent visit to Jena, where he had been afforded every facility for examining all the processes of manufacture as carried out in the factories of Dr. Zeiss. He also described his interviews with Prof. Abbe, and the way in which they had together tested numerous objectives which he had taken for the purpose.—Dr. A. C. Stokes's paper, on some new American freshwater Infusoria, was read.—The nominations for the new Council were read, and auditors appointed.

PARIS

Academy of Sciences, January 31.—M. Gosselin, President, in the chair.—On the commensurability of the mean movements in the solar system, by M. F. Tisserand. The object of this paper is to throw some light on the delicate question, how far exact commensurability is compatible with the stability of two or more bodies revolving round a common centre, as maintained by Gauss, and more recently by Gyldén and Harzer, and denied by W. Meyer in his memoir on "The System of Saturn," Geneva, 1884.—Metals and minerals from ancient Chaldæa: on the sources of tin in the Old World, by M. Berthelot. The analysis of certain metallic remains from the Palace of Sargon at Khorsabad and from Tello in Babylonia, combined with recent reports of tin mines now being worked in various parts of Khorassan, suggests the question whether tin may not have been derived from that region by the Assyrians and Chaldæans long before its arrival from the more remote Sunda Islands and Malay Peninsula in the East, or from Cornwall and one or two other parts of Europe in the West.—Experiments on the effects of transfusions of blood in the head of decapitated animals, by MM. G. Hayem and G. Barrier. The results are described of experiments on the head of dogs immediately, and some time after separation from the trunk, such as those studied some thirty years ago by M. Brown-Séquard, but not since renewed by physiologists. The authors conclude generally that the extinction of feeling and will is extremely rapid, if not instantaneous, after decapitation; that conscious life may be sustained by the immediate injection of arterial blood from any animal of the same, or even of a different species; and that such transfusion, made after some minutes' delay, may stimulate certain automatic and multiple reflex movements, but is powerless to re-awaken either sense or will.—Observations of the new comets of Brooks and Barnard, made at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan.—Observations of the same comets made at the Observatory of Bordeaux with the 0·38 m. equatorial, by MM. G. Rayet and Courty.—On a method for determining the constant of aberration, by M. J. C. Houzeau. The author points out that the fundamental principle of this method, as recently submitted to the Academy by M. Lœwy, had already been indicated by him in a paper on the study of the movements of the stars, published in 1871, in vol. xxxviii. of the Mémoires of the Belgian Academy.—On the mean periodicity of the spots in Jupiter, by Dom Lamey. By a careful study of older maps of this planet (which is still in a state of incandescence analogous to that of the sun), combined with more recent observations at the Observatory of Grignon, the author deduces a mean periodicity of 5·43 ± 0·07 years for its spots.—On the theory of algebraic forms with *p* variables, by M. R. Perrin.—Researches on the transmission of electricity of feeble tension through the medium of hot air, by M. R. Blondlot. This is a summary of the author's researches on the transmission of an electric current through heated air, which form the subject of a memoir presented by him to the Academy. It is shown that hot air has, properly speaking, no resisting power, and he feels inclined to attribute the phenomenon to the principle of *convection*, as described by Faraday.—On the variable period of the currents in the case of circuits containing an electro-magnet, by M. Leduc.—On a halo accompanied by parhelia, observed at Fontainebleau on January 28, by M. A. Bouisson. This phenomenon, observed between 9.30 and 10 a.m., presented the appearance of a luminous circle, with a radius of about 23°, concentric with the sun, passing from a light brown in the centre to a greyish-yellow on the periphery. A second luminous circle, concentric with the preceding, with a radius of about 47°, showed in its upper segment the colours of the rainbow, red on the inner side. Tangential to both circles were vividly coloured arcs, the brilliancy of the latter decreasing rapidly towards the extremity, while a luminous horizontal band passing through the centre of the sun stretched across the firmament, showing three parhelia—two very bright on the small, one faintly illumined on the large, circle.—Combinations of the glycerinates of soda with the monatomic alcohols, by M. de Forcrand. This paper deals with the glycerinates of methylic, ethylic, propylic, isobutylic, and amylic soda.—On the comparative actions of solar heat and light, by M. E. Duclaux. It is shown that all the effects of combustion produced by heat may also be produced by light; but the reverse does not hold, there being a large number of reactions, which light alone seems capable of determining. All these reactions are resumed in the displacement of the primitive molecule, which becomes decomposed in a few simpler elements, such as the formic, acetic, and butyric acids, the methylic and ethylic alcohols, &c.—On the properties of inosite, by M. Maquenne. Continuing his study of this substance, the author shows that in its transformation it may give rise to several well-defined aromatic compounds. Its other properties, he considers, may now be anticipated theoretically.—On a combination of paratoluidine and chloride of copper, by M. E. Pomey.—On the composition of the grains of *Holcus sorgho*, and their application to the agricultural industry in the south of France, by M. Bordas. The analysis of this grain shows a mean of 42 per cent. of starch, 100 kilogrammes yielding 26 litres of good alcohol at 33° above proof.—On the jugal and pterygoid stems in the vertebrates, by M. A. Lavocat.—On the heterogamy of *Ascaris dactyluris*, by M. Macé.—Reply to M. Balbiani on the subject of *Leucophrys patula*, by M. E. Maupas. The author shows that he has in no way exaggerated the novelty and interest of his observations on the various reproductive processes of this organism, as asserted by M. Balbiani.—On diurnal and nocturnal physiological variations of the cerebral pulse, by MM. Rummo and Ferrannini. The authors' observations establish a complete cycle or periodicity in these variations, from which they hope to deduce the biological theory of normal sleep.—On the secreting ducts and aquiferous apparatus of *Calophyllum*, by M. J. Vesque.—On certain phenomena of linear corrosion in the limestone formations of Couzon, Rhone Valley, by M. Ferdinand Gonnard.—On the epoch when the submerged valleys of the Gulf of Genoa were formed, by M. A. Issel. All these riverain valleys along the coast of Liguria appear to have been submerged towards the close of the Messinian and during the Astian epoch.

Berlin

Meteorological Society, December 7, 1886.—Prof. von Bezold in the chair.—Dr. Hellmann stated that he had examined the observations of the County Fire Insurance Society in Schleswig-Holstein for the years 1874-83 for the purpose of investigating the question of lightning flashes in this province, and communicated the results of that investigation. As is the case in every other locality in which investigations of this description had been carried out, it was shown that generally over the whole province of Schleswig-Holstein there is an increase in the amount of damage wrought by lightning for the decade in question. On a comparison, however, of the different districts, it was found that the territory to the south of the Eider had experienced an abatement of damage by lightning, while to the north of the Eider, along the North Sea, and especially in the marshes, there had been a considerable increase. A computation of damage from lightning for one year demonstrated a very decided maximum in August in the continental, southern, and south-eastern districts, whereas in the north and west a summer maximum of less intensity and two still weaker maxima in May and October became apparent. In respect of a daily period it appeared that in the case of the first group of districts a maximum appeared in the hours from noon to 3 in the afternoon, while in the remaining part of the province the maximum was attained from midnight to 3 in the morning. This night maximum was specially characteristic of winter. The frequency of thunderstorms had no relation to the danger from lightning. The number of destructive lightnings depended in large part on the way in which the houses were roofed. The number was considerably greater in the case of soft than of hard roofs. In the case of churches the danger from lightning was 39 times, in the case of windmills 52 times, as great as in the case of houses having hard roofs. In regard to the cause of the different degrees of danger from lightning in the different districts, investigation indicated two points as determinative: first, the way in which the ground was built upon, and second, the geological nature of the ground. Whilst in the west, which was very liable to destructive strokes of lightning, the farmsteads were detached and scattered over the whole land; in the east and south they were grouped together into villages, and the danger from lightning was always considerably less for larger collections of houses than for scattered houses forming the only prominent objects throughout wide spaces. In point of fact, the danger from lightning was everywhere considerably less for towns than for rural districts. With reference to the geological bearings of the question, the danger from lightning was least for calcareous sand and greatest for clay. Dr. Hellmann had likewise discussed the statistics of lightning for Baden and Hesse Darmstadt, with the result that he found during the period investigated a considerable increase of damage by lightning for the southern part of Baden, and a decrease for the north of Baden and for Darmstadt. Besides a confirmation of the results arrived at for Schleswig-Holstein there appeared in the Baden-Darmstadt region a decided preponderance of danger from lightning in the Rhine plain as contrasted with a very low degree of danger in the mountains.

BOOKS AND PAMPHLETS RECEIVED

Notes of a Naturalist in South America: J. Ball (Kegan Paul and Co.).—United States Commission of Fish and Fisheries, Report, 1884: (Washington).—Berichte von dem Erzbischöflich-Haynaldschen Observatorium zu Kalocsa in Ungarn: C. THE ORIGIN OF MOUNTAIN RANGES

The Origin of Mountain Ranges considered Experimentally, Structurally, Dynamically, and in Relation to their Geological History. By T. M. Reade, C.E., F.G.S. (London: Taylor and Francis, 1886.)

THAT the skin of our mother Earth's face is wrinkled and shrivelled, is one of the common facts of geology. True it is that with fine feminine instinct she strives to hide the ravages of time beneath a fair covering of grass, moss, and herbage, and gracefully does her best to make her old age comely; and we love her for her skill in covering up the signs of her years. But we are fain, directly we look below the surface, to admit that the wrinkles are there. And the parallel is not a fanciful one, for it has long been a favourite theory among geologists that the wrinkled skin of old age, and the foldings and bendings which are everywhere to be discerned in the layers of the skin of the earth, are due to similar causes. In both cases, something underneath the skin, which in youth kept it stretched and tense, has shrunk away, and the skin has shrivelled up. In the case of the earth it is the gradual contraction of the interior as it cools, which has caused it to draw away from the outer shell; and the crust, as it follows down the shrinking nucleus, has to pack itself into a smaller space, and consequently becomes crumpled up. This explanation is known as the "Contraction Hypothesis." Numbering as it does many supporters, it has had at the same time some vigorous opponents. In his "Physics of the Earth's Crust," the Rev. Osmond Fisher was led to the conclusion that the contraction hypothesis would not furnish anything like the amount of elevation that has actually occurred in the case of the earth. We admire the ingenuity and elegance of Mr. Fisher's mathematical work, but we cannot help recollecting Prof. Huxley's warning, that mathematics is like a mill, and that what you get out of it depends entirely on what you put in. Mr. Fisher puts in a supposition made by Sir W. Thomson, as to the way in which the earth cooled. There have been people bold enough to think that in making this supposition a great master of physics for once lent his name to an hypothesis which is in itself physically not very probable; and these same people are inclined to hold that probably Mr. Fisher's calculations tend to show that this is the case, rather than that the contraction hypothesis is inadequate.

Capt. Dutton, of the United States Geological Survey, is another doughty opponent of the contraction hypothesis. His notion as to what that hypothesis is appears in the following passage, which is quoted in the volume before us (p. 126, note):—

"The line of argument which is relied upon to sustain a cooling globe proves, when pushed to its consequences, that the great interior of the earth has not as yet undergone any sensible amount of cooling. The only cooling which that argument admits of has been located in a thin external shell. . . . In short, the cooling would be only skin deep, while the nucleus is about as hot as ever."

This may be called "pushing an argument to its consequences"; but if it be, that phrase certainly means, in plain English, putting, of course unintentionally, into your opponents' mouths, statements which they never made. If it is asserted that the crust cools faster than the nucleus, which is all the supporters of the contraction hypothesis ask for, is this the same as saying that the nucleus does not cool at all?

Now Mr. Mellard Reade joins the attack, and in an elaborately illustrated volume of some 300 pages gives us his reasons for dissenting from the contraction hypothesis, and for preferring a modified form of the explanation put forward originally by Scrope and Babbage. These geologists pointed out that whenever a great thickness of sedimentary deposits was laid down the subterranean surfaces of equal temperature would necessarily rise, the increase in temperature would cause expansion, and as a result of this a rise in the surface would follow. Mr. Reade maintains that vertical elevation would not be the only result, but that pressures would be set up in the mass competent to produce folding, contortion, inversion, crushing, and all the violent disturbances which are found in mountain-chains and other disturbed portions of the earth's crust.

The book has two merits: it takes nothing for granted, and it does not err on the side of assuming too much knowledge on the part of its readers. But it is a question whether virtue may not run to excess, and there is reason to fear that this has been the case here, for a very large part of the volume is taken up with the establishment and illustration of physical facts of the most elementary character, and of geological truths which are to be found in every text-book. For instance, Chapters III. and IV. are devoted to the establishment of the facts that metals and stone expand when their temperature is raised; that, when they are prevented by constraint from relieving themselves by lateral expansion, they buckle up; and that if their elasticity, or, as the author prefers to call it, their tensile strength, is small, they do not return to their original shape on cooling. The cases quoted, and the experiments which are illustrated by six full-page plates, are apt and to the purpose; they would be admirably suited for illustrating class-teaching in an elementary school. But it is hard to believe that any one could have seriously thought they would be required by the class of readers to whom the book is presumably addressed.

Chapter V. opens with the statement that "It has been a subject of remark and wonder to more than one eminent geologist that all the greatest mountain ranges are, geologically speaking, so comparatively modern." A broad generalisation like this deserves to have stress laid upon it, but it has been so long one of the common truths of geology, that it has ceased to be, if it ever was, a source of wonder to any one who has an elementary knowledge of the science. Indeed, there is an air of *naïve* surprise running through the book which now and again moves a kindly smile as we read, and we feel it refreshing to discover that truths, which have grown somewhat hackneyed to the majority of geologists, still retain a certain charm of novelty for the author. Thus Mr. Reade seems in more than one passage to take a little credit to himself for having discovered that what are generally called "anticlinals" are really elongated ellipsoidal domes—a fact which is rapidly brought home to any one who happens to work for a few weeks in a country where the rocks are moderately folded, and which was insisted on and fully illustrated in a manual of geology published fourteen years ago, and then could hardly have been said to be new. The distinctive characters of mountain chains are treated of in the same spirit. Little, if anything, is here added to the masterly summary of these characters which Dana gave us years ago, but much space is taken up with illustrations of truths which every one admits, in the form of long quotations from sundry sources. All this speaks to much reading and patient industry, and we cannot but admire the conscientious care with which Mr. Reade has striven to inform himself of all that has been said and done on the subject of which he is treating; but we cannot help asking ourselves whether it was necessary to print at length the contents of his note-books. This accumulation of evidence, where it is not needed, has brought with it an attendant evil: it has swelled the book to an undesirable size. Now in these busy days, and in the interest of readers, if there is one thing against which, more than anything else, a resolute stand ought to be made, it is unnecessary printing. The day is yet far distant when every page of printed matter shall contain something that is new, and nothing that is not new; but this is the impossible ideal, the asymptotic consummation, which all writers should ever keep prominently in view.

But we would not press this point, because, even if the author has given us rather an excess of matter that is not new, what he has given is good of its kind; and it is of more importance to weigh his arguments against the contraction hypothesis, and in favour of the Scrope-Babbage explanation with the additions he suggests to it. Holding as he does that expansion by heat is the main factor in producing the disturbances of the earth's crust, he made experiments to determine the coefficients of expansion of sundry rocks. He arrives at a mean which agrees very nearly with that found by Mr. Adie. Mr. Reade's experiments ranged from temperatures of 60° to 220° F., and he assumes that the coefficient of expansion will be the same for the enormously higher temperatures with which he has to deal when considering the case of the earth—a risky proceeding, to say the least. But he has fallen into a far more serious mistake: he has assumed that rocks weighted with a thickness of twenty miles of overlying strata will expand to the same extent for a given increase of temperature as rocks under atmospheric pressure. The oversight involved in this assumption so thoroughly vitiates all his numerical results that no conclusion can be drawn from them.

In Chapter XI. we have the objections to the contraction hypothesis succinctly stated. The numerical results we put aside for reasons just given, but in his general argument the author does not seem to us to realise the full meaning of the hypothesis. He seems to hold that according to the contractionists crumpling is produced by unequal contraction *in the solid shell itself*, which certainly is not their view. And he entirely omits all reference to the one fact which is the life and soul of the hypothesis, that the earth's crust is not strong enough to stand by itself without support, a fact which admits of rigid mathematical demonstration. It is a decided case of a seriously mutilated representation of the play of "Hamlet."

We cannot therefore admit that Mr. Reade's arguments are very damaging to the hypothesis against which they are directed; and we cannot see how expansion due to rise of temperature could alone produce the results which he attributes to it. The strains produced in this way would tend to be relieved by yielding in the direction of least resistance—that is, vertically; and if there were no impediment to the perfect transmission of strain, the yielding would be wholly in this direction. In the actual case a certain amount of deformation would doubtless be produced within the heated mass itself, but hardly enough, it would seem, to cant over a huge anticlinal, and lay it nearly flat on its side. The machinery invoked by the contraction hypothesis may or may not have been the means by which such overthrusts were brought about, but it is the only machinery yet suggested which seems competent to produce them. "Seems," we say throughout, for the question between rival hypotheses is as yet only one of probability.

And we think no one will contend that the Scrope-Babbage hypothesis ought to be entirely put on one side when we speculate on the cause of earth-movements; great broad folds, such as those of the plateau-region of Utah, described by Capt. Dutton, and figured on Plate 39 of the book, may have been caused by the bulging up of heated masses below, though they can be explained equally well by the contraction hypothesis.

It remains to notice that the book is rich in figured illustrations. A number of the plates are devoted to somewhat diagrammatic landscapes of contorted rocks, and these bring out well the points they are intended to illustrate; but they do not add to the stock of our knowledge. They would be serviceable to a geologist, if such a one there be, who had never stirred out of the fen-country, but he of course would do still better if he took an excursion ticket to some of the localities from which the views are taken.

A. H. GREEN

ORGANIC EVOLUTION

The Factors of Organic Evolution. By Herbert Spencer. (London and Edinburgh: Williams and Norgate, 1887.)

MR. HERBERT SPENCER has done well to reprint in a permanent form his two articles on the "Factors of Organic Evolution," which were published last year in the *Nineteenth Century;* for, although they present substantially the same doctrines as are to be met with upon this subject in his "Principles of Biology," they do so in the light of fuller knowledge and more matured judgment.

The object of the essay is that of taking stock, so to speak, of natural selection as compared with other "Factors." Mr. Spencer's treatment of this subject is admirable, and ought to be read by all working naturalists who have any interest in the problems of evolution. The literature of Darwinism has now become so extensive that even first-rate naturalists who are engaged on other lines of work are apt to get left behind, or, with respect to Darwinism, themselves to become examples of what are now called "vestiges": their ideas are the superseded survivals of some previous phase of evolutionary science. And most of all is this true with regard to the fundamental question so ably discussed by Mr. Spencer. As he remarks, "Nowadays most naturalists are more Darwinian than Mr. Darwin himself," by which he means that most naturalists attribute more to the agency of natural selection than was attributed to it by the final judgment of its discoverer. The reason of this is that most naturalists have neither read with any care the later editions of Mr. Darwin's works, nor probably even so much as heard of the sundry essays which led him to modify his views upon the comparative importance of natural selection and other factors of organic evolution. Such naturalists, therefore, are not true Darwinians. Still believing in natural selection as almost the only factor of organic evolution, they are archaic enough to suppose that distinctions of specific value are almost universally of an adaptive kind. In this respect, indeed, they share what is no doubt still the popular impression of Darwinism, but an impression, nevertheless, which does a great injustice to the genius of their master. In order that there may be no mistake upon this matter, we will here supply a few quotations from the latest editions of Mr. Darwin's works, over and above the numerous extracts which Mr. Spencer has selected for the same purpose.

"I now admit, after reading the essay by Nägeli on plants, and the remarks recently made by various authors with respect to animals, more especially those recently made by Prof. Broca, that in the earlier editions of my 'Origin of Species' I perhaps attributed too much to the action of natural selection, or the survival of the fittest. I have altered the fifth edition of the 'Origin' so as to confine my remarks to adaptive changes of structure; but I am convinced, from the light gained during even the last few years, that very many structures which now appear to us useless will hereafter be proved to be useful, and will, therefore, come under the range of natural selection. Nevertheless, I did not formerly consider sufficiently the existence of structures, which, so far as we can at present judge, are neither beneficial nor injurious; and this I believe to be one of the greatest oversights as yet detected in my work." ("Descent of Man," 2nd edition, p. 61. He goes on to explain how he was led to the "tacit assumption that every detail of structure, excepting rudiments, was of some special, though unrecognised, service," and concludes by remarking that "any one with this assumption in his mind would naturally extend too far the action of natural selection.")

"In the earlier editions of this work I underrated, as it now seems probable, the frequency and importance of modifications due to spontaneous variability" ("Origin of Species," 6th edition, p. 171). "It appears that I formerly underrated the frequency and value of these latter forms of variation, as leading to permanent modifications of structure independently of natural selection. But as my conclusions have lately been much misrepresented, and it has been stated that I attribute the modification of species exclusively to natural selection, I may be permitted to remark that in the first edition of this work, and subsequently, I placed in a most conspicuous position—namely, at the close of the Introduction—the following words: 'I am convinced that natural selection has been the main but not the exclusive means of modification.' This has been of no avail. Great is the power of steady misrepresentation; but the history of science shows that fortunately this power does not long endure" (*Ibid.* p. 421).

"When, from the nature of the organism and of the conditions, modifications have been induced which are unimportant for the welfare of the species, they may be, and apparently often have been, transmitted in nearly the same state to numerous, otherwise modified, descendants. . . . A structure, whatever it may be, which is common to many allied forms, is ranked by us as of high systematic importance, and consequently is often assumed to be of high vital importance to the species. Thus, as I am inclined to believe, morphological differences, which we consider as important—such as the arrangement of leaves, the division of the flower or of the ovarium, the position of the ovules, &c.—first appeared in many cases as fluctuating variations, which sooner or later became constant through the nature of the organism and of the surrounding conditions, but not through natural selection; for, as these morphological characters do not affect the welfare of the species, any slight deviation in them could not have been governed or accumulated through this latter agency" (*Ibid.* pp. 175, 176).

These quotations are added to those which have been supplied by Mr. Spencer, in order still further to advance the "motive" with the expression of which his essay concludes. After directing attention to the present views of Prof. Huxley upon the subject—viz. "How far natural selection suffices for the production of species remains to be seen"; and "Science commits suicide when it adopts a creed"—Mr. Spencer closes with the following remarks:—

"Along with larger motives, one motive which has joined in prompting the foregoing articles has been the desire to point out that already among biologists the beliefs concerning the origin of species have assumed too much the character of a creed; and that while becoming settled they have become narrowed. So far from further broadening that broader view which Mr. Darwin reached as he grew older, his followers appear to have retrograded towards a more restricted view than he ever expressed. Thus there seems occasion for recognising the warning uttered by Prof. Huxley as not uncalled for. Whatever may be thought of the arguments and conclusions set forth in this article and the preceding one, they will perhaps serve to show that it is as yet far too soon to close the inquiry concerning the causes of organic evolution."

Of these two articles the first is devoted to a consideration of use and disuse as causes of such evolution, while the second treats of the influence of surrounding conditions. The latter is the more highly speculative, and therefore may be here considered in fewer words. The idea is that all external parts of organisms, being exposed to different physical conditions from the internal parts, must be differently affected thereby: natural selection apart, there must here be recognised the differentiating agency of a direct or purely physical kind. Hence a certain rough analogy is drawn between a cell-wall, or cuticle, and the oxidised exterior of an inorganic body. Many of the differentiations undergone by the epiblast in the course of organic evolution may, it is argued, be best explained by the immediate action of external agencies—just as we know that a surface of mucous membrane, when brought into permanent relation with such agencies, changes from cylinder epithelium to squamous epithelium: "the effect of the medium is so great that, in a short time, it overcomes the inherited proclivity, and produces a structure of opposite kind to the normal one." Many other examples of the same general principle are given; but the essay as a whole is ingenious rather than convincing. Not, of course, that we dispute the principle—which, indeed, is recognised by Mr. Darwin, in one of the passages above quoted, and elsewhere—but it is of too general a kind to admit of being clearly traced in particular instances, where we have to do with all the other elements in the complex of living material.

The main question, however, with which Mr. Spencer is concerned is as to the place which should be assigned to use and disuse as factors of organic evolution. This long-standing question is one of fundamental importance to the whole philosophy of evolution; and as it has now reached a critical phase, the publication of Mr. Spencer's essay furnishes a fitting opportunity for considering its present position in all its bearings. This, therefore, we shall endeavour to do at an early date, in the form of a general article dealing with all the more important literature upon the subject. GEORGE J. ROMANES

TEXT-BOOK OF BRITISH FUNGI

An Elementary Text-book of British Fungi. By William Delisle Hay, F.R.G.S. Royal 8vo, cloth, illustrated. (London: Swan Sonnenschein, Lowrey, and Co., 1887.)

WE have little sympathy with such publishers as produce books written "to order" for the purpose of utilising illustrations, or matching. Still, we cannot help feeling some sympathy with, and pity for, the poor unfortunate who is called upon to perform such an unthankful office as the preparation of "copy." In so far as the book before us corresponds with such conditions our author commands our sympathy, perhaps he deserves it, for even in the preface he seems to fall on his knees, and sue, *in formâ pauperis*, for pity from readers and critics alike. There is doubtless a history connected with this volume. The woodcut blocks which accompany the text, but do not illustrate it, formerly did duty in the "Hand-book of Fungi" published more than fifteen years ago. In the way of business they were transferred, and, in order to utilise them, the "Text-book" seems to have been projected. There are 64 pages of figures and 238 pages of letterpress, but only about 16 pages of the plates have anything to do with the letterpress, and are not even mentioned, so that there are no less than upwards of 40 plates which are supplementary to the letterpress, and have nothing whatever to do with it, except to increase the bulk of the book. We do not know what purchasers would expect to meet with in "an elementary text-book of British fungi," but we suspect that they would scarcely be satisfied with a "treatise on edible and poisonous fungi," or, as set forth in the preface, an attempt "to cover as comprehensively and accurately as possible the entire subject of fungi, considered as aliment." Indeed, it would have been more correct to call this "An Elementary Text-book of some Species of British Fungi."

The professed object of this book, in so far as its writer was concerned, was to present a guide, which above all things should be safe and trustworthy, on the subject of fungus-eating—"so far as toadstool-eating goes," he writes, "I believe I have a right to speak with authority"—and hence if this professed object is not attained, the book must be confessedly a failure. "For the most part," he says, "subsequent authors have added little to what Dr. Badham had advanced." The inference must be that he was ambitious of making a considerable advance, "directed and inspired by a wide acquaintance with mycological literature." After this spontaneous confession it is surprising to find him stating as a fact that "some four hundred and fifty species of the genus *Agaricus* are recorded as occurring in Great Britain," on the faith of a work published now sixteen years ago; his knowledge of mycological literature having stopped short of the fact that nearly 700 species have already been figured, and the latest work on British fungi records 782 species as British, so that the total is nearly double that which his "wide acquaintance with mycological literature" had revealed to him. Leaving, however, such trivial details, let us turn to the "Comprehensive Catalogue of Esculent British Fungi." The first thought is naturally one of order. To assist in reference, and in producing favourable results, one would have hoped to see some method in the grouping of the 221 supposed esculent species. Scientific method there is none, for the white-spored, pink-spored, and brown-spored Agarics are jumbled together in glorious confusion. This would be tolerable if in compensation the species had only been grouped in sequence, or in sections according to their esculent value, but even this has not been done. In two or three instances, however, the species of a given genus are classed in the alphabetical order of their specific names.

Space will not permit of our remarking upon all the individual species included in this miscellaneous list of fungi recommended for common consumption by one who "believes he has a right to speak with authority." For ourselves, we should not have recommended *Agaricus asper*, for with considerable experience we do not remember to have met with it but once in thirty years; nor *Agaricus cæsareus*, for we venture to declare that it has never been found in the British Islands at all, and the same must be said of *Polyporus corylinus* and *Polyporus tuberaster*. Why, then, are they included in a "Catalogue of Esculent British Fungi"? Worse still—because far more dangerous—why are such species included as *Agaricus sinuatus*, which nearly killed Mr. Worthington Smith, and *Lactarius piperatus*, *Lactarius turpis*, and *Lactarius torminosus*? If there are such things as dangerous fungi at all, these are of them. If this writer is really acquainted with these species, and pronounces them edible, let him eat them and enjoy them, but not recommend them to an unsuspecting public. It is our firm and conscientious belief that a book which seriously recommends such things as articles of food might produce calamitous results, if widely circulated, or even, if not, in the event of other books or journals repeating upon its authority that these may be eaten. We read in the preface these significant words: "It has never been my privilege, as yet, to meet with any person versed in mycology from whom I could derive instruction." When the writer meets with such persons we advise him to propose to them an experiment in eating *Lactarius piperatus*, or *Lactarius torminosus*, or even *Agaricus sinuatus*, and we rather fancy that such mycologists will have but little faith in his practical mycology. We sincerely hope that he will not meet with "persons versed in mycology" for the first time in a coroner's court, over a case of poisoning induced by his recommendations. It would have given infinitely more satisfaction, and been far safer for his reputation, had the list of esculent fungi been confined exclusively to species known to be good eating and worth the trouble of collecting, excluding such minute species as *Agaricus clavus*, and *Agaricus esculentus*, and *Agaricus griseus*, with a cap as large as one's little finger nail, and a stem but little thicker than a horsehair, and including *Agaricus elvensis* and *Agaricus hæmorrhoidarius*, with a few others, large, fleshy, and as safe and delicious as the finest mushroom ever cultivated. But perhaps, though known to mycologists, they were disregarded by the writer of the "Text-book," or contemptible in his eyes beside such delicacies as *Agaricus sinuatus* and *Lactarius piperatus*. Perchance some mycologist, hesitating whether to purchase or not, may read this notice. Let us state for the information of such a one that the hard, woody *Polyporus fomentarius*, which grows on old trunks, and the equally well-known *Polyporus squamosus*, are with all seriousness and gravity introduced into the "Catalogue of Esculent British Fungi;" that the excellent *Agaricus sylvaticus*, which we are only too glad to get the chance of eating, is condemned to the "Catalogue of Poisonous British Fungi," together with *Agaricus lacrymabundus*, which is at least a considerable ingredient in the modern "mushroom catsup," as sold in the shops; and, if he seeks further evidence of "vast experience," he will find it in the novel information that *Agaricus mucidus* is rare, that *Cortinarius cinnamomeus* may be used as a substitute for cinnamon, that the difference between *Agaricus giganteus* and *Agaricus maximus* is only nominal, that *Lactarius subdulcis* is easily confounded with *Lactarius rufus*, that *Lactarius camphoratus* smells of camphor (when ?), and that *Russula decolorans* is common under beeches and is "a good comestible."

Finally, we must protest against the wholesale manufacture of new names, many of them barbarous enough, and some of them ridiculous, under the vain supposition that they will become popular names for the species of edible and poisonous fungi. The old "fairy-ring champignon" is to be called the "oread," the common mushroom is the "white pratelle." The *Russula emetica* is "the sickener," and *Russula fragilis* is the "sickener's sister." In one place we are told "how to prepare parasols," but not whether this includes umbrellas, or whether it is based on the principle that "it's never too late to mend." Earnestly we hope it is, for there is vast scope for amendment in this book, and the sooner it is commenced the better. As it stands, it is difficult to determine whether it should be classed with comic literature, novels, or ancient history.

M. C. C.

OUR BOOK SHELF

The Structure and Life-History of the Cockroach (*Periplaneta orientalis*). An Introduction to the Study of Insects. By L. C. Miall, Professor of Biology in the Yorkshire College, Leeds, and Alfred Denny, Lecturer on Biology in the Firth College, Sheffield. (London: Lovell Reeve and Co., 1886.)

THIS volume forms the third of a series of studies in comparative anatomy, the object of the authors being to lead the student, by the investigation of some one animal form, to an interest in, and a comprehension of, other kindred forms. While it will be generally conceded that this is a sound method of research, it is evident that its success will very much depend on the special forms selected, and we think that it may be open to some doubt whether, in selecting the cockroach for an introduction to the study of the Insecta, the authors have not selected a too little specialised form, since they have been obliged to omit the investigation of so characteristic a feature of insect life as that of metamorphosis. Nevertheless, they have given us a very fully detailed and interesting account of an easily obtained insect, and we hope it may be the means of encouraging many others to follow up the subject for themselves. As an introduction to this volume, we have a short account of the writings of those wonderfully patient pioneers in the field of minute anatomy—Malpighi, Swammerdam, Lyonnet, and Straus-Durckheim. This is followed by a sketch of the zoological position and the life-history of the cockroach. In this latter there is a brief record of the internal parasites of this insect—a record that might be greatly extended. The chapters on the outer skeleton, the myology, the neural system, the alimentary canal, and the organs of circulation and respiration, are well written and illustrated. The section relating to the respiratory movements of insects is written by Prof. Felix Plateau; that on the embryonic development, by Joseph Nusbaum, who very pertinently remarks that the inexperienced embryologist will find it more profitable to examine the eggs of bees, of Aphides, or of such Diptera as lay their eggs in water. Indeed, the difficulties in the way of the investigation of the eggs of the cockroach are so great that even the author has had to pass over the early stages of segmentation. A chapter on the cockroach of the past, from the able and experienced pen of Prof. S. H. Scudder, concludes a volume which, though not exhaustive of its subject, nor yet quite even in its treatment of all the branches of that subject, may be placed with the greatest safety and advantage in the student's hands. The authors tell us, in their preface, that, from the description of the cockroach in Huxley's "Anatomy of Invertebrated Animals," came the impulse which has encouraged them to write the present work. We hope that it will in its turn encourage many another to undertake equally honest researches.

The Administration Report of the Meteorological Department, India, 1885-86.

MR. BLANFORD'S Report, as usual, gives a good account of work. It commences with the actinometric observations. The records from Leh for twenty-three months were not found to be as valuable as had been expected, the climate having turned out unfavourable. The results have been sent home to the Solar Physics Committee, and meanwhile the observations are being continued at Dehra Doon and Mussooree, under the superintendence of Colonel Haig.

In the matter of forest observations, considerable activity is recorded; pairs of stations, on the system devised by Ebermayer for Bavaria, have been established at Dehra Doon and Ajmere. These observations have, however, been going on for too short a time for the results to be worth quoting, but much is to be expected from these investigations in India.

Mr. Blanford gives an account of his forecast of the character of the monsoon rains of 1885 from the character of the Himalayan snowfall, and he shows that the facts fully carried out his theory. The Report goes on with a brief notice of the theory of the South-west Monsoon, which, Mr. Blanford says, he is in a position to show, by his forthcoming Indian Ocean wind-charts, is not the South-east Trade simply drawn across the equator.

The remainder of the Report is occupied by details of the observational system, which seems to be in a good state of efficiency.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Mr. Romanes on Physiological Selection

I HAVE just seen Mr. Romanes's article in the *Nineteenth Century*, and his letter specially replying to myself in your issue of January 13 (p. 247). I do not propose to continue the discussion, but ask leave to make a few observations on some features of his reply in both the article and the letter.

On the question of the "inutility of specific characters," he appeals to authority against me, and especially to Darwin's very cautious remarks, which seem to me to support my view much more than they do those of Mr. Romanes; but in any case this is a matter in which I decline to accept authority as an infallible guide. The impossibility of proving a negative is proverbial, but my opponent declares that his negative—the uselessness of specific characters—wants no proving, but must be accepted till in every case the affirmative is proved. Here, again, is a canon of criticism the validity of which I wholly deny.

As to the swamping effects of intercrossing, there is again an appeal to authority, and Mr. Romanes now explains away (in the *Nineteenth Century*) what he had said about "simultaneous variations," by asking me to show such variations as the occurrence of an incipient spur on a duck's foot or horn on the head of a racehorse, in the belief, apparently, that these are the class of characters which are distinctive of closely-allied species! Such a demand, seriously made, appears to me so preposterous as to render further discussion of the matter with such an adversary out of the question.

The argument to show that the supposed physiological variations would be perpetuated, seems to me as weak and unsatisfactory as ever. The question is really not worth further discussion till the required variations are proved to exist in the requisite abundance and possessing the peculiar relations to each other and to the rest of the species which would alone give them any chance of survival.

I now leave the question, as between myself and Mr. Romanes, to the consideration of those naturalists who may be able to bestow upon it the requisite time and attention.

Instantaneous Shutters

IN reference to the interesting paper by Mr. Mallock in NATURE (February 3, p. 325), I quite agree with him in his condemnation of a drop-shutter of any form.

But I would point out a form of shutter that I have myself found of the greatest value—one, namely, working horizontally across the lens. It has the very great advantage in landscape work that it can carry an aperture of this form ▽ or any modification thereof, the advantage gained thereby being that the sky receives a far shorter exposure than the foreground, a point of much importance in landscape photography. The ▽ piece is loose, and any shape cut out of black cardboard or paper can be inserted. Of this power I have frequently availed myself when photographing snow-clad mountains.

The shutter can be made to pass across the lens at any speed, from the most instantaneous flash to slower motions, and it has the further advantage of working immediately behind the lens—the proper place, I think, for a shutter.

South Kensington Museum, February 4

Svastika Cross and Sun

Is there any evidence that the *svastika* represents the sun? and is it not a simple conjecture? (NATURE, February 10, p. 345).

The *svastika* 卐 is a complex emblem, and there is a possible origin which has not been investigated. It decomposes into two ʅ, and this is a character to be found extensively distributed throughout the syllabic and alphabetic systems. If ʅ is a symbol for man and fish, it will not be related to sun immediately.

The theory of Mr. Haliburton and others, and mythological conformity, give the cross or Tau as naturally derived from the Pleiades, and not from the sun. The cross is also a symbol for the nose in prehistoric sculpture.

HYDE CLARKE

Life-Energy, or the Dynamics of Health and Disease

SINCE it is admitted that matter is indestructible, it is obvious that life can be only the manifestation of that energy which is set free by the reduction of compounds embodying more energy to states of combination which embody less energy.

Life therefore is the result of the continuous interchange of partners between the compound molecules constituting chemical and organic compounds.

"In any transformation which takes place without the application, or the giving out, of work, the heat developed is the equivalent of the excess of the original over the final potential energy due to the chemical affinities involved; the *final state of every combination is that in which the potential energy of chemical affinity is a minimum*" (Tait).

If these words formulate the law which governs those combinations of elementary substances known as inorganic compounds, how much more must they refer to the combinations of the same elementary substances which go to form organic compounds?

Life thus becomes an expression for the sum of the difference between the original potential energy of the food and the final potential energy of the excretions. All change in the configuration of matter, whether physical or chemical, must be accompanied by either the evolution of, or the absorption of, energy.

Energy, as far as is known, has but one source, the sun.

Whether that energy act by direct impingement of solar rays producing the ascending scale of effects from genial warmth to fatal sunstroke, or whether it be second-hand, from the decomposition of vegetable matter, or third-hand, from the decomposition of animal substances which obtained it from vegetable substances, its origin is still the same.

Assuming then the universality of this energy, which shows itself in all the intangible forms of life, and growth, and all organic change, it will be the effort of the writer to adduce evidence to prove that much which is still mysterious in both health and disease is due to its subtle action too.

The vibrations of direct solar energy which fall upon the optic nerve give rise to those molecular disturbances which produce the subjective sensation of light.

Physical change is thus originated by an immaterial agent. Work is done, and cannot continue to be performed without renewal of the material acted on.

But when the vibrations of direct solar energy fall upon the tissues of a growing plant, energy is incorporated into those tissues. This energy so attunes the atomic vibrations in the plant molecules as to bring them into combining harmony with the carbon and hydrogen atoms present in the forms of carbonic acid and water.

The hydrocarbon compound, starch, is formed, and embodies within itself the energy which made it starch.

Each molecule of starch maintains its individuality as starch only so long as it retains within itself that solar energy under the influence of which it became starch; as soon as part of that energy is lost the starch is degraded to its original condition of carbonic acid and water. Yet that energy which works such molecular miracles is sought for among the products of decomposition in the form of heat only, and if not recognisable as such is put out of count in the world's work.

While it is thus evident that the vegetable kingdom lives a constructive life, storing up energy from an extra-terrestrial source, it is equally demonstrable that the animal kingdom lives a destructive life, unable to add aught to the sum of energy required for the work of the planet. Consequently an approximate expression for the value of the energy incorporated in the plant may be found in the work done, as a result of its consumption, by the animal.

4500 grains of plant carbon are daily excreted by every average man in the form of carbonic acid. Carbon and oxygen independently embody a greater sum of original energy than is found in the compound formed by their union; therefore the result of their combining together must be a loss of energy: the value of this energy is estimated by the heat evolved. The heat recognisable on the combination of 4500 grains of carbon with the required equivalent of oxygen amounts to 118 units, and represents in foot-pounds the raising of 40 tons one foot high.

Such, then, is the enormous supply of solar energy obtained by a man when he compels the elementary atoms of carbon and oxygen to enter into a combination of greater stability and less energy, and to surrender their surplus energy that he may live.

But the converse of this is also true, viz. that when a plant proceeds to utilise this carbonic acid for the reproduction of 4500 grains of carbon, it can do so only by obtaining from some external source energy equivalent to the raising of 40 tons one foot high and adding this to the rates of vibration already existing in the carbonic acid. Thus the condition of energy of the carbonic acid is altered till finally the oxygen and carbon atoms are compelled to dissociate themselves and to resume their elementary forms of less stability and greater energy. They then become available for plant assimilation, and fix in its tissues the energy which forced them apart.

If, then, the union of oxygen and carbon in the human body sacrifices such energy that man can live thereby, is it not obvious that under whatever circumstances that union takes place the same energy must appear? If that be so, the question must arise whether in estimating the effect of vegetable decomposition upon the health of man too much notice has not heretofore been taken of the carbonic acid and kindred stable products given out, and too little attention paid to the energy evolved,—in fact, whether from the surface of every seething swamp there be not poured forth streams of that powerful energy which originally fed the growing plants, and which when eliminated within the body of man is known by the name of Life. To assume that such energy is powerless is to assert that the mother's heat is not the force that hatches out the egg.

That the theory which attributed all noxious influence to the gaseous resultants of decomposition did not satisfy the requirements of science is shown by the greedy acceptance of the germ theory which now prevails. But this, after all, is but coming one step nearer to the action of that universal energy which is the inseparable concomitant of all material interchange. For has not Dr. Burdon Sanderson well said, "Bacterial life is a middle term between chemical antecedents and consequents"? They reduce all unstable compounds in the world to final stable products, and live with vigour or in apathy in proportion to the effect upon themselves of the energy evolved from the medium they destroy. Thus, too, is produced much of that form of secondary energy recognised as heat of decomposition, and while this heat is known to possess marvellous influence over vegetable germination it has up to the present been credited with but little action on the life of man.

The gaseous consequents and the bacterial agents have borne the blame of every human ill, while that energy which ruled the universe before the first vegetable cell had varied towards animal functions is allowed to go unchallenged.

If, then, suspicion can be legitimately directed towards this heat as a factor in physiological change hitherto overlooked, it becomes necessary to pursue the subject of heat in all its latest developments.

Dr. Doherty, in his "Organic Philosophy," says: "Light is nothing but the velocity of a force which in slow motion is called heat." From the facts that are known in relation to light it may be possible to deduce by analogy much that is yet unproven with regard to heat.

It has been shown that light consists of certain colours which, when taken together, produce the sensation of light; each of these colours acts upon certain specialised molecules of the optic nerve and not upon the remainder, just as Professor Tyndall has shown that the invisible heat rays, "powerful as they are, and sufficient to fuse many metals, can be permitted to enter the eye and to break upon the retina without producing the least luminous impression."

May it not therefore be inferred that heat consists of a series of velocities of force which when taken together produce the sensation of heat, yet each of which is capable of acting upon certain specialised molecules of the nerves of sensation, while being unperceived by the remainder?

Light has been proved by Captain Abney to be the visible velocities of wave-lengths from 38,000 to the inch to 60,000, and within this range from 38,000 to 60,000 to the inch all the varied sensations of colour are produced; nevertheless, by the higher velocities, from 60,000 to 120,000 wave-lengths to the inch, the great chemical actions of the world are performed. Is it not evident, then, that if the recognition of wave-lengths from 38,000 to the inch and upwards depended solely upon the subjective sensation of light all appreciation of them must cease at the 60,000 wave-lengths, and that the great powers of the ultra-violet wave-lengths must have remained in darkness for ever?

But Captain Abney has also shown that there are measurable wave-lengths extending downwards from 38,000 to 10,000 to the inch; if, therefore, these are credited with such action only as is recognisable by the subjective sensation of heat, is it not equally possible that powerful influences which change for good or ill the configuration of the molecules of the nerves of sensation may be left unregistered?

It is therefore allowable to infer from this analogy that in the dark region descending from the fading red to the cold of zero there may be many rates of velocity, some of which, harmonising with some phase of life, produce the most potent physiological effects without at the same time exciting the molecular resistance which corresponds to the sensation of heat.

In other words, is it not probable that in estimating the actions of the forces of Nature upon the animal system some most subtle influences have been overlooked because unrecorded by the index of the thermometer?

Professor Tait says: "The energy of vibrational radiations is a transformation of the heat of a hot body, and can be again frittered down into heat, but in the interval of its passage through space devoid of tangible matter, or even while *passing unabsorbed through tangible matter, it is not necessarily heat.*" And Mr. Pattison Muir in his work on "Thermal Chemistry" asks: "Must all energy which is lost by a changing chemical system during a definite operation make its appearance in the form of heat? Energy appears in chemical operations in forms other than that of heat, electrical energy for instance; we must distinguish in chemical processes between that part of chemical energy which is freely changeable into other forms, and that which can leave the system only in the form of heat."

The most recent researches thus point to the probability that while the bacterium carries on through Nature its never-ending work of reducing chemical antecedents to chemical consequents it must as continuously set free energy in forms other than that of heat.

One of the most pregnant discoveries made of late is that which demonstrates that, even in the case of the powerful friction requisite for boring iron, heat ceases to be recognisable as heat when the iron operated on is strongly magnetised; that is, that heat developed by friction in a magnetic field disappears in some form other than heat. By this the idea is suggested that heat energy impinging upon the sentient extremity of a nerve in action may be taken up and carried in a form other than heat to the central brain, just as sound is conveyed in a form other than sound across the interval between the telephone and the receiver; and if the multiple wave-lengths which produce the subjective sensation of heat can be thus transferred from the surface to the centre, why not fractions of that multiple which when taken together make the whole?

Since, then, science cannot specify the difference between the energy contained in dead carbonic acid and that of the living hydrocarbon, neither can it draw a line more definite than the equator between those series of decompositions which on the one side are termed life, and on the other are designated death. In each and all the compound descends from instability towards stability, and in every degradation is energy evolved.

Yet that energy, no matter in what companionship it may be found, or through how many existences it may have transmigrated, has still but one original source, and consequently it is impossible to conceive a condition in which that energy, primarily possessed of such "phenomenal modes of action," can be regarded as absolutely inert.

So far, then, it is claimed that grounds have been established for asserting that from the surface of every decomposing swamp forms of energy must be momentarily poured forth, the potency of which is as yet unknown.

Again, while it is at present impossible to isolate the fractions of energy the sum of which make heat, still it would contribute vastly to the proof of their independent existence if it could be shown that the nerves of sensation are specialised in sections, each reacting separately, to different gradations of heat.

This has been apparently accomplished.

"Dr. Goldscheider at a meeting on April 9 of the Physiological Society of Berlin discussed the action of menthol on the sensory nerves; he therefore concluded that the sensations in some places of cold and in other places of heat, produced by menthol, were purely subjective, and consequent on the direct stimulation of *the special nerves of temperature, those usually cognisant of cold* being far more sensitive to its influence than were those adapted to receive impressions of higher temperatures."—*Brit. Med. Journ.*, August 21, 1886.

Here, then, is strong evidence that the sentient nerve-endings over the surface of the body are graduated to respond to the various rates of energy that may impinge thereon; and if so, how can it be admitted that the varieties of energy by which these nerve-endings are stimulated must be limited to those already identified?

That some such idea has shaped itself in the minds of observers may be gathered from the independent opinions expressed by several of the members of the Cholera Commission of 1885.

Prof. Aitken sums up his valuable contribution in these words:—

"Some influence (as yet unknown, and therefore so far mysterious) seems to create in cholera times and places an epidemic activity. It is probable that this may be due rather to some meteorological condition—some peculiar state of the atmosphere, electrical or other—combined with unwholesome conditions of surroundings, and conditions of life; a co-existence of physical phenomena rather than anything in the individual. It is well known that electrical conditions such as prevail in a thunderstorm will cause milk to become sour, the formation of the acid being associated with, or due to, the formation of the bacterium lactis, and thus confined to very definite areas."

In the last paragraph lies the key to some of the foregoing mystery.

The mode in which to use it can be learned from the marvellous researches of Pasteur.

It is obvious that if the cause of sourness be the bacterium, the cause of greater sourness will be the bacterium still, and that the reason for the increased reduction by the bacterium of chemical antecedents to chemical consequents, which produces the additional sourness, must lie in some condition affecting the life of the bacterium too.

Pasteur has shown that a fundamental difference exists in the mode of action of the beer and grape ferments when "the introduction of the free oxygen of the atmosphere is permitted and when such introduction is prevented." When free oxygen is admitted, "the ferment shows an activity *even more extraordinary* than it did in the deep vats; the life of the ferment is singularly enhanced, *but* the proportion of the weight of the decomposed sugar to that of the yeast formed is absolutely different in the two cases: while, for example, in the *deep vats* a kilogramme of ferment sometimes decomposes 70, 80, 100, or even 150 kilogrammes of sugar; in the *shallow* troughs 1 kilogramme of the ferment will be found to correspond to only 5 or 6 kilogrammes of decomposed sugar. In other words, the more free oxygen the yeast ferment consumes the less is its power as a ferment; the more, on the contrary, the life of the ferment is carried on *without the presence of free oxygen* the greater is its power of decomposing and of fermenting the saccharine matter."

Here, then, is the clue to the cause of the increased sourness of milk during electrical conditions such as prevail in a thunderstorm. The bacterium lactis evidently finds itself in a situation in which the free oxygen of the atmosphere has, owing to some atomic disturbance in its molecules, become less available as an energy-provider.

The organism is consequently compelled to revert to the *condition of the ferment in the deep vats*, and to find in the increased decomposition of the constituents of the milk that energy which is necessary for its existence.

Further, it is known that electricity does affect the condition of oxygen, that the conversion of its molecules from the di-atomic to the tri-atomic state can be brought about by its influence, and that this latter state has been recognised as ozone.

If, then, it can be thus proved that the presence or absence of oxygen so materially alters the mode of existence of microscopic organisms, is it not reasonable to accept changes in the lives of the organisms as evidence of the altered condition of oxygen? and since certain conditions of free energy are thus found to interfere with the mode of nutrition of the minutest forms of life, can it be doubted that similar forces may exercise a material influence upon the most complex being, who, after all, is but a larger multiple of the original protoplasmic element?

Thus it becomes possible that energy existing in forms other than those of light or heat exerts a power which has up to the present been ignored.

By this reasoning too, based on the altered mode of nutrition of the bacterium lactis during a thunderstorm, much that has been hitherto obscure in the history of the diseases, or blights, of the vegetable world becomes intelligible.

When it is found that all the bacteria lactis over a considerable area at the same moment change their mode of existence, and, from leading a comparatively sluggish life in the milk substance, suddenly break up almost the whole of that substance at a time when electrical disturbances are present, it is easily conceivable that in the case of potato-blight, which is almost invariably accompanied by obvious atmospheric changes, like conditions may arise; in fact, that the universally present bacteria, which, under ordinary circumstances, continue to exist without apparent injury to the tuber and leaves with which they are in contact, may, when driven by the stress of altered atmospheric conditions, turn upon the tissues of the plant for nutrition as the bacterium lactis upon the milk.

If, then, these effects of certain unrecognised forms of energy be established, it will go far to help the elucidation of the mysterious subject of cholera.

Dr. Bryden, from prolonged study of the cholera statistics of India, arrived at the following conclusions: "That the disease was endemic in the Soonderbunds, and that its cause was *earth-born* and *air-borne*;"—to repeat the words of Prof. Aitken, "due rather to some meteorological condition, some peculiar state of the atmosphere, to a co-existence of physical phenomena;" and Deputy-Surgeon-General Marston has added: "Cholera spreads along rivers, but against their current in Bengal. It invariably advances from Bengal proper to the Himalayas, and never the reverse."

Here, then, are the conclusions arrived at by some of the most skilled observers on this subject.

It is thus admitted that cholera is endemic in the Soonderbunds, and that its track from thence lies in a north-westerly direction; that is, that its home is a surface of 12,000 square miles of decomposing tropical vegetation, and its direction that from whence the Ganges and its tributaries flow.

From this it may be inferred that its cause is such that it can be carried atmospherically, and that its course is the line of the least resistance.

Were the cause of cholera solid or liquid, it would doubtless long ere this have been demonstrated. Were it gaseous, it must follow the law of the diffusion of gases. What, then, remains to be sought for over the surface of the Soonderbunds? Naught but some form of that universal energy which fell as a sunbeam upon the growing plant, but which, when filtered through its substance, is evolved in a less vivid but still a potent form from its decaying structure.

That such returned energy has the power of incorporating itself with water, till it passes upward as a vapour, every steaming dung-heap shows; and in what prodigious force it can be again eliminated may be understood from the calculation of Prof. Haughton, that the condensation of vapour sufficient to afford one gallon of rainfall gives out sufficient heat to melt 45 pounds of cast iron.

From this may be estimated the enormous output of bottom heat which must day and night pass from a decomposing surface of 12,000 square miles to the vapour-carrying air above.

To comprehend the distance to which this energy may be transported before doing visible work it is only necessary to consider the Gulf Stream, which is described by Prof. Tait as "a vast convection current whereby the solar heat of the tropics is carried into the North Atlantic;" and to measure the work done thereby it needs but to weigh the luxuriant vegetation of the United Kingdom against the frigid barrenness of Labrador.

If, then, such vast stores of force can be transported from the tropics to England, it cannot be irrational to assert that from the surface of the Soonderbunds, and like places, much of the energy of decomposition must ascend with the rising vapour, and that whether drawn landward by the heated earth-surface, or pushed inward before the advancing monsoon, this vapour must follow the line of least resistance along the course of the river beds.

Again, when it is remembered how intense are the effects on the nerves of the animal body of the chemical affinity evolved as electricity from a few square inches of decomposing zinc, it may well be contended that the energy of chemical affinity evolved from so great an area of decomposing organic substances cannot be innocuous, and that the fact of its action not being acknowledged by the subjective sense of feeling is no proof that it is non-existent.

Thus it becomes conceivable how the energy evolved in the Soonderbunds may, when vapour-borne across the interval, affect the inhabitants of Oude, and so alter the individual condition as to admit of local causes producing foreign effects.

Many of the most careful observers have asserted that malarious fevers arose from chill; yet, while this did not solve the question, it at least established one fact, that malarious fevers arose under circumstances which necessitated vapour condensation, one gallon of which would set free energy sufficient to melt 45 pounds of cast iron.

Familiarity with malaria will furnish many arguments in support of the contention that fever infection is at least coincident with vapour condensation. A boat's crew ashore at night on a West African station will often be affected, while those but a few miles seaward will remain exempt.

In the deep valleys of Zululand leading from the St. Lucia swamp, fever is contracted at a distance of many miles inland, while high ground much nearer to the swamp may be occupied with impunity. In the Terai, at the foot of the Himalayas, a night's sojourn brings to the unseasoned traveller certain fever, while a day journey is almost free from risk.

Since, then, the search for a material cause of cholera and of malaria has been as unsuccessful as if one sought a material cause for sunstroke, it may legitimately be suggested that, as the more rapidly fatal affection is the result of the action of direct solar energy upon the sentient nerve-endings, so the less rapid maladies may result from subordinate rates of the same energy acting upon subdivisions of the nerve-endings, which, as Dr. Goldscheider has shown, are specialised to respond to lower velocities of that force, and that the chill to which so many attribute the origin of fever is really the acknowledgment, by what Dr. Goldscheider terms "the special nerves of temperature usually cognisant of cold," of that obscure energy hitherto unregarded as a factor in the production of disease, but which the investigations of thermo-electricity may one day bring within the ken of man.

NATHL. ALCOCK

Military Prison, Dublin

THE CRUISE OF THE "MARCHESA"[1]

THIS is one of the most interesting books of trave that it has been our good fortune to meet with for several years. Apart from its excellent maps and wealth of illustration, it commends itself by a charm of style not usually to be met with in works of this nature, and by the judgment shown in the narrative. Many countries were visited which lie in the well-beaten track of every tourist round the world, but these have not even been alluded to. The attention is riveted to the details of discoveries among little-known scenes, and sometimes in quite unexplored regions.

The *Marchesa*, an auxiliary screw schooner of 420 tons, Mr. C. T. Kettlewell, captain and owner, was commissioned in the Clyde in November 1881, and left Cowes on the 8th of the January following. She reached Colombo on April 24, having touched at Socotra and Oolegaum Island, one of the Maldive group, on her way from Aden. From Ceylon she proceeded *viâ* Singapore to Formosa; and, coasting along the south-eastern side of Formosa, she visited the small Island of Samasana. While she was running nearer to the coast at Chock-e-day, the stupendous cliffs of this part of Formosa were seen rising, to a height of some 5000 feet, upright from the water's edge.

The little-known islands of the Liu-Kiu group were next visited. These lie some 250 miles to the east-north-east of Formosa; they are partially volcanic, and lie just north of the tropic. The account of the short sojourn at Napha, and of the wonderfully successful visit to Shiuri, the capital, where are the ancient palaces of the Liu-Kiu kings, will be found in Chapters II. and III. Some time was spent at Japan, then the yacht's head was turned northwards for Kamschatka, and on the morning of August 13, when the fog lifted, the sharp peak of Vilutchinska Volcano enabled them to steer for Avatcha Bay, within which lies the once well-known little harbour of Petropaulovsky.

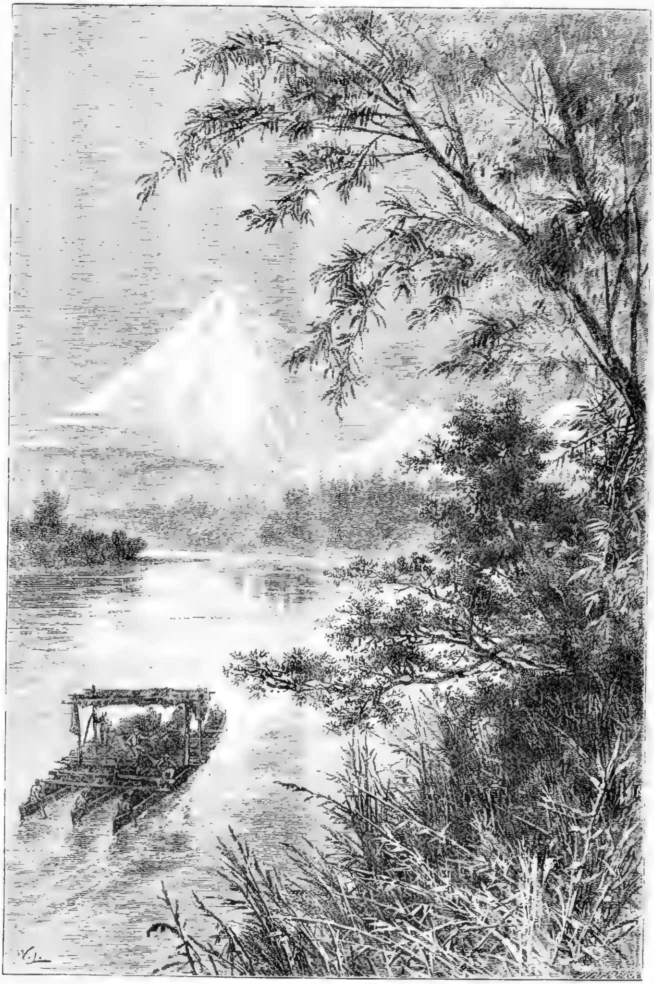
"Avatcha Bay is one of the finest harbours in the world, if not actually the finest. Rio and Sydney have no mean claims for this position of honour, but those of us who had seen both were unanimous in awarding the palm to their Kamschatkan rival. A nearly circular basin of some nine miles in diameter, and within a narrow entrance opening to the south-south-east, it is roomy enough to accommodate the navies of the world. It is entirely free from dangers, has an even depth of ten or twelve fathoms, and owing to its affording excellent holding ground and being well protected from all winds it is perfectly safe in all weathers. But the ordinary traveller will be struck not so much with its nautical excellences as with the superb scenery with which it is surrounded. To the south rises the Vilutchinska Volcano, now quiescent, a graceful cone of about 7000 feet; and a little farther eastwards a huge flat-topped mass exceeding it in height by a thousand feet or more obtrudes itself, as a rare exception to the rule of cone-shaped mountains which seems to obtain throughout the country. It is nameless in the charts, for we are in the land of volcanoes and it is only 8000 feet in height! On either hand on entering are the two secondary harbours, Rakova and Tareinska—the latter nearly five miles in length—and within them again are others on a still smaller scale. Nature here at least has treated the mariner right royally. The iron-bound coast without may be as bad a lee shore as any skipper need wish to see, and the Pacific Ocean may too often belie its name, but here he can rest quietly, and sleep *sur les deux oreilles*, until such time as he weighs anchor for the homeward voyage" (vol. i. p. 67).

In spite of its imposing name, it did not take the explorers long to see all the sights of Petropaulovsky, and a plan was soon formed to make an expedition into the interior. Travelling northwards from Avatcha Bay, they soon struck the head waters of the great Kamschatka River, on which they floated down to the sea. The well-known naturalist Dr. Dybowski gave them great assistance in their undertaking. The yacht was to remain in harbour for some six weeks, and then to proceed, as it did, to the mouth of the river to await their arrival. Of this delightful river journey our space will permit us to give no details. As far as Narchiki, where they met the river, they journeyed on ponies, and then they floated down its stream, sometimes in boats, sometimes on rafts, until, after many an adventure, and, indeed, many a trial, they reached Ust Kamschatka in safety. In places, the river swarmed with salmon; bears were in abundance; the weather, though not always of the best, was generally bright and clear; but the natives were very difficult to deal with—always exorbitant in their charges, and often placing the travellers in sad dilemmas; and constant rows took place about the hire of the canoes. One morning, after a harder fight than usual with the Mashura men, with much time and some temper lost, they came in sight of the magnificent range of volcanoes on the lower reach of the great river. The five already-known volcanoes have elevations of from 11,700 to nearly 19,000 feet, and there were two much lower cones, now first described, which they called after Gordon and Herbert Stewart. The account of the travellers' first view of these mighty peaks must be told in their own words.

"We floated silently down stream for a couple of hours or more, thinking over the discussions that we knew only too well would be renewed at the earliest opportunity,

[1] "The Cruise of the *Marchesa* to Kamschatka and New Guinea; with Notices of Formosa, Liu-Kiu, and various Islands of the Malay Archipelago." By F. H. H. Guillemard, M.A., M.D. (Cantab.), &c. With Maps and numerous Illustrations. Two Volumes. (London: John Murray, 1886.)

when turning a sudden corner we found ourselves face to face with a view that banished all thought of past and future annoyances in a moment. Before us, eighty miles or more away, stood one of the grandest groups of volcanoes in the known world. Others there are, it is true, that are higher, although in most cases the elevation of the ground from which they take their rise detracts in no little degree from their apparent height. But here, from a base elevated scarce a hundred feet above the sea, a series of cones of the most exquisitely symmetrical shape



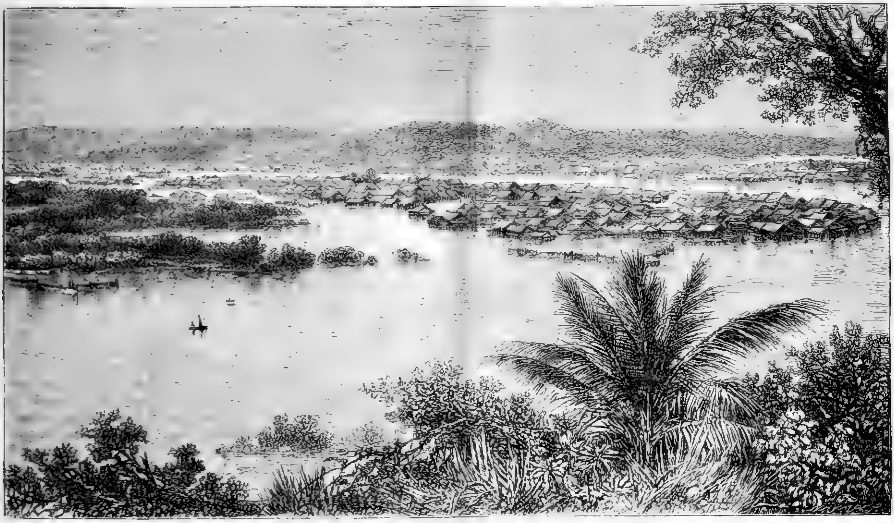
The Volcano of Kluchefskaya.

rose in heights varying from twelve to seventeen thousand feet. They were three in number. Nearest us was Tolbatchinska, dog-toothed in shape, with its apex on the western side, a long thin puff of white smoke drifting from its shoulder; and beyond, apparently in close proximity to one another, rose the twin peaks of Kojetevska and Kluchefskaya, perfect in their outline, pyramids of the purest snow, before which one felt how poor was all language to express the sense of their perfect beauty. Snow mountains were no novelty to us. We had seen the

Andes and the Alps, and had watched the sun rise on Cotopaxi, on Etna, on Fujiyama, and a dozen other mountains of equal note. But here all questions of comparisons would have been a sacrilege; and floating noiseless over the unruffled surface of the river, we sat spellbound drinking in the view. The sun sank slowly as we crept along, and slope and peak, at first a dazzling white, turned slowly to a glowing gold. On either hand the fast-approaching night had changed the glories of the autumn tints to a sombre shade of violet, and behind us the river was a mere streak of light. The glow of the fire upon the other raft lit up the bearded faces of our Russian guides around it; and when the daylight had fairly waned, the head of Kluchefskaya stood out a pale greenish white—a spectral mountain against the fast-darkening sky. Come what might, even if we were never again to get a glimpse of them, we had seen the great volcanoes, and we felt that the sight was one that we should not easily forget for many years to come" (vol. i. p. 149).

After rejoining the yacht the party visited the well-known breeding-places of the fur seal at Bering Island; from thence back to Kamschatka, and then to Yokohama to refit and repair. A brief history of Russian discovery in these seas, and a record of a little-known defeat of the allied forces of England and France in 1854 at Avatcha, will also be found in this volume.

In Volume II. the scene changes from the snowy north to the tropics, where for a long time the *Marchesa* wandered from one island of the Indian Ocean to another. The little-known Island of Cagayan Sulu is described as perhaps the most beautiful of all tropical islands. A revised chart of the island is given; and its three crater-lakes, one of the most interesting phenomena to be met with in the Eastern seas, were visited and described. The third lake had escaped the notice not only of Admiral Keppel, who had twice visited this island, but also of Captain Chimmo, who had in 1871 surveyed Cagayan Sulu. This lake was of rather smaller size than the others, being two-fifths instead of three-fifths of a mile in diameter: but the basin was perfectly circular, and filled with water to about the level of the second lake. Thick jungle clothed its precipitous sides, but the latter, instead of running sheer down into the water, left room for a small beach on which wild bananas were growing.



Brunei.

The islands of the Sulu Archipelago are described in Chapters II. to IV. of this volume. Natural history rambles were made over Sulu; and the Sultan, with and without his wives, visited the yacht. Some days were spent with the Spaniards at Jolo, a fortress on the northern side of the island. The fauna and flora of the Philippines and Borneo are contrasted with those of Sulu, and the Sulu Archipelago is determined to be, zoographically, purely Philippine, the Sibutu Passage forming the boundary line.

The newly-acquired territories of the British North Borneo Company were next visited, and some details are given of the existing state of things in this new colony. The colony at Labuan was found to be retrogressing. The Sultan was interviewed; and Brunei, the Venice of the East, in which, except its market, there is little of interest, was explored. The great dexterity of the boatmen in the use of their paddles is noted. "From a rapid and beautifully clean stroke of forty or more to the minute, they would drop instantaneously to a long steady swing of twenty, without any apparent signal having been given, and without a hair's-breadth of deviation from the perfect time."

We pass over the chapter on Sumbawa, and next find the yacht at Celebes. Macassar is the Hong Kong of the Dutch, and is not attractive from the sea.

"The town is much as other Dutch Malayan towns. A row of white shops and merchants' offices lines the sea; and dust of a lightness and powderiness that is not excelled even in California or the Diamond Fields covers the streets to the depth of an inch or more. These are otherwise clean enough, and the spare time of the native servants, and they appear to have plenty of it, is occupied in perpetual watering. There is of course a fort, and equally of course a '*plein.*' The cemetery is significantly full. Almost all the tombs are kept whitewashed, and as many of them are curious chapel-like erections with flying buttresses, the effect at a distance is something between an ice palace and a clothes'-drying ground. The houses of the Dutch residents, shadowed in peepul or galela trees, stand back a little distance from the road, long, low, and cool, with thick white posts at their entrance gates. A long avenue of magnificent overarching trees leads eastwards from the pier, adown which the Governor may be seen driving any afternoon in a four-in-hand, with sky-blue reins. It is lighted by means of lamps hung midway between the trees, for the Hollander, even although gas may be unattainable, considers civilisation incomplete without these adjuncts. Then too there is the club, with its zinc-topped tables set out *café*-fashion beneath the trees. It is called the 'Harmonie,' as is every Dutch club in Malaysia, and within all is dark and deserted and cool during the mid-day heat. The servants are curled up asleep behind the bar or in the corners of the rooms, and would stare in dumb astonishment at the apparition of a European; for the early business of the day over, and the *rijst tafel*, or lunch, despatched, the white residents get into their *pyjamas* and take a siesta till three or four o'clock. A couple of hours or so are then devoted to business, and towards sunset the male portion of the population meet at the 'Harmonie' to chat and drink *pijtjes*. Billiards is the most violent exercise taken; cricket, bowls, and lawn-tennis are unknown" (vol. ii. p. 156).

Among the pleasant reminiscences of the travellers about their travels in the north of Celebes will doubtless be those of their visits to the Tondano Lake with its pretty waterfall; to Talisse Island, where at "Wallace Bay" the habits of the maleo (*Megacephalon maleo*) were observed, and a good store of their eggs and bodies were collected; and to Kema, where a great babiroussa hunt was held.

The name Moluccas, at one time restricted to the little chain of volcanic islets lying off the western coast of Gilolo, of which Ternate is the chief, now includes all the islands between Celebes and the Papuan group. As regards magnificence of scenery, Ternate is perhaps the finest harbour in the Dutch Indies. The Resident, Mr. Morris, kept a large aviary of rare birds, amongst which the gems were two superb specimens—both full-plumaged males—of the twelve-wired bird of paradise. These exquisite creatures were fed on the fruit of the pandanus, with an occasional cockroach as a *bonne bouche*. "The feelings of admiration with which I watched these birds, which are among the most beautiful of all living beings, I need not," says the writer, "attempt to describe." The concluding chapters of this volume bring us to New Guinea, the very home of paradise birds. The portion of this great island visited was the western half, that claimed by the Dutch; which, from the variation in species from island to island, and the peculiarity of these birds of paradise, is perhaps the most interesting to a naturalist. A safe anchorage was secured at the extreme east end of the Island of Batanta, in "Marchesa Bay." The first ramble on shore was unsuccessful. Scrambling over the mangroves' slimy roots, and struggling up to their knees in liquid ooze, they found that the land was hard to reach; the shore rose steeply from the sea; and the dripping wet jungle made progress all the more difficult. The party returned disappointed to the yacht, to find that some of the hunters were already back, equally empty-handed. Presently, however, "Usman and his *compagnon de chasse* appeared triumphant, carefully carrying a prize that we had hoped, but hardly expected, to obtain—the curious and exquisitely lovely little *Diphyllodes wilsoni*, smallest of all the birds of paradise. Behind the head, a ruff of canary-coloured feathers stands erect above the scarlet back and wings. The breast is covered by a shield of glossy green plumes, which towards the throat are marked with metallic green, and violet spots of extraordinary brilliancy. The two centre feathers of the tail, prolonged for five or six inches beyond the others, cross one another, and are curved into a complete circle of bright steely purple. But the chief peculiarity of the bird is the head, which is bald from the vertex backwards, the bare skin being of the brightest imaginable cobalt blue (the figure in Gould's 'Birds of New Guinea' gives no notion of the extreme brilliancy of the colouring of this part). The *bizarre* effect thus produced is still further heightened by two fine lines of feathers which, running lengthways and from side to side, form a dark cross upon the brilliant azure background. I could hardly make up my mind to skin this little ornithological rainbow, whose exquisite plumage it seemed almost a sacrilege to disarrange, but the climate of New Guinea allows of but little delay in this operation, and I set about my task at once. The bird had been scarcely injured by the shot, and I succeeded in making a perfect skin of it" (vol. ii. p. 254).

Dorei Bay, well known as the settlement of the Dutch missionaries, and the residence of Mr. Wallace in 1858, was the next station. Some few miles south of Dorei Bay is Andai, a small village nestling at the foot of the Arfak Mountains. The dense forests that clothe these mountains are the favoured haunts of such magnificent paradise birds as the great velvet-black Epimachus, with its tail a yard in length; the Astrapia, in its uniform of dark violet, faced with golden-green and copper; and the orange-coloured Xanthomelus. There D'Albertis had shot his Drepanornis, with its two fan-like tufts, one flame-cloured, the other tipped with metallic violet; and there Beccari braved the climate and made such splendid collections. The summits of the mountains were less than ten miles from where the yacht was, and yet this land of promise could not be entered. Our readers must seek the reason why in the narrative: here we can only add that the homeward voyage had begun.

In so short a sketch it is simply impossible to do more than give the reader an idea of what he may expect to find within the pages of these volumes. Students of geography, ethnology, and, above all, zoology, will discover therein a great deal that is of interest, and also much that is novel; and every reader will be pleased by the writer's freshness of style and keen enjoyment of Nature. To enjoy travelling, especially in the tropics, one must be of an equable, not to say of a cheerful, frame of mind. We close the perusal of Dr. Guillemard's delightful volumes with the impression that the company on board the yacht *Marchesa* was certainly of this kind.

In several appendixes to Volume II. there are lists of the birds met with in the various regions visited, and of the shells. There is also a list of the Rhopalocera collected in the Eastern Archipelago, and of the languages of Sulu, of Waigiou, and of Jobi Island. Tables are given of the total export in 1884 of the chief articles of produce in the Netherlands India, North and South Celebes, Amboyna, and Ternate.

THE SMITHSONIAN INSTITUTION

THE annual Report of Prof. Baird, Secretary of the Smithsonian Institution, has just been issued. It relates to the period from July 1, 1885, to the close of June 1886, and includes, in addition to the account of the operations of the Institution itself, a summary of the work done by the branches of the public service placed by Congress under its charge, namely, the National Museum and the Bureau of Ethnology. To this is added a sketch of the work of the U.S. Fish Commission, which is also under Prof. Baird's charge, and of that of the U.S. Geological Survey, which, although independent of the Smithsonian Institution, is in close relation with it by reason of its field of exploration, and especially through the valuable accessions of material furnished by it to the National Museum.

With regard to the Smithsonian Institution itself there is not much to be said, except that its usual operations were steadily carried on during the year, with a marked increase in routine work. In the way of explorations there was less activity in the year 1886 than there has been in some previous years, but important collections of objects of scientific interest were received from various parts of America and Asia. Of the different classes of works issued by the Institution, the most valuable are the quarto "Contributions to Knowledge." A work in this series, entitled "Researches upon the Venoms of Poisonous Serpents," by Dr. S. Weir Mitchell and Dr. E. T. Reichert, was printed during the past year, and will soon be ready for distribution. Among the "Smithsonian Miscellaneous Collections" of 1885-86 may be mentioned "A Catalogue of Scientific and Technical Periodicals (1665 to 1882), together with Chronological Tables, and a Check-List," "The Scientific Writings of Joseph Henry" (not yet published, but entirely stereotyped), "Index to the Literature of Uranium, 1789-1885" (one of a series of bibliographies especially directed to the indexing of chemical literature), and "Accounts" of the progress of astronomy, chemistry, physics, geography, anthropology, and other sciences in 1885. The Smithsonian Institution has also issued the Bulletins and Reports of the Proceedings of the National Museum, and valuable publications of the Bureau of Ethnology.

It is well known that in bequeathing to the United States the fund with which the Smithsonian Institution was established, Mr. Smithson stipulated that his bequest should be devoted to "the increase and diffusion of knowledge among men." The Institution has always complied with this condition in a most liberal spirit, and now its system of "free exchanges" has reached vast proportions. For the year ended June 30, 1886, the receipts for foreign transmission were 94,093 packages, weighing 195,404 pounds. The transmission filled 764 boxes, having an aggregate bulk of 5208 cubic feet. For domestic exchanges the number of parcels received and distributed during the fiscal year was 14,496, of which 2533 parcels (or about one-sixth) were received for the library of the Institution. Twenty years ago the Institution was made by law the agent of the United States Government for conducting the international exchanges of public official documents between it and foreign Governments, and during the past year 29 boxes, containing 56,229 packages, were received for Government exchanges, and 114 boxes were sent abroad. The exchange system of the Institution is found to be of so much public service that Congress supports it by an annual grant of 10,000 dollars.

Perhaps the most interesting part of the report is that which relates to the National Museum. It is five years since the work of moving into the new Museum building was begun. Two years ago the Director reported that the packing-boxes, several thousand in number, containing the accumulations of many previous years, had for the most part been unpacked, and that the entire floor space of the building would soon be occupied by exhibition collections. During the past year this result was attained, and (with the exception of one corner of one of the central halls still occupied by one or two collections received at the close of the New Orleans Exhibition, and which have not been opened on account of delay in preparation of cases for their reception) the entire floor space of about 100,000 square feet is open to the public, and the collections arranged in accordance with the provisional plan of installation. The work of mounting and labelling is still in progress, and each month shows marked advances.

The development of the Museum during the past year was unexpectedly great. About fifteen hundred separate lots of specimens were received. A certain proportion of these were obtained from Government expeditions and surveys, and material of perhaps equal value through exchange, but by far the largest part of the increase, both in quantity and value, was in the form of gifts.

A census of the collections made in 1884 showed an estimated total of 1,471,000 "lots" of specimens in the Museum. The number at the present time is 2,420,934. The total number of "lots" of specimens received during the year and separately entered on the record of accessions was 1496, including 6890 separate packages. The construction of cases was constantly in progress, and during the year there were received and fitted for use and placed in the exhibition halls 84 cases, chiefly of the standard patterns. Forty-five storage cases were made for use in the laboratories, 5400 wooden drawers and trays, and 54,000 pasteboard trays. There were also purchased 3504 glass jars, for storage and exhibition of alcoholic specimens, and 24 barrels (1115 gallons) of 98 per cent. alcohol.

The distribution of duplicates was much the same as in previous years. About twenty-four thousand specimens were sent out to 118 institutions and societies: those to institutions in the United States are generally gifts, though many were sent in the way of exchange. For all foreign sendings, equivalents in the way of exchange were received or promised.

Many interesting details are given as to the various Departments in which the collections of the Museum are grouped. In the Department of Arts and Industries a prominent place is held by the section of textiles, which includes a very full series of the animal and vegetable fibres used throughout the world, together with good representations of devices for spinning and weaving, and of the various products of the textile industries. This collection is nearly all permanently installed, provided with printed labels, and illustrated by diagrams. For lack of room, fully half of the material ready for exhibition has been stored away, and the cases prepared for its display are in boxes in the Armoury building. The space assigned to the exhibition series is still so crowded that the objects cannot be satisfactorily examined. To the collection of food substances, in the same Department, is assigned a large quantity of unassorted material. The few cases now on exhibition contain the foods of the North American Indians, of Japan and China, and some of the more curious and unusual articles of diet. There are also two cases of educational importance, which exhibit graphically the composition of the human body and its daily expenditure of tissues, and the manner in which this is compensated for by daily rations of food. This collection is modelled after the famous collection of a similar character prepared by Dr. Lankester and others for the Bethnal Green Museum in London. It is, however, based upon an entirely new series of analyses, and upon a revised plan prepared by Prof. W. O. Atwater, of the Wesleyan University and corresponds to the latest views in physiological chemistry. The collections in chemical technology already have a good nucleus, and the increase during the year in the collections of materia medica was greater than during any previous year except the first. The fisheries collection was opened to the public in May 1884, and since that time there has been constant improvement in the condition of the material exhibited. Some gaps in the series of illustrations of foreign fisheries have been filled by collections received from the Governments of Siam and Japan, and by the extensive collections from Great Britain, Sweden, Spain, France, Holland, and Greece, acquired at the close of the London Exhibition.

Of the collection of historic relics in the Department of Arts and Industries, we learn that it includes several hundred objects of national interest connected with the history of soldiers, statesmen, and important events. Closely related to the historical collection is the series illustrating the history of steam transportation, under the charge of Mr. J. E. Watkins, of Camden, N.J. The "John Bull" engine, imported from England in 1831, the model after which all subsequent American engines have been constructed, has been given to the Museum by the Pennsylvania Railroad Company, and placed on exhibition; and adjoining this is a case in which there are already assembled about forty objects illustrating the beginnings of the American railroad system. The collection of scientific instruments owes its interest at present chiefly to the historical associations of most of the apparatus displayed, including, as it does, instruments used by Priestley, Henry, and Hare. The original telegraphic instrument of Morse and Vail is also here shown. The collections of musical instruments, modern pottery, and porcelain, lacquer, and the process of engraving are partially displayed, and when cases and floor space shall become available, will soon develop into important features.

The Department of Ethnology, although one of the youngest, is one of the largest in the Museum; and its growth during the last year was very great. Certain large classes of objects, such as weapons of war and the chase, implements of agriculture, and other primitive industries, have been carefully grouped. In addition to these great series of objects, classified according to function, other groups of objects have been arranged in accordance with another idea of classification, which is deemed of equal importance, namely, that of race. The Eskimo collection, for instance, has been arranged in table cases in one of the exhibition halls, in accordance with the ethnic idea, although, in the minor details of classification, function and form, as well as geographical distribution, have been followed. A preliminary study of the collection of basketry has been completed. A paper upon the baskets of uncivilised peoples, with numerous illustrations, was published in the Museum Report for 1884, and a representative series placed on exhibition with provisional labels. The throwing-sticks and sinew back-bows have been the subject of papers, and are now on exhibition. The curator has in progress investigations upon several groups of objects, notably the history and technology of archery; upon transportation as effected by man without the aid of domestic animals or mechanism; upon the peculiar industries of several handicrafts; upon the Hoopah Indians of California. The underlying ideas in these investigations, a first instalment of which was published in the last Report of the Museum, are (1) that the methods of strict classification and nomenclature already applied in the other natural sciences are equally applicable to anthropology; (2) that a trustworthy and minute study of modern savage and barbarous *technique* is absolutely requisite to the archæologist and technologist in reconstructing the history of civilisation.

The collections in the Department of American Aboriginal Pottery have continued to increase with astonishing rapidity, and the extensive accessions which have been received through the Bureau of Ethnology, and from other sources, have been of the greatest scientific importance and popular interest. One of the four large central halls of the Museum is devoted entirely to this subject, and the removal of the collections of South American aboriginal pottery and of the extensive collections from the mounds which have for many years been accumulating in the Archæological Hall of the Smithsonian building, have filled it up to such an extent that it is difficult to find room for the new material as it comes in. During the year a portion of the hall was thrown open to the public. The exhibition case surrounding the walls of this room is probably the largest in existence in any museum, being 260 feet in length, 4 feet 9 inches in depth, and, being double throughout, its entire length is virtually 520 feet. Double the space now allotted to this Department is necessary for its proper display, and the value of the material here concentrated is practically inestimable; since even the modern tribes, who are still making pottery similar in its general character to that which is here preserved, have deteriorated to such a degree in their artistic capacity or skill that their products are not an exponent of their original artistic capabilities. So exhaustive is this collection that it is impossible that any thorough work can be done upon the American aboriginal pottery which shall not in great part be based upon it.

The total number of accessions in the Department of Antiquities was 2751; and all excepting eighty-four were of sufficient importance to be added to the exhibition and study series, which now include over 40,000 specimens. Dr. Rau, the Curator of this Department, is engaged upon the preparation of an illustrated work on North American prehistoric objects, which is designed to serve as a guide for visitors to the Department, and as an explanation of the terminology of North American archæology. This will bear the title, "A Classification of the North American Prehistoric Relics in the United States National Museum." This book will be fully illustrated, and, it is hoped, will be published in the ensuing year.

The most important accessions to the Department of Mammals, as in previous years, were in the shape of single specimens sent from zoological gardens and menageries, which have shown a great deal of liberality to the Museum in this respect.

The growth of the Department of Birds during the year was very satisfactory, the number of specimens added to the collection being 4147. The largest single accession was the collection made by the U.S. Fish Commission steamer *Albatross* in the Bahamas, of 1000 specimens and about 75 species, of which 5 were new to science. Another valuable collection, 243 specimens, 81 species, 1 new to the fauna of North America, was obtained in Alaska by Mr. Charles H. Townsend, while on a mission for the Fish Commission. Mr. Henry Seebohm, of London, gave to the Museum 171 specimens, 68 species, chiefly from Siberia, and of great value to the collection. The number of specimens in the collection is now 55,945, 7000 of which have been set apart for the exhibition series.

Very much was accomplished during the year in the classification and arrangement of the collection of eggs and nests of birds. The total number of specimens added is 2556, in 253 lots, and there are now more than 44,000 specimens in the collection, of which 1491 are in the exhibition, and 31,124 in the reserve collection, the remainder having been set aside as duplicates.

The remaining Departments of which accounts are presented are those of Reptiles, Fishes, Mollusks, Entomology, Marine Invertebrates, Comparative Anatomy, Invertebrate Fossils, Fossil and Recent Plants, Minerals, Lithology and Physical Geology, and Metallurgy and Economic Geology. In dealing with the Department of Entomology, the author of the Report has to record a fine instance of the generosity and public spirit for which the best class of American citizens are famous. In October last, Dr. C. V. Riley formally presented to the Museum his private collection of North American insects, representing the fruits of his own labours in collecting and study for over twenty-five years. This collection contains over 115,000 pinned specimens, and much additional material unpinned and in alcohol. This generous gift to the Government had long been contemplated by Dr. Riley, who wishes to be, as far as possible, instrumental in forming a national collection of insects. In his letter of presentation he remarked:—"While the future of any institution dependent on Congressional support may not be so certain as that of one supported by endowment, I make this donation in the firm belief and full confidence that the National Museum is already so well established in public estimation that it must inevitably grow until it shall rival, and ultimately surpass, other institutions in this country, or the world, as a repository of natural history collections

If there shall in the future result the concentration here at the national capital of the extensive entomological material which naturally comes here, and which in the past has been scattered among specialists in all parts of the country, so that in the future the student may find valuable material to further his work in any order, I shall feel amply rewarded for the action I have taken."

The Curators of all the Departments complain that in the new Museum building there is not nearly room enough for the display of the treasures placed under their care, and Prof. Baird presses upon the attention of the Board of Regents the urgent necessity for "additional quarters." One of the arguments used by him may, perhaps, not be without effect on public opinion. Efforts are being made to secure that in 1892—the four hundredth anniversary of the discovery of America by Columbus—there shall be an exposition, presenting a complete illustration of the New World at that date, and of its progress in the arts and industries in the 400 years intervening. Prof. Baird points out that the collections of the National Museum for the most part tend towards such a display, and expresses his belief that if the new building for which he asks were erected it would be a very easy matter to organise and arrange it with this object in view, without unnecessary labour or great expense, and by the date mentioned, as the result of the current work of the Museum, without any spasmodic or unusual effort.

Of the Bureau of Ethnology we need only say that, during the fiscal year 1885-86, it continued its ethnologic researches among the North American Indians. Enthusiastic investigators carried on mound-explorations, explorations in ancient and modern stone villages, and general field studies. Much good office work was also done. This was, as usual, to a large extent the supplement to, and discussion of, the results obtained by exploration, and was executed by the same officers who had previously sought for materials and information in the field.

We have not space for further details, but probably we have said enough (as far as possible in the words of the Report itself) to indicate the very flourishing condition of the Smithsonian Institution and the establishments associated with it. The Institution is one of which Americans have good reason to be proud, and we cannot doubt that the claim for a new building, advanced by Prof. Baird on behalf of the National Museum, will be promptly and very carefully considered by Congress.

NOTES

PROF. BÉCLARD, Dean of the Medical School of Paris, died a few days ago of pneumonia. He was buried with great ceremony on the 12th inst. A large number of professors and students attended the funeral. His best work is on the thermic phenomena accompanying muscular contraction. He was a pleasant man, of fluent and happy eloquence, and a good writer. His place will probably be filled by Ch. Richet, the editor of the *Revue Scientifique*.

THE Academy of Vienna intends to have a special meeting for the celebration of the centenary of the death of Father Boscovich, the astronomer. A similar ceremony will take place at Ragusa, his native place.

WE have received a proof copy of the annual address to the Asiatic Society, Calcutta, delivered by Mr. E. T. Atkinson, the President, on the 2nd inst. It is an able and very interesting survey of the work done by the Society in the past year, and of the progress made outside the Society in the subjects to which the attention of its members is directed.

THE sixth annual meeting of the Sanitary Assurance Association was held at the offices, 5 Argyll Place, W., on Monday last. Mr. Joseph Hadley, Secretary, read the annual Report, from which it appeared that the business of the Association during 1886 was much greater than in any previous year. The Report said that, of all the properties inspected, in only two cases of first inspection had the arrangements been such that the Council could certify the sanitary condition of the property without alteration. The Executive Council reported having held several meetings for the purpose of revising the Sanitary Registration of Buildings Bill of 1886, and a new Bill had been prepared for presentation to the House of Commons. In the new Bill, the principle of compulsory registration would be restricted to schools, colleges, hospitals, asylums, hotels, and lodging-houses. On the motion of Mr. Mark H. Judge, seconded by Mr. H. Rutherfurd, the following resolution was unanimously passed:—"That, as soon as the Sanitary Registration of Buildings Bill, 1887, is in the hands of members of the House of Commons, the President of the Local Government Board be asked to receive a deputation in support of the Bill."

ON Tuesday last the forty-first session of the General Medical Council was opened, and an address was delivered, as usual on such occasions, by the President, Dr. Acland, F.R.S. Starting with a reference to the Jubilee, he traced some of the changes which have taken place during the last fifty years in medicine and in the methods of medical education.

LORD RAYLEIGH will begin a course of six lectures on "Sound" on Saturday, February 26, at the Royal Institution.

IN the latest of his annual reports, President Eliot, of Harvard University, refers to the present position of science in the secondary schools of America. "A serious difficulty," he says, "in the way of getting science well taught in secondary schools has been the lack of teachers who knew anything of inductive reasoning and experimental methods. This he attributes in part to the fact that "good school methods of teaching the sciences have not yet been elaborated and demonstrated," and he urges that "it is the first duty of University departments of science to remove at least this obstacle to the introduction of science into schools."

WE have received the third part of the first volume of "The Proceedings of the Linnean Society of New South Wales," second series. It contains the papers read at the meetings held in July, August, and September 1886, and there are four plates. Among the contents are the fifth part of a "Catalogue of the described Coleoptera of Australia," by Mr. George Masters, an elaborate paper on the "Revision of Australian Lepidoptera," by Mr. E. Meyrick, and "Miscellanea Entomologica: No II. The Genus Liparetrus," by Mr. William Macleay.

IN the United States there is a very much larger number of female than of male teachers. According to the *Woman's Journal*, men are hardly ever employed in elementary schools in cities, save as principals or as teachers of some special branch. In the ten cities of Baltimore, Boston, Brooklyn, Chicago, Cincinnati, New Orleans, New York, Philadelphia, San Francisco, and St. Louis together, there are 12,719 public-school teachers, of whom 11,540 are women. The average percentage of male teachers in these cities is 9.

DR. M. TREUB, Director of the Botanical Gardens in Buitenzorg (Java), will be on furlough in Holland from the beginning of March till the end of November. In Dr. Treub's absence Dr. W. Burck will serve as Acting Director of the Gardens. Only the correspondence about the *Annales du Jardin Botanique de Buitenzorg*, together with private correspondence, is to be addressed to Dr. Treub himself (Voorschoten, near Leyden, Holland).

A French translation has just been issued of Preyer's "Physiology of the Embryo." This book is a valuable one, dealing with a very obscure subject, and also one of great interest to the physician as well as to the psychologist and physiologist. All the functions of the adult being are in turn considered in the embryo, the differences and similitudes being well pointed out. M. Preyer understands the value of a good method.

MM. Charcot and Richer have issued an interesting book on "Les Démoniaques dans l'Art," that is, on hysteria studied in art manifestations of the past. The book contains quite a number of pictures after the old masters, which show that all the convulsions and attributes due to hysteria had been noticed and accurately pictured, although the manifestations were ascribed to diabolical influence The scenes figured in this book relate especially to exorcising and similar feats, and very well illustrate the power of observation of many of the old painters.

A new medical paper is to be published shortly in Paris, under Prof. Grancher's direction, at a very low price, containing much matter and appearing twice a week. It will be called the *Univers Médical*, and the editor intends to devote a much larger part to foreign news than is usually given in French papers.

M. Duclaux, Professor in the Faculty of Sciences, issued on February 12 the first number of a new scientific periodical, the *Annales de l'Institut Pasteur*, of which he is editor, with a Committee comprising Messrs. Chamberland, Grancher, Nocard, Roux, and Straus. This periodical is to be published monthly, and will contain papers on bacteriology, physiologically and clinically considered. The first number contains a letter from Pasteur, giving very encouraging and positive facts concerning the efficacy of preventive inoculations, obtained in his own laboratory and in those of Russia and Italy.

Herr W. Engelmann, of Leipzig, has issued the first number of a monthly scientific periodical called *Zeitschrift für physikalische Chemie*. The editors are Profs. W. Ostwald, of Riga, and J. H. van't Hoff, of Amsterdam.

According to the *American Meteorological Journal*, an attempt is about to be made at St. Augustine, Flo., to sink a 12-inch artesian well to a depth sufficient to obtain water hot enough to heat buildings, pure enough for domestic purposes, and with pressure enough to run heavy machinery. Water can be found in Florida by boring 250 feet; and it is known that the artesian wells in that State have considerable pressure, and from a depth of 600 feet send water of warm temperature to a height of 45 feet when piped. The earth's internal heat is already forced into practical service at Pesth, where the deepest artesian well in the world is being sunk to supply hot water for public baths and other purposes. This well supplies daily 176,000 gallons of water heated to 158° F., and the boring is to be continued until the temperature of the water is raised to 176°. Heavy machinery is run by artesian well power in many parts of France, and the experience of the French shows that the deeper the well the greater the pressure and the higher the temperature. At Grenelle, a well sunk to the depth of 1802 feet, and flowing daily 500,000 gallons, has a pressure of 60 lbs. to the square inch, and the water from this well is so hot that it is used for heating the hospitals in the vicinity.

There is now ample evidence that the use of oil may be of considerable service in lessening the effect of dangerous seas. In one case the "slick" made by the oil extended 30 feet to windward, and the U.S. Hydrographic Office concludes that the oil is of use when the vessel is reaching ahead at the speed of eight or nine knots, with a beam wind and sea.

Herr Schiller, a well-known German architect, reports some facts which are of interest as indicating the radius of the circle of protection of good lightning-rods. On June 17 last, at the village of Mottingen, lightning struck a pear-tree 33 feet high. On one side, 115 feet away, was a school-house, with a rod 56 feet high. On the other side was a church, 328 feet away, and having a lightning-rod reaching up 154 feet. Both rods are well placed, and had worked well when tested, and the level of the foot of the tree is about the same as that of the two buildings. It is evident, then, if the facts have been accurately reported, that the radius of the circle of protection is not more than twice the height of the rod.

Another earthquake is reported from Aquila. On the night of February 3, three shocks were felt, two of which were accompanied by strong undulatory motion.

Earthquakes are also reported from the Vilayet Konia, in Asia Minor. On January 8, a subsidence of the ground was noticed at Holan Gola (Feneke district), accompanied with loud subterranean noises; many landslips took place in the adjacent hills. The shocks continued for six days, and the inhabitants of Feneke and the neighbouring villages took refuge in the fields. The earthquakes have destroyed seven villages.

On January 15 the Hawaiian volcano Mauna Loa began to discharge. Frequent shocks of earthquake were felt. A letter written on January 19 says:—"There have been thirty-six hours' continuous earthquakes. The lava flows down the south slope, and if its course be unchanged it will flow into the sea without doing much damage."

The Russian traveller M. Ogorodnikoff was told at Meshed that there are tin mines near that city and in various parts of Khorassan. In an article in the *Revue Scientifique* M. Berthelot points out that this accords with a passage in Strabo, who speaks (book xv. ch. ii. 10) of tin mines in Drangiana, the ancient name for the region now called Southern Khorassan. If there really have been tin mines in this district from time immemorial, there can be little doubt that they supplied the tin for the bronzes of ancient Egypt and Assyria.

The first zoological station in the tropics has been founded by Dr. Sluiter, at Batavia. This gentleman is already well known by his works on the fauna of the Sunda Islands. The Natural History Society of the Dutch Indies has presented Dr. Sluiter with sufficient means to establish three work-tables with the necessary apparatus, and to purchase a sailing-boat.

Mr. Abbott Kinney writes to the Los Angeles *Weekly Tribune* that the floods in Southern California are becoming every year more violent and destructive. The testimony on this point, he says, is uniform, complete, and unimpeachable. The streams now nearly all bring down more sand, gravel, and boulders, rise more rapidly, cut away more land, and dry up more quickly than formerly. Valuable valley lands are thus cut away or covered up, and in some cases the streams have spread out and deposited great fan-shaped mounds of sand and boulders. Mr. Kinney attributes the change chiefly to the destruction of forests. The brush and forests on the hills and mountains have been to a large extent swept away, and the result is that there is nothing to hold the water back. The rains do not penetrate into the soil and rocks which supply the springs, but rush suddenly off the mountains as from a roof, carrying the soil first, and then the gravel and boulders with them. The springs, deprived of their supply, diminish. The principal agent in the destruction of the natural verdure and protection of the mountains has been fire. Fires accidentally lighted, fires made by stock-men, bee-men, and fools, are, according to Mr. Kinney, producing effects that must eventually make Southern California a desert.

It is proposed that a school of hygiene shall be established at the University of Michigan, and the State Legislature is about to be asked to authorise the necessary expenditure. The scheme was suggested by the State Board of Health. The school would include in its curriculum climatological studies, air analyses and ventilation.

Last week there was a Convention of Photographers in the Hall of the Society of Arts, and the attendance was good and representative. The proceedings in the morning were opened by a few remarks from Capt. Abney, the President, who, in the afternoon, delivered a more elaborate address, projecting on a screen a succession of diagrams and pictures illustrative of his statements. At a dinner in the evening the toast of the Camera Club was proposed by Mr. V. Blanchard, who, in recalling the time when he made his first practical acquaintance with photography by watching a friend develop a paper negative, expressed the opinion that photographers might perhaps return to the use of paper negatives.

Prof. Liversidge, of the University of Sydney, who is about to return to England on leave of absence, has been requested by the Minister of Public Instruction of New South Wales to inquire into and report upon the mode of teaching natural science in the elementary schools of Great Britain and Ireland.

New South Wales will be represented at the Conference of Astronomers to be held in Paris in April next, by Mr. H. C. Russell, the Government Astronomer.

A valuable "Report on the Medusæ collected by the U.S. Fish Commission Steamer *Albatross*, in the Region of the Gulf Stream in 1883-84," by Mr. J. Walter Fewkes, has lately been reprinted, at the Government Printing Office, Washington, from the Annual Report of the Commissioner of Fish and Fisheries for 1884. Mr. Fewkes is not sure that certain of the Medusæ recorded by the *Challenger* from great depths do not also live and flourish at or near the surface. There is need, he thinks, for greater accuracy in the determination of the exact depth from which a deep-sea Medusa is taken, and for an improvement of the apparatus used in this kind of collecting. In the case of fixed hydroids, or such Medusæ as *Cassiopeia* and others, which live upon the bottom, the determination of the depth at which they live is an easy task. With such genera as *Atolla*, *Rhizophysa*, and others, this determination is more difficult. Mr. Fewkes points out that it is of great importance, from a morphological stand-point, that the question whether Medusæ are confined to certain depths, should be definitely answered. "I can at present," he says, "imagine no place on the globe where the uniformity of conditions under which Medusæ are placed can be the same as at great depths of the ocean. I do not mean necessarily on the floor of the ocean, since that may be raised or depressed, and the varieties of conditions which come from such motions may result, but in the depth of the sea, separated from the surface by a wall of water of great depth, and from the ocean-bed by a similar wall of equal amount. Here, if anywhere, may we look for the continuance of ancestral features unmodified by environment. On this account the determination of the bathymetrical limits of free Medusæ, no less than that of those animals which inhabit the bottom, is a most important thing, and from it should be eliminated all possibility of error."

Dr. Otto Hermes has just published the results of some interesting investigations concerning the phosphorescence of marine fish. He wished to ascertain whether the phosphorescence was caused by the same Bacillus which Dr. Fischer, an eminent authority on Bacteria, has discovered and brought from the West Indies. Marine fish are easily rendered phosphorescent after death by being moistened with a little sea-water. Dr. Hermes took a fragment of a specimen of *Gadus callarias*, which had been made strongly phosphorescent in this manner, to the laboratory of Councillor Koch; and Dr. Frank, a pupil of the latter, was enabled to isolate it after a few days. This is undoubtedly a new species. Like Dr. Fischer's Bacillus, it can be transferred upon sterilised fish, and after forty-eight hours it emits an emerald-green light; the sea-water is also rendered phosphorescent. A point of difference is that the Bacillus of Dr. Fischer develops best in a high temperature (20°–22°), while that of Dr. Hermes develops better in a low one. Examined microscopically, the latter is much smaller than the former. Dr. Hermes has given it the name of *Bacterium phosphorescens*.

The German Fishery Association lately asked the German Chamber of Commerce to put a premium on seals, it being maintained that these animals are most destructive to the fisheries. The petition was refused. The Association, in support of its views, stated that a full-grown seal requires 10 lbs. of fish a day for its food, making 3650 lbs. in a year. At the same rate, 1000 seals would consume the enormous quantity of 3,650,000 lbs. a year. As the seal is a faithful attendant upon herring-shoals, it causes enormous havoc among a species of fish which is one of the greatest sources of revenue to the fishermen on the North German coast. It is maintained that these depredations have greatly decreased the quantity of fish in recent years. Complaints of the serious destruction of fish by seals have also lately been made by Swedish fishermen in the Baltic.

The additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus* ♂) from West Africa, presented by Mr. Charles W. Demprey; a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mr. G. S. Copeland; a Common Otter (*Lutra vulgaris*), British, presented by Mr. John Hall; two Rufous Tinamous (*Rhynchotus rufescens*) from Brazil, presented by Mr. Francis Monckton; two White-throated Finches (*Spermophila albogularis* ♂ ♀) from Brazil, deposited; a Collared Fruit Bat (*Cynonycteris collaris*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

A Method for the Determination of the Constant of Aberration.—Referring to M. Lœwy's plan for the determination of the constant of aberration by measuring the relative positions of stars situated in distant parts of the sky at successive epochs by means of a double mirror placed in front of the object-glass of an equatorial (Nature, vol. xxxv. p. 282), M. Houzeau points out (*Comptes rendus*, tome civ. No. 5) that the same idea occurred to him some years ago, and that the fundamental principle of the method, and an enumeration of the advantages attending its application, were published by him in 1871, in a paper entitled "Considérations sur l'Etude des petits Mouvements des Etoiles," which appeared in tome xxxviii. of the Mémoires de l'Académie de Belgique. It appears, therefore, that M. Lœwy's method cannot, strictly speaking, be considered a new one, though we believe it has never been put into actual practice—a work which we hope to see before long accomplished at the Paris Observatory.

The Application of Photography to the Determination of Stellar Parallax.—In the *Monthly Notices* for January 1887, Prof. Pritchard publishes the results of his measurements of the photographs of 61 Cygni and neighbouring stars, taken on fifty nights ending December 7, 1886, with a view to the determination of the parallax of this well-known star. Using measures of distance only, the relative parallaxes of each of the components, referred to each of four comparison-stars, are:—

Star	Parallax of 61^1 Cygni	Probable error	Parallax of 61^2 Cygni	Probable error
	"	"	"	"
a ...	0·4412 ...	0·0154 ...	0·4204 ...	0·0229
b ...	·4529 ...	·0330 ...	·4139 ...	·0185
c ...	·4433 ...	·0197 ...	·4721 ...	·0215
d ...	·4158 ...	·0161 ...	·4574 ...	·0252

The means for the parallaxes thus obtained for the four independent sets of measures of 61^1 and 61^2 Cygni respectively are as follows:—

For 61^1 Cygni, 0″·438; for 61^2 Cygni, 0″·441.

Prof. Pritchard explains that this determination is to be regarded as provisional only, and that the work will be continued to the end of the annual cycle. The method certainly appears to be a most promising one, and the publication of the full details of the Oxford researches will be awaited with interest.

OBSERVATIONS OF VARIABLE STARS IN 1885.—No. 151 of Gould's *Astronomical Journal* contains Mr. Edward Sawyer's observations of variable stars made in 1885. The following epochs of maximum brightness were observed:—R Andromedæ, 1885 January 10; R Leonis, about 1884 December 24; R Leo. Min., 1885 June 26; R Boötis, 1885 May 16; R Ursæ Majoris, July 1; S Ursæ Majoris, May 7; U Herculis, July 8; *g* Herculis, June 4, August 2 (?), October 16; S Coronæ, May 11; χ Cygni, 1886, January 10; R Scuti, 1885 June 17, August 10 (?), and November 16; Mira Ceti, February 10; R Aquarii, January 4. β Pegasi and α Cassiopeiæ appeared constant, and ρ Persei nearly so, during the observations. R Coronæ was well observed, and showed numerous but slight fluctuations of light. An unusally bright phase, 6·2 m., occurred on August 15, followed by a rather faint minimum, 7·4 m., on October 13. T Monocerotis was well observed: last minimum, April 20, 15h. 26m. Camb. M.T.; last maximum, April 27, 15h. 55m. U Monocerotis was observed at minimum on April 1, and at maximum on April 14. W Cygni was observed at maximum on August 20 and December 16, giving a period of 118 ± days, and at minimum on October 30.

THE ALLEGED ANCIENT RED COLOUR OF SIRIUS.—Mr. Lynn, in the current number of the *Observatory*, shows that the evidence for this star having formerly been of a red colour is much less strong than has frequently been supposed. Prof. Schjellerup had pointed out in his notes on his translation of Sûfi, that the designation ὑπόκιῤῥος applied to the star in our editions of Ptolemy was probably an error of transcription for σείριος; whilst it had been suggested long ago that, for the word "ruber" which we find used in reference to it by Seneca, we should really read "fulgor." It certainly has always seemed improbable that a star of such vast dimensions as Sirius must be should have so entirely changed its colour in less than 2000 years.

BRIGHT LINES IN STELLAR SPECTRA.—Mr. O. T. Sherman, in No. 149 of Gould's *Astronomical Journal*, brings together various observations of the bright lines which have been observed by Vogel or Copeland in the spectra of β Lyræ, γ Argûs, R Geminorum, and some smaller stars, and compares them with Hasselberg's observations of the low-temperature spectrum of hydrogen and the high-temperature spectrum of oxygen, and draws the inference that the stellar bright lines belong to these spectra. The inference seems scarcely warranted, however, for, on the one hand, the lines in the spectrum of hydrogen are so numerous that, wherever the star-lines lay, it would be easy to find lines near them, so that the accord would have to be very close for any such deduction to be safely based upon it; and, on the other, the observations of the lines in the stellar spectra are less accurate than Mr. Sherman seems to think. The slight differences in the recorded positions of the bright lines as given by different stars are probably indications simply of a roughness in the readings, and the lines are most likely the same in general in the different spectra. The following may be taken as rough mean positions for the bright lines in these interesting spectra: 600 mm., 581, 568, 540, 466, together with the F line of hydrogen, and, in some cases, D_3 and the third line of hydrogen at 434, assuming that the lines are the same in the various spectra of the type. The close correspondence of the bright lines in R Geminorum to those observed by Cornu in Nova Cygni, 1876, indicates that we probably have there the coronal line 1474 K, the principal chromospheric lines, and the typical nebular line at about 500.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 FEBRUARY 20-26

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on February 20

Sun rises, 7h. 6m.; souths, 12h. 13m. 56·7s.; sets, 17h. 21m.; decl. on meridian, 10° 55′ S.: Sidereal Time at Sunset, 3h. 22m.

Moon (New on February 22) rises, 5h. 52m.; souths, 10h. 25m.; sets, 15h. 2m.; decl. on meridian, 17° 6′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	7 33	12 58	18 23	7 34 S.
Venus	7 49	13 27	19 5	4 59 S.
Mars	7 38	13 9	18 40	6 23 S.
Jupiter	23 16*	4 17	9 18	12 11 S.
Saturn	12 59	21 8	5 17*	22 23 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

Feb.	h.	
20	2	Jupiter stationary.
22	—	Annular eclipse of the Sun; visible only in parts of South America, Australia, and the South Pacific Ocean.
24	17	Venus in conjunction with and 1° 17′ north of the Moon.

Variable Stars

Star	R.A. h. m.	Decl. ° ′		h. m.	
U Cephei	0 52·3	81 16 N.	Feb. 20,	20 38	*m*
			,, 25,	20 17	*m*

δ Cephei	22 25·0	57 50 N.	,, 23,	21 0	*m*

M signifies maximum; *m* minimum.

Meteor-Showers

February 23–25, near β Trianguli, R.A. 30°, Decl. 35° N. Also from Monoceros, R.A. 120°, Decl. 5° S.

GEOGRAPHICAL NOTES

IT would seem that Dr. Oscar Lenz is only to leave Zanzibar this week. The *Times* Vienna Correspondent is mistaken in thinking that the Royal Geographical Society expects Dr. Lenz to come direct to London. He must, of course, first render his account to the Vienna Society, which sent him out; but after that, it is hoped, he will come to London and tell his story. It is possible that before leaving Zanzibar he may have an opportunity of giving Mr. Stanley the benefit of his experience. Mr. Joseph Thomson, in a letter to the *Times*, endeavours to show that Mr. Stanley is taking a too rosy view of the prospects of his expedition. Mr. Thomson naturally insists on the superiority of the Masai Land route over all others. Certainly Mr. Stanley exaggerated the difficulties of this route, and we are inclined to believe that, had it been selected, the expedition might have reached Emin Pasha sooner than by the Congo. It should be remembered that, even if all the vessels on the Middle and Upper Congo are available, they could not possibly convey a thousand people in one journey—a good authority assures us that there must be at least three journeys; so that, unless Mr. Stanley starts on his land journey with only one-third of his caravan, instead of 35 days after leaving Stanley Pool it will take 100 days to reach the mouth of the Aruwimi. At the same time we must believe that Mr. Stanley knows what he is about, and is not likely to lay himself open to the reproach of being so far out in his calculations.

IN the official report, just issued, on the administration of Lower Burmah during 1885-86, and Upper Burmah during 1886, there are some interesting passages relating to the resources of the new British province. Agricultural products, such as rice, wheat, maize, and other cereals, are grown in large quantities. The country is believed to be rich in mineral resources, and the subject is at present under the examination of the Geological Survey. Meanwhile it is known that the country to the north-east of Mandalay is the richest, if not the only, ruby-producing tract yet discovered. As to gold and silver, nothing trustworthy is known. Jade and amber are found in parts. But the most valuable of the Upper Barmah minerals is likely to be coal, of which there are certainly four fields, one of which has already yielded excellent fuel.

DR. HOLUB, whose murder to the north of the Zambesi is doubtfully announced, may be remembered as the author of "Seven Years in South Africa," published about six years ago. He set out some three years ago to march from the Cape to Cairo, partly for purposes of exploration, and partly to open up markets in Central Africa for Austrian commerce. He does not seem to have made much speed.

PROF. MIGUEL MARAZTA has made what seems a curious anthropological discovery in the valley of Rebas (Gerona) at the end of the Eastern Pyrenees. There exists in this district a somewhat numerous group of people, who are called *Nanos* (dwarfs) by the other inhabitants, and as a matter of fact are not more than four feet in height (1·10 to 1·15 metres). Their bodies are fairly well built, hands and feet small, shoulders and hips broad, making them appear more robust than they really are. Their features are so peculiar that there is no mistaking them among others. All have red hair; the face is as broad as long, with high cheek-bones, strongly developed jaws, and flat nose. The eyes are not horizontal but somewhat oblique, like those of Tartars and Chinese. A few straggling weak hairs are found in place of beard. The skin is pale and flabby. Men and women are so much alike that the sex can only be told from the clothing. Though the mouth is large, the lips do not quite cover the large projecting incisors. The *Nanos*, who are the butt of the other inhabitants, live entirely by themselves in Rebas. They intermarry only among themselves, so that their peculiarities continue to be reproduced. Entirely without education, and without any chance of improving their condition, they lead the life of pariahs. They know their own names, but rarely remember those of their parents, can hardly tell where they live, and have no idea of numbers.

JOHN HUNTER

THE Hunterian Oration was delivered on Monday afternoon in the theatre of the Royal College of Surgeons by the President, Mr. Savory, F.R.S., Senior Surgeon to St. Bartholomew's Hospital. After a few introductory remarks, Mr. Savory proceeded to say that surgeons with one voice have proclaimed the supremacy of Hunter above all who have ever studied surgery. Students of science have acknowledged him to be among the chief of those who have in any age advanced human knowledge. He was, and is, beyond and above all surgeons, a philosopher in surgery. His idea of the subject of his thoughts was far more adequate than that of other men. He was supreme in the scope and method of his work. He understood much better than those around him how to engage in the interpretation of Nature; he knew best how to approach and to disclose truth. For he not only understood that the problems which lay immediately before him were, of all, the most complex and difficult to solve, but he could see also that they were not isolated but dependent ones. He saw in the necessary relation in which they stood to others the only means by which they could be worked out; and on this understanding he resolved to investigate the questions he desired to answer. Mr. Savory next spoke of the passion of Hunter for collecting. His museum included, he said, not only—to use the words of Professor Flower—"illustrations of life in all its aspects, in health and in disease; specimens of botany, zoology, palæontology, anatomy, physiology, and every branch of pathology; preparations made according to all the methods then known; stuffed birds, mammals, and reptiles, fossils, dried shells, corals, insects, and plants; bones and articulated skeletons; injected dried and varnished vascular preparations; dried preparations of hollow viscera, mercurial injections, dried and in spirit; vermilion injections; dissected preparations in spirit of both vegetable and animal structures, natural and morbid; undissected animals in spirit, showing external form or awaiting leisure for examination; calculi and various animal concretions; even a collection of microscopic objects, prepared by one of the earliest English histologists, W. Hewson; but it extended to minerals, coins, pictures, ancient coats of mail, weapons of various dates and nations, and other so-called 'articles of *vertu*.'" Hunter's labours in surgery were next referred to. He was ever searching for principles, but strove to reach them only through facts. Facts always first, but never facts only; from facts to principles. He understood that all progress mainly depends on the power of grouping and uniting for some new purpose facts that have been discovered independently and that are daily being revealed, yet with little or no reference to the principles they are found to support. He saw that surgery, in his time, was but a rude, empirical art, consisting of little else than a knowledge of many facts which stood in no visible relation to each other, and of many more opinions which, for the most part, had no relation, or but a very distant one, to any facts whatever. He held that surgery should be raised from a collection of such creeds to the rank of a science, but this could be only by founding its practice upon some principles. The discovery of some, at least, of these principles was Hunter's final aim. But those principles could not be reached by guessing. They could be approached only through the orderly investigation of facts. But then an explanation of these facts themselves could be only through the truths of physiology. The signs of disease could be understood only by him who had studied the laws of life and health. An intelligent interpretation of the one could be only in proportion to a previous knowledge of the other. But the problems of life, of health, are presented to us in man in their most complex form—in a form so difficult that even Hunter could not solve it. They must be reduced to simpler terms through a study of the lower forms of life. Thus, with the ultimate aim of relieving human suffering, Hunter studied the phenomena of motion in plants. Nay, he went further, to crystals and other forms of inorganic matter; and he says: "The better to understand animal matter, it is necessary to understand the properties of common matter, in order to see how far these properties are introduced into the vegetable and animal operations." The singleness of purpose with which Hunter worked is made evident, Mr. Savory continued, not only in the actual result of his labours, for no human being with divided interests could rival such achievements, but in the record, as we have it, of the life he led. He gave not only the whole of his time—yes, the whole of it in no mere conventional sense—and all his great powers, his mind and body alike, to the one object of his life; but to this he sacrificed all that he possessed, all that he could gain. To this he devoted, without stint or scruple, his money, his friendships, all his other interests. What any other man would have considered impossible, he made practicable. And this to no personal end. He was careless of all rewards save that which was to him paramount, the discovery of truth. A noteworthy point in the character of Hunter appears to be found in the relation which, in him, thought bore to action. He combined in himself in a singular degree the power of conception and of execution. He not only saw much further, but he was able to do much more than most others. He saw as Bacon saw—and the idea was probably as original with him as with Bacon—that the systematic and thorough examination of facts was the first thing to be done in science, "and that, till this had been done faithfully and impartially, with all the appliances and all the safeguards that experience and forethought could suggest, all generalisations, all anticipations from mere reasoning, must be adjourned and postponed; and further, that, sought on these conditions, knowledge, certain and fruitful, beyond all that man then imagined, could be obtained." But he went immeasurably further than the great prophet of science in putting his conceptions to the proof in imperishable work on the lines he had laid down. "I only sound the clarion," said Bacon, proudly, "but I enter not into the battle." Hunter sounded a clarion the echoes of which are reverberating still, but he entered into the battle also, and was always found where the blows fell thickest, and we are in possession of the spoils. In his museum there is, at once, the clearest evidence of the idea and the richest fruits of execution. In speaking of Hunter's general education, Mr. Savory proceeded to say that if Hunter had received a good general education in early years he would have been all the better for it. He would have lost nothing. His mental powers could have been in no way impaired; on the contrary, enhanced. He would have recorded the results of his labours in better order, with more light and greater effect, and we should have had the advantage of a clearer revelation of his thoughts. But all this is very far from saying that Hunter was not, in the strictest sense, an educated man. He was not, indeed, a scholar. If the subtle rendering of a Greek poet, or the skilful turning of a Latin verse be the sole test of culture, he gave no sign of it. Of ancient lore he was sadly destitute. In *Literis Humanioribus* he could have had no place. But if a transcendent knowledge of Nature and her ways, if a firm and ample grasp of her noblest truths, be accounted education, if the devotion through a lifetime of gigantic intellectual powers and of a truly loving heart to the reverent study of God's works be culture, then Hunter, though not a man of letters, was surely a highly educated man. The fame of Hunter, after all, falls far short of him. It may, without exaggeration, be said that he is really greater than to most men, even to most surgeons, he appears to be. It is only after a review of the whole of his vast labours, in their mutual relation, not merely after a study of the merits of his numerous papers, each taken by itself, but in an attempt to apprehend the scheme to which all his labours were subservient, that we are in any measure able to realise the strength of Hunter's genius. Then, as the chief merit of his work is not of a character to catch at once the eye, even of one who searches for it, so his subject is not one of widespread or popular interest. Of all men who have achieved greatness, Hunter requires to be studied with most diligence, the more so because of the absence of all literary skill. And there can be no doubt that he shared the fate of all those who have been, like him, in advance of their time. He was so far beyond his contemporaries as to be, for the most part, out of their reach, and therefore they left him alone; and even his successors have not always found him out. It may, indeed, be said to have been almost by an accident that, in association with the possession of his museum, we have periodically a festival in honour of his memory. Such, then, at least in the eyes of one who, though from afar, has long and earnestly looked up to him, was John Hunter. Beyond all cavil, if the word have any meaning for us, he was a man of genius—a man supremely endowed with power and faculties for the discovery of truth. With little education at the outset of life, without the advantage of the schools, he found himself face to face with the deepest and most mysterious problems of Nature, and he was forthwith able to take full measure of the magnitude of the task. It seems never to have occurred to him that he could snatch an answer by surprise; that a solution could be reached by any short or sudden means. But his survey assured him that upon one plan only, but by that abundantly, could success be made certain. So with patience, which of itself has been called genius, he went back to the beginning. It was genius too, and that of the highest order, to discern, at so vast a distance, where the beginning lay. But there he placed himself, and from that point went forward only when he had made each footstep sure. Who shall say that his imagination was not fertile, or that he faltered in the use of it? Yet no seductive theory tempted him into undue haste, and though sometimes drawn aside by a specious speculation, he seems hardly ever to have been lost in an unsound conclusion. And when he fell, the treasures he had won were found not only in the multitude of facts he had garnered, or even in the principles which, by virtue of the facts he had discovered, were made plain, but also in the very plan and purpose of his work. For, from the height on which at length he stood, not only can the path he trod be clearly traced, but the highway thenceforward is disclosed. So is the greatness of John Hunter to be estimated, not only by what he discovered, but rather by the lesson and example of his work. Truly it may be said of him that he did much. Truly it may be said of him that he showed how much more there is to be done. "He being dead yet speaketh," still speaks to us as no other man before or since has spoken. But when and where can his voice be heard most plainly? Are the spirits of those who have shaken off "this muddy vesture of decay" permitted to revisit the scenes of their earthly labours? Can they still be with us on our way? If the soul of this mighty son of science is ever in our midst, surely his favourite haunt must be now within these walls—in the museum which will soon almost surround us, at once his most graphic and glorious monument. The memory of Hunter, like the memory of the greatest men of every age, is imperishably enshrined. Art, in her noblest efforts, has striven to make his form familiar to us. His name is stamped in indelible characters on the records of human progress. But, before all, he lives in, and draws the breath of life from, his own immortal works. And of these none can be so truly a memorial of the very man as this; no other can so resemble him, can possess so much of him, can tell so fully of what he was; can so perpetuate him in the vast store of facts, in the purpose for which they are set forth, in the illustration of principles, in the suggestion of truths beyond those it can show, above those it can reach—in all this, I say, no memorial, however majestic, can rival our museum. The foundation of this with his own hand and his whole heart he laid; it has grown, and still is growing, from his strength, and it must be made for ever worthy of his name.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

Oxford.—The following new Examiners have been appointed in the Natural Science School: Mr. V. H. Veley (Chemistry), Dr. W. H. Gaskell and Prof. Ray Lankester (Biology), Mr. J. V. Jones (Physics). Mr. W. W. Fisher and the Rev. F. J. Smith are to be Examiners in the Pass Schools.

The Sibthorpian Professorship of Rural Economy is now vacant, and canditates for it are requested to send in their applications to the Registrar of the University before March 10.

The Board of the Faculty of Medicine has issued a list of subjects to be offered in the first examination for the B.M. degree under the new medical statutes.

Scholarships in Natural Science are announced for competition at Merton, Corpus, and Queen's, and at New College.

SCIENTIFIC SERIALS

American Journal of Science, January.—The Muir glacier, by G. Frederick Wright. The paper contains an exhaustive study of this interesting glacier, which lies in the Alpine region of Alaska at the head of Muir Inlet, Glacier Bay, in 58° 50′ N. lat., 136°40′ W. long. It forms a frozen stream some 5000 feet wide by 700 deep, entering the inlet at a mean rate of 40 feet, or 140,000,000 cubic feet, per day, during the month of August. The vertical front at the water's edge is from 250 to 300 feet, and from this front icebergs are continually breaking away, some many hundred feet long, with a volume of 40,000,000 cubic feet. The glacier appears to be rapidly retreating, there being indications that even since the beginning of this century it has receded several miles up the inlet, and fallen 1000 or 1500 feet below its former level.—On the age of the coal found in the region traversed by the Rio Grande del Norte, by C. A. White. The carboniferous beds occurring at various points in this region vary greatly in quality, but none of them appear to be earlier than late Cretaceous age.—The viscosity of steel and its relations to temper (continued), by C. Barus and V. Strouhal. Among the chief results of the authors' further experiments, as here described and tabulated, is the light thrown on the crucial importance of the physical changes which steel undergoes during annealing at high temperatures between 500° and 1000° C. Within these limits occur several nearly coincident phenomena: such as Gore's sudden volume expansion; Tait's sinuously broken thermoelectric resistance; Gore-Baur's sudden disappearance of magnetic quality; the passage of carbon from uncombined to combined; Jean's critical cementation temperature; and the authors' own unique maximum of viscosity.—On the nature and origin of lithophysæ, and the lamination of acid lavas, by Joseph P. Iddings. The data upon which the conclusions here stated are based were obtained from a study of the various forms of structure and crystallisation assumed by acid lavas in cooling, as observed while prosecuting the work of the United States Geological Survey in the Yellowstone National Park under Mr. Arnold Hague. The lithophysæ, composed of prismatic quartz, tridymite, soda-orthoclase, fayalite, and magnetite, appear to be of aqueo-igneous origin, having been produced by the action of the absorbed gases upon the molten glass from which they were liberated during the crystallisation consequent upon cooling. It also seems highly probable that the differences in consistency and in the phases of crystallisation producing the lamination of this rock were directly due to the amount of vapours absorbed in the various layers of the lava and to their mineralising influence.—The latest volcanic eruption in Northern California, and its peculiar lava, by J. S. Diller. The volcanic district here described is that of the so-called "Cinder Cone," near Snag Lake, North California, where the recent character of the eruptive phenomena is most striking as compared with other outbursts in the same region. The lava field, some three square miles in extent, is of basaltic type, but remarkably anomalous in containing numerous grains of quartz, and very high percentages of silica and magnesia with correspondingly low quantities of the oxides of iron. — On the texture of massive rocks, by

George F. Becker. From his researches the author infers that porphyries may form at any depth and no matter how slowly the temperature of the magma may sink, while granular rocks can scarcely ever have been thoroughly fluid or homogeneous, but have often consolidated at pressures extremely moderate compared with those at which it is certain that porphyries would form.—A fifth mass of meteoric iron from Augusta County, Virginia, by George F. Kunz. This specimen, which comes from the same place where was found the largest of the three masses first described by Prof. Mallet, yielded, on analysis: iron 90·293; nickel, 8·848; cobalt, 0·486; phosphorus, 0·243; carbon, 0·177; with traces of copper, tin, sulphur, silica, manganese, chromium, and chlorine.—Note on the origin of comets, by Daniel Kirkwood. It is argued that, although most comets are of interstellar origin, some of short period may have had their rise within the solar system.—The bichromate of soda cell, by Selwyn Lewis Harding. The experiments here described tend to show that this is a most efficient cell, whose effectiveness, as far as its constancy is concerned, might be materially increased by interchanging the positions of the electrodes with their surrounding liquids, after the fashion of the Fuller cell.

SOCIETIES AND ACADEMIES

London

Royal Society, January 13.—"Supplementary Note on the Values of the Napierian Logarithms of 2, 3, 5, 7, and 10, and of the Modulus of Common Logarithms." By Prof. J. C. Adams, F.R.S.

In vol. xxvii. of the Proceedings of the Royal Society, pp. 88-94, the author has given the values of the logarithms referred to, and the value of the modulus, all carried to 260 places of decimals.

The calculations in that paper were carried to several more decimal places, but the application of an equation of condition which supplied the means of testing the accuracy of the whole work, showed that errors had crept into the work which vitiated the results beyond 263 places of decimals.

Through inadvertence, however, the results were printed in the above paper exactly as they were given by the calculations, although several of the later decimals, especially in the value found for the modulus, were known to be wrong.

The author has now succeeded in tracing and correcting the errors which occurred in the former calculations, and the equation of condition which tests the accuracy of the work is now satisfied to 274 places of decimals.

The present paper gives the parts of the several logarithms concerned which immediately follow the first 260 decimal places as already given in the former paper, and likewise the corrected value of the modulus, which is found to be—

M = ·43429	44819	03251	82765	11289	13216	60503	22943	97005	80366
65661	14453	78316	58646	49208	87077	47232	24949	33843	17483
18706	10674	47663	03733	64167	92371	58963	90656	92210	64662
81226	58521	27086	56867	03295	93370	86965	88266	88331	16360
77384	90514	28443	48666	76864	65860	85135	56148	21234	87653
43543	43573	17253	83562	21868	25				

which is true to 272 or 273 places of decimals.

February 10.—"Contributions to the Metallurgy of Bismuth." By Edward Matthey.

"An Inquiry into the Cause and Extent of a Special Colour-Relation between certain Exposed Lepidopterous Pupæ and the Surfaces which immediately surround them." By Edward B. Poulton.

Linnean Society, February 3.—W. Carruthers, F.R.S., President, in the chair.—Dr. M. C. Grabham and Capt. G. Wingate were elected Fellows of the Society.—Mr. G. Maw exhibited a *Narcissus cyclamineus* grown by him from bulbs sent by Mr. A. W. Tait, of Oporto. The plant in question was known to Parkinson (1640), afterwards was lost of, and rediscovered by Mr. Johnston, near Oporto, in 1885.—Mr. Maw showed a drawing of *Crocus Karducharum*, and another, for comparison, of *C. zonatus*, from the Taurus, to which it is allied.—Brigade-Surgeon J. E. T. Aitchison read a paper on the fauna and flora of the Afghan boundary. The zoological collection obtained comprised, in round numbers, 20 species of mammals, 130 species of birds, 35 species of reptiles, 7 species of fish, and over 100 species of insects. Among these, many were new to science. Of special interest is the mole-like rat, *Ellobius fuscicapillus*, hitherto only known from the type obtained forty years ago at Quetta. In certain places the ground is riddled with the burrows of this and other rodents. The geographical range of the tiger goes east and north to Bala Murghab; that of the cheetah to the valley of the Heri-rud. A pheasant (*Phasianus principalis*) and woodpecker (*Gecinus gorii*) are new. With some exceptions, the birds are chiefly migratory, their arrival in spring following each other in quick succession. The Brahmini duck (*Casarca rutila*), unlike its congeners, nests and remains throughout the year. The most abundant species of birds are, among the genera *Saxicola*, *Lanius*, *Sylvia*, *Motacilla*, and *Emberiza*. An adult fine example of *Naia oxiana* is a museum acquisition, as the species heretofore has only been recognised from young undeveloped specimens. Regarding the insects, 20 are new, though, taken as a whole, the insect fauna resembles that of Arabia and North Africa, rather than that of India proper. The botanical collections amount to 800 species, and probably 10,000 specimens of plants. Over 100 are new to science. The author gave some account of the physical features of the districts traversed, and of the climate. Taking these into consideration, he states that the plants do not represent what is generally recognised as an Oriental flora, being chiefly composed of northern Persian and Arabian forms, augmented by Central Asian and Siberian types, with a few West Himalayan or Tibetan, and still fewer representing the Punjab or Scind. Beside these are a fairly representative local flora; say, one-sixth of the collection. *Juniperus excelsa* is the only indigenous conifer; neither oaks nor species of *Æsculus*, *Olea*, or *Myrtus* were met with. *Populus Euphratica* forms forests in the river-beds, but as long as the tree is situated near water it is indifferent to altitude. Out of 75 natural orders, Compositæ and Leguminosæ greatly preponderate over the others, containing 81 and 80 species respectively. In Compositæ, *Cousinia* heads the genera with 18 species; *Centaurea* has 10 species. Of 80 species of Leguminosæ, 39 belong to the genus *Astragalus*, 14 of these being new. Of 61 species of Gramineæ, all are well known. The Cruciferæ collected number 56 species; several are new. Chenopodiaceæ follow with 39 species, Labiatæ with 35, Boraginaceæ 32, Umbelliferæ 30, Caryophyllaceæ 30, Rosaceæ 27, Lilliaceæ 26, Euphorbiaceæ 16, Polygonaceæ 15, Ranunculaceæ 14, Rubiaceæ and Cyperaceæ each 13, Scrophularineæ and Plantagineæ 10 and 11 respectively. The orchards at some of the villages are surrounded with high walls, inside which is a row of mulberry-trees grown for the breeding of silkworms. In the Afghan gardens, beetroot, carrots, turnips, cabbages, radishes, and tomatoes are raised, and these are of excellent quality. In the fields, besides wheat, rye, and barley, opium, tobacco, melons, and certain oil-seeds are cultivated. Cotton is grown, but the quality of the fibre is poor. Several plants of pharmaceutical value flourish—Galbanum, Ammoniacum, &c., and of these the author gave a full account.

Zoological Society, February 1.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—Mr. F. Day exhibited and made remarks on a hybrid fish supposed to be between the pilchard and the herring, and a specimen of *Salmo purpuratus* reared in this country.—Mr. W. L. Sclater exhibited and made remarks upon some specimens of a species of *Peripatus* which he had obtained in British Guiana during a recent visit to that country, and added some general observations on the distribution and affinities of this singular form of arthropods.—Mr. A. Thomson read a report on the insects bred in the Society's Insect House during the past season, and exhibited the insects referred to.—A communication was read from Dr. B. C. A. Windle, containing an account of the anatomy of *Hydromys chrysogaster*.—Mr. Martin Jacoby read a paper containing an account of the Phytophagous Coleoptera obtained by Mr. G. Lewis in Ceylon during the years 1881, 1882. About 150 new species were described and many new generic forms.—Mr. F. E. Beddard read some notes on a specimen of a rare American monkey, *Brachyurus calvus*, which had died in the Society's Gardens.—Mr. Oldfield Thomas read a note on the mammals obtained by Mr. H. H. Johnston on the Camaroons Mountain.—A paper was read by Capt. Shelley, containing an account of the birds collected by Mr. H. H. Johnston on the Camaroons Mountain. The collection contained thirty-six specimens referable to eighteen species, and of these four were new to science.—Mr. G. A. Boulenger read a list of the reptiles collected by Mr. H. H. Johnston during his recent visit to the Camaroons Mountain.—Mr. Edgar A. Smith read a paper on the Mollusca collected at the Camaroons Mountain by Mr. H. H. Johnston, and gave the description of a new species of *Gibbus*, proposed to be called *Gibbus johnstoni*, of which specimens were in the collection.—A communication was read from Mr. Charles O. Waterhouse, containing a list of some coleopterous insects collected by Mr. H. H. Johnston on the Camaroons Mountain.

Geological Society, January 12.—Prof. J. W. Judd, F.R.S., President, in the chair.—The President announced the sad loss which the Society had sustained since the last meeting by the death of Mr. John Arthur Phillips, F.R.S., who had been for several years a valuable member of the Council, and one of the Vice-Presidents of the Society.—The following communications were read:—The Ardtun leaf-beds, by J. Starkie Gardner, with notes by Grenville A. J. Cole. The description of these beds by the Duke of Argyll thirty-five years ago indicated that enormous tracts of trap in the Inner Hebrides were of Tertiary age. Prof. Edward Forbes, who described the leaves, inclined to the idea that they might be Miocene; but in estimating the value of this conjecture, we must remember that at the time the existence of Dicotyledonous leaves of similar aspect, but of undoubtedly Cretaceous age, was quite unsuspected, and that no typical Eocene flora had then been properly investigated or described. Prof. Heer adopted the opinion that the age of this formation was Miocene, and unfortunately extended its application to formations containing similar floras in Greenland and elsewhere. The writer of the present communication tried to show that instead of belonging to the Miocene, these floras are of Eocene age, and in fact older than the Thanet beds. He also re-described the plant-beds, and maintained that they are part of a rather extensive series of sedimentary rocks intercalated among the traps.—On the Echinoidea of the Cretaceous strata of the Lower Narbadá region, by Prof. P. Martin Duncan, F.R.S.—On some Dinosaurian vertebræ from the Cretaceous of India and the Isle of Wight, by R. Lydekker.—Further notes on the results of some deep borings in Kent, by W. Whitaker.

January 26.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—On the correlation of the Upper Jurassic rocks of the Jura with those of England, by Thomas Roberts.—The physical history of the Bagshot Beds of the London basin, by the Rev. A. Irving. The author, in reviewing the position taken up by him, attempted to estimate the value of such palæontological evidence as exists, and insisted on the importance of the *physical* evidence in the first place. He gave reasons for considering the evidence of pebbles, pipe-clay, derived materials, irony concretions, percentages of elementary carbon (ranging in the more carbonaceous strata up to nearly 2½ per cent.) taken together with the evidence of carbon in combination, as adduced in former papers, *freshwater Diatoms* (now, perhaps, recorded for the first time in the Middle and Lower Bagshot), and the microscopic structure of the sands and clays, as furnishing such a cumulative proof of the fluviatile and delta origin of the majority of the Middle and Lower Bagshot Beds, as can hardly be gainsaid; while he regarded the wide distribution of the Sarsens as indicating, along with the fauna, a much greater areal range formerly of the Upper Bagshot than of the strata below them.

Mineralogical Society, January 11.—Mr. L. Fletcher, President, in the chair.—Messrs. A. Pringle, G. T. Prior, and J. M. Thomson, were elected Members.—The following papers were read:—On a specimen of meteoric iron found at Yundagin, West Australia, in 1884, by Mr. L. Fletcher, President.—Additional notes on the feldspar from Kilima-njaro, by Mr. L. Fletcher, and Mr. H. A. Miers.—On the occurrence of greenockite in a new locality, by Prof. M. F. Heddle.—Note on a form of calcite from Heilim, Sutherlandshire, by Prof. M. F. Heddle.—Note on the occurrence of bismutite in the Transvaal, by Mr. H. Louis.—Notes on celestine from Gloucestershire and on apatite from East Cornwall, by Mr. R. H. Solly.—Note on the presence of lead in calcite from Leadhills, by Mr. J. Stuart Thomson.—On the use of gnomonic projection, by Mr. H. A. Miers.—Prof. Judd exhibited a specimen of a new terrestrial alloy of iron and nickel (Ni_2Fe) discovered in New Zealand by Prof. Ulrichs.—Colonel MacMahon exhibited a crystal of sapphire from a vein which had been revealed by a landslip in the south-east of Cashmere, about the year 1880.

Paris

Academy of Sciences, February 7.—M. Gosselin, President, in the chair.—Movements of a bird's wing represented according to the three dimensions of space, by M. Marey. In continuation of his first communication on the flight of birds, the author here shows, by a series of chrono-photographic images, how the movement of the wing is made according to the three dimensions of space. One of the illustrations gives a synoptic view of the projections of the wing on three different planes at ten successive instants of a single revolution, thus containing all the elements necessary to determine the continuous action of the wing. Further chrono-photographic experiments are promised, which will convey a complete representation of all the alar movements, and in general of all notions relating to the kinematics of flight.—On the red fluorescence of alumina, by M. Lecoq de Boisbaudran.—On the composition of the ashes of cider, by M. G. Lechartier. The study of the composition of the ashes which ciders yield by incineration is here undertaken, both for its scientific interest and on account of the indications it may give of their purity. The author inquires whether this composition presents uniform distinctive characters whatever its local origin, and finds that the ashes of the cider apple are in no way modified by the nature of the soil. He also shows the differences existing between the ashes of the fruit, the leaf, and the wood of the apple-tree.—Experiments relative to the anti-phylloxeric disinfection of the grape-vine, by MM. Georges Couanon and Etienne Salomon. The varying results of M. Balbiani's already-described process are here reported from various districts throughout France for the year 1886. Although generally satisfactory, the remedy was found in some cases to be as bad as the evil, the failure being attributed either to the unhealthy state of the plant or to climatic or other local conditions.—Fresh researches on the action exercised by cuprous preparations on the development of the Peronospora of the vine, by MM. Millardet and Gayon. These experiments, carried out last September, fully confirm the conclusion already anticipated by the authors, that in these mixtures the essential prophylactic agent is the copper dissolved by rain-water and dew.—Memoir on the developments of naval geometry, with application to the calculations of stability, by MM. Guyou and Simart. The authors consider their method as a distinct improvement on those of their predecessors, Charles Dupin, Bravais, Rankine, Reech, Leclert, and Daymard. Thanks to their new formulas, the still laborious calculations which are required even by Daymard's method (recently crowned by the Academy) are much shortened.—Geographical co-ordinates of Punta-Arenas, by M. Cruls. For this important station the following values have been recently determined: Latitude 53° 9′ 38″·6 S.; Longitude 4h. 43m. 36·09s. west of Greenwich.—Equatorial observations of the new comets, Brooks and Barnard, made at the Observatory of Algiers with the 0·50m. telescope, by MM. Trépied and Rambaud.—On entire algebraic series, by M. L. Lecornu.—Some experiments on aërial eddies, by M. Ch. Weyher. The experiments here described deal with waterspouts in the open air, with whirlwinds in an inclosed space, with the attraction produced by vortices, and with the variation of temperature in an eddy.—On the electrolysis of alkaline solutions, by M. Duter. In the electrolysis of aqueous solutions of potassa, soda, baryta, or lime, the volume of oxygen liberated on the positive electrode is considerably less than half that of the hydrogen liberated on the negative electrode. But with a wide platina plate for positive and a fine platina wire for negative electrode, the author obtains one volume only of oxygen for four of hydrogen. In the electrolysis of alkaline solutions there appear to be formed small quantities of a superoxygenated compound combined with an alkali in such a way that it cannot be liberated by ebullition but only by an acid. This appears to be a peroxide of hydrogen, by the existence of which M. Berthelot explains various reactions, such as that of the permanganate of potassa on oxygenated water.—The principle of maximum labour and the laws of chemical equilibria, by M. H. Le Chatelier. It is shown that under a single law may be reduced all the phenomena without exception of vaporisation, allotropic transformation, and dissociation from − 200° C., boiling-point of oxygen, to + 1000° C., point of dissociation of the oxide of iridium.—Action of the oxide of lead on some dissolved chlorides, by M. G. André. Some true oxychlorides are here described, which the author has obtained by studying the action of certain oxides on the solutions of the alkaline earthy chlorides.—Combinations of the glycerinate of potassa with the monatomic alcohols, by M. de Forcrand. The glycerinates here studied are those of methylic, ethylic, propylic, amylic, and isobutylic potassa.—On phosphoplatinous chloride, $PhCl_3PtCl_2$, by M. E. Pomey.—On a combination of orthotoluidine and the bichloride of copper, by M. E. Pomey. The formula of the combination here determined is shown to be $CuCl_2 . 5(C_7H_9N . 4Cl)$.—On the hydrochlorate and platinochlorate of di-isobutylamine, and the platinochlorate of tri-isobutylamine, by M. H. Malbot. These substances, apparently not hitherto produced, have for formulas: $HCl . N(C_4H_9)_2H$; $PtCl_4 . 2HClN(C_4H_9)_2H$; and $PtCl_4 . 2HClN(C_4H_9)_3$.—On gluconic acid, by M. L. Boutroux. The author has succeeded in preparing sufficient quantities of this acid by means of the process indicated by MM. Kiliani and Kleemann.—On the characteristic properties of olive oils, by M. Albert Levallois. It is shown that the most constant character of olive oils prepared in the laboratory from various berries from the south of France is density. A simple method is described for distinguishing these from the oils of sesame, cotton, colza, linseed, and cameline.—On sardine-fishing, by M. Launette. The abundance and scarcity of this fish on the west coast of France is shown to be intimately associated with the animal refuse drifting across the Atlantic from the Newfoundland cod-fisheries.—On the formation of the so-called "red wood" (*bois rouge*) in the fir and Epicea, by M. Emile Mer. The occasional development of these hard and yellow-coloured layers in the relatively soft and white wood of the fir and Epicea is here attributed to the superabundance of nutritive elements at certain points under various conditions of growth.—On the Miocene vertebrate fauna of Grive-Saint-Alban, Isère, by M. Charles Depéret. Amongst the most interesting remains of this fauna is an anthropoid ape, Sansan's *Pliopithecus antiquus*, whose molars point to a relationship with the present gibbons.—Synthetic experiments on the abrasion of rocks, by M. J. Thoulet. These experiments have been carried out to determine the laws regulating the weathering of rocks under the action of drift sand.—On the age of the bauxite deposits in the south-east of France, by M. Louis Roule. This formation seems to have been deposited on the bed of the lake formerly stretching between Provence and Languedoc, and belongs to the lacustrine series closing the Chalk epoch in this region.—On the distribution of mean cloudiness on the surface of the globe, by M. L. Teisserenc de Bort.

BERLIN

Physiological Society, December 10, 1886.—Prof. du Bois-Reymond in the chair.—Dr. Hermes showed the luminous Bacillus brought some time ago with marine fish from the West Indian Ocean and bred in pure cultures. In nutrient gelatine the Bacillus formed funnel-shaped cultures at the surface. Inoculated into sterilised fish it rendered them luminous to a very high degree. The Bacillus developed also in fresh-water fish, but only when these were placed in salt water. In fresh water the Bacillus disappeared. At temperatures below 15° Celsius, the luminosity ceased. It was easy with this fish-Bacillus to render a large quantity of sea water luminous. If, however, the water were allowed to stand for twenty-four hours, only the surface was luminous; but by stirring it up the whole mass again became luminous in consequence of the interpenetration of the air.—Prof. Zuntz reported on experiments which, in conjunction with Dr. Berder, he had instituted with a view to ascertaining the effect of alcohol on metastasis in man. The respiration was especially examined. An essential preparatory condition for such experiments was the complete cessation of all muscular activity, which increased the absorption of oxygen and the formation of carbonic acid, as was also protection against the too rapid cooling, promoted by the flow of blood in the skin, consequent on the operation of the alcohol. With the moderate use of alcohol (20 ccm.), so as to produce no perceptible sign of intoxication, the absorption of oxygen was somewhat increased without corresponding increase in the formation of carbonic acid, a relation corresponding with the combustion of the alcohol, in which two molecules of carbonic acid are formed for every three molecules of oxygen consumed.—Dr. Wurster described a new reagent for the demonstration of active oxygen in the living organism. Tetramethylparaphenylenediamine and dimethylparaphenylenediamine were colourless substances not liable to be changed in the air; but with active oxygen, in form of ozone, peroxide of hydrogen, or nitrous acid, they formed colouring matters, the tetramethyl-compound giving a blue colouring matter, which with an excess of active oxygen again lost its colour; whilst the dimethyl-compound with a little oxygen yielded a red colouring matter, and with excess of oxygen a violet colouring matter. The speaker had saturated paper with these substances. Reagent papers of this description were admirably adapted in all cases for the detection of active oxygen. In cutaneous evaporations, and, in particular, in perspiration, copious quantities of active oxygen were in this way capable of being demonstrated. The presence of such active oxygen might further be demonstrated in the saliva of healthy persons, and in the sap of plants, especially in the milky juices of plants. Seeing that in all these cases ozone was absent, otherwise it would have been recognised by its odour, only peroxide of hydrogen or nitrous acid could be present. By means of other reactions it was shown that in these cases there was no question of anything but peroxide of hydrogen.

January 14.—Prof. Munk in the chair.—Dr. Gad communicated the results of some experiments, which had been carried out by him in conjunction with Dr. Wurster, respecting the active oxygen in the animal organism. By means of the two reagents in active oxygen discovered by Dr. Wurster—dimethylparaphenylenediamine and tetramethylparaphenylenediamine, the properties of which were demonstrated by Dr. Wurster at the last meeting of the Society—animal fluids and tissues were tested in respect of the presence in them of active oxygen. On the skin the reagent papers either remain colourless, or they become coloured symptomatic of slight oxidation, or they become rapidly coloured and rapidly discoloured, which was an invariable phenomenon in the case of stronger oxidation of the diamines. Blood produced no change on either the dimethyl or the tetramethyl, whereas fresh muscles, and even flesh bought at the butcher's, yielded a very strong reaction, an energetic oxidation. If moderate quantities of a solution of the two diamines were injected subcutaneously into frogs or rabbits, or into their venous system, then they got completely oxidised in the body and were no longer capable of being demonstrated. They were altered into colourless combinations; and only in the heart, in the liver, and at the places of application were strong colorations discernible. The stomach was coloured at all places to which the oxygen of the air had entrance; the places, on the other hand, which were protected from the air were colourless, and became coloured only when they were exposed to the air. The brain presented a colouring of olive-green—a phenomenon which would have to be more particularly investigated, seeing that the colourings of oxidation under dimethyl were red or blue, under tetramethyl, blue. In consideration of the fact that the living protoplasm of the cells did not readily take up foreign substances, and taking account of the fact above demonstrated, that the blood did not oxidise either of the two substances in question, the speaker assumed that the complete consumption occurring after the introduction of the two bodies into the living organism was accomplished by the juices of the tissues, or by the fluids which secreted the protoplasm of the cells. The objection made against the experiments, that the diamins were not found because they were not absorbed, was refuted by the fact that the animals operated on always showed the phenomena of intoxication proceeding from the central nervous system. Experiments would be further continued by Dr. Gad and Dr. Wurster. The experiments had hitherto yielded the important fact that in the living organism the protoplasm worked in an especially oxidising manner.

Physical Society, December 17, 1886.—Prof. von Bezold in the chair.—Prof. Neesen exhibited a tuning-fork of variable pitch of tone. It had a hollow stem and hollow prongs, so that it could be filled with quicksilver to any desired height. With the increasing mass of the vibrating-fork the pitch of its tone changed. The excitation was effected by electro-magnetic methods.—Dr. Aron developed the theory of the inductionless coils constructed by him. In this task he pursued the practical object of putting an end to, or at least very much reducing, the spark arising from the extra-current on the interruption of the electric current, and very soon rendering the contacts unavailable. The induction exercised by the iron-nucleus on the windings might, as was well known, be obviated by a copper case, and the induction of the different windings of the spirals on one another was overcome by the speaker by intercalating a tin-foil layer between each layer of windings and embedding the isolated wires in a good conductor. The speaker showed theoretically that by this encasement the heat, and consequently the opening spark, became considerably reduced, especially in the case of weak currents. The efficacy of this method of procedure was confirmed by the experience that a contact which had been in constant operation for two years remained unchanged.—Dr. Richarz spoke of the formation of peroxide of hydrogen by electrolysis. If a current were conducted through diluted sulphuric acid, then there was formed at the positive electrode a strongly oxidising substance, formerly taken for peroxide of hydrogen, but demonstrated by M. Berthelot to be per-sulphuric acid, S_2O_7. In experiments on the electrolysis of concentrated solutions of sulphuric acid with wire-shaped platinum electrodes, the speaker had obtained in the solution, beside per-sulphuric acid, ozone and peroxide of hydrogen, and assumed that all three bodies made their appearance at the positive electrode. This assumption had been disputed by Traube, and, on the ground of experiments with diluted acids, he had maintained that the peroxide of hydrogen arose only at the negative electrode by reduction of the atmospheric oxygen. Dr. Richarz repeated his experiments, and found that in concentrated sulphuric acid, on electrolysis, peroxide of hydrogen occurred always at the positive electrode when per-sulphuric acid was formed; but that it occurred temporarily later on, and was not a direct product of the electrolysis, but arose through secondary chemical reactions, by oxidation of water through the per-sulphuric acid. The following experiment served as a proof thereof:—A 40 per cent. sulphuric acid solution was subjected to electrolysis, and thereby, on account of too great attenuation, no peroxide of hydrogen, but only per-sulphuric acid, came to view. If, now, into the 40 per cent. sulphuric acid 60 per cent. acid were poured, after the electrolysis was finished, then did peroxide of hydrogen show itself in the fluid.—Dr. Dieterici communicated how he rendered galvanometers insensible to the disturbances of the earth's magnetism by surrounding with an iron cylinder, and setting in an iron box provided with suitable apertures for observation, the windings of the galvanometer up to the height of the mirror set above the needle. Residual magnetism, which was readily recognised, was easily removed by heating and by adjusting the mutual position of the two parts of the iron case.

Meteorological Society, January 4.—Prof. von Bezold in the chair.—The yearly report having been read by the Secretary, and officials elected, Dr. Zenker explained the arrangement and contents of the meteorological calendar edited by him.—Dr. Sprung then read a paper on Hadley's principle. Starting from the phenomenon, now and again observed, of an air-current proceeding in the direction of the meridian, while the gradients of atmospheric pressure operated in a direction perpendicular thereto, the author referred to the circumstance that Hadley had last century resolved the direction of the trade-winds into the simultaneous action of the difference of temperature and of the earth's rotation resulting in a mean course, an explanation which first obtained general acceptance through Dove. The derivation of the curve described by a mass-particle on the earth when it had received an impulse to the north and was rotating in a parallel with the earth had been attempted in two different ways—one way by Mousson and another by Schmidt. The speaker discussed such derivations for the simplest case—that of a rotating disk and of a mass-point thereupon impelled with a certain energy and free from friction towards the centre. Through analytical development of the results, he adopted the method of taking as approximately accurate Schmidt's derivation, which presupposed the force in the direction of the meridians to be a constant value, but the force in the direction of the circle of parallel to augment with the time. After further consideration of the centrifugal force, a basis for the mechanics of atmospheric currents on the earth might be determined by Hadley's principle.

Chemical Society, January 10.—Prof. A. W. Hofmann, President, in the chair.—Prof. Rud. Weber communicated the results of his experiments on some compounds of sulphuric anhydride with phosphoric and iodic anhydrides; he has isolated compounds of the composition $P_2O_5 + 3SO_3$ and $I_2O_5 + 3SO_3$, and he describes their preparation and analysis.—O. N. Witt described a new method of producing the azines; they can be obtained from the decomposition of the azo-compounds produced from diazobenzenesulphonic acid and phenyl-, paratolyl-, and xylyl-β-napthylamine.—C. Friedheim criticised the method recommended by Weil for the volumetric determination of hydrogen sulphide; the method is not only troublesome and complicated, but the reaction does not take place in the manner assumed by Weil. The author gives analytical results showing that the method cannot be depended on.—Prof. Pinner read abstracts of papers by Liweh, and Ramsay and Young.

BOOKS AND PAMPHLETS RECEIVED

Westindische Skizzen, Reise-Erinnerungen: K. Martin (Brill, Leyden).—Sitz. der Kaiserlichen Akademie der Wissenschaften (Mathematische-Naturwissenschaftliche Classe), Zweite Abth., 1, 2, 4, 5, 6, 7, 8, 9, 10; Dritte Abth., 3 to 10; Erste Abth., 1, 2, 3, 5, 6, 7, 8, 9, 10 (Gerold's Sohns, Wien).—Journal of the Chemical Society, February (Gurney and Jackson).—Bulletin du Musée Royal d'Histoire Naturelle de Belgique, tome iv., No. 4.—A Text-book of Euclid's Elements, part 1: H. THE OWENS COLLEGE

The Owens College: its Foundation and Growth, and its Connection with the Victoria University, Manchester. By Joseph Thompson. (Manchester: J. E. Cornish, 1886.)

THE future historian of the progress of education in England during the nineteenth century will regard the foundation of the Owens College, Manchester, as an event of the first importance. The idea of establishing, in the midst of our great manufacturing towns, institutions devoted to the higher learning was not new. The experiment had been tried in various forms in Manchester itself, but had always failed. A College of Arts and Sciences was founded in 1783 by some of the leading men in the town and county, but, owing to "a superstitious fear of a tendency of a taste for knowledge to unfit young men for ordinary business, this excellent institution had not a long existence." In 1836 meetings were held, and a scheme was drawn up for the establishment in Manchester of a College for general education. In the spring of 1837 it was proposed to elect a Medical Faculty in connection with the College; but, before another year passed, the scheme was abandoned, as very few pupils came forward.

Institutions which aimed chiefly at the preparation of candidates for the Nonconformist ministry were more successful. The Manchester Academy, and the Lancashire Independent College, founded in 1786 and 1840 respectively, are active now; but while the latter is in close alliance with the Owens College, the former has migrated to London. It was not the desire of business men for culture or for technical education, but a demand on the part of Nonconformist professional men for a training which the tests imposed by the older Universities debarred them from obtaining there, which enabled these institutions to survive when others failed. Nay, more; the strongest argument which George Faulkner brought to bear on his friend John Owens, to persuade him to alter the will by which he had made him his heir and to found a College, was "that as he had such strong prejudices against the tests imposed at the older English Universities, he could enable young men to obtain an education equal to that of the favoured institutions, without these hindrances."

But, whether or no Owens was influenced mainly by a feeling of indignation at an injustice which has now been long removed, his benefaction has produced results even wider than those which have followed the abolition of the tests he disapproved. The Owens College was the first example of the successful establishment in a manufacturing town of an institution which gave to all comers a University education. When Manchester had proved that success was possible, others were not slow to follow where she had led. The Owens College was opened in 1851. For some years it seemed that it was to share the fate of its predecessors. At length the tide turned, and the passing of the Owens Extension College Act in 1870 marked the attainment of assured success. In that year Newcastle established a College of Physical Science, the Yorkshire College was founded in Leeds in 1874, and now no large town considers its educational equipment complete if it cannot point to a "University College" in its midst. The importance of this result can hardly be exaggerated. In the midst of a great democratic movement, it has been practically proved that culture and learning need not be the exclusive property of the few. The provincial Colleges have made it possible for the young artisan to obtain instruction from, and to test his own abilities by contact with, teachers who are masters of the subjects they profess. The Owens College is, no doubt, as far as its day classes are concerned, a middle-class institution. But its authorities have also developed a system of evening lectures, by means of which many a working-man has made his first step upwards from the ranks.

At first, the Council and Staff of the College had to face the difficulties which beset pioneers. The religious difficulty met them at the outset. An early attempt at amalgamation with the Medical School failed. The Professors one and all complained that, through lack of a sound elementary training, their students were unable to profit by the instruction they gave. "The worst that can be said of [the College]," remarked the *Manchester Examiner* of July 20, 1858, "is that it is too good for us. It is out of place here, just as a missionary may be said to be out of his place on the coast of Africa. He offers the Gospel, and the people want Sheffield blades. . . . The crowd rolls along Deansgate, heedless of the proximity of Plato and Aristotle. . . . And where is poor learning all the while? Going through its diurnal martyrdom of bootless enthusiasm and empty benches."

The men who had the fate of the College in their hands were not, however, daunted by cold comfort such as this. Gaps in the Staff were promptly filled up. Principal Scott resigning on account of ill health, his place was filled by Prof. Greenwood, and Mr. Roscoe was selected to fill the vacant Chair of Chemistry. Nor was this confidence misplaced. Almost contemporaneously with these appointments, the dwindling number of students began to increase, and within some half-dozen years the difficulty of preventing failure was followed by the difficulties of providing for success. In 1864 we hear of the "insufficient or unsuitable accommodation furnished by the College buildings." In 1865 Prof. Clifton reported that the percentage of carbonic acid in the air of his lecture-room at the conclusion of a lecture was more than four times the maximum consistent with health. Students of the biological sciences complained of the difficulty of finding admission to well-arranged and complete collections of natural history.

It would take too long to follow step by step the advance of the College, but in reading Mr. Thompson's full account of the way in which each difficulty was overcome, the reader cannot but be struck with the fact that the work of the Council and Staff was essentially that of pioneers. Everything had to be discussed; nothing was determined by precedent. In 1860 it was decided that a Professorship of Physics should be founded, but before this step was taken it was thought necessary to inquire not only whether the students were numerous enough and the College rich enough to warrant the change, but whether a Professorship of Physics was in itself a desirable thing. Professors De Morgan and Stokes were asked for formal written opinions on this knotty point. The new Chair was only established when it was held to have been proved that the field of mathematics and natural philosophy was wide enough for the employment of two labourers in different parts. There can be no doubt that the College was remarkably fortunate in the members both of its Council and of its Senate. The Neilds—father and son Mr. Ashton, Mr. Oliver Heywood, and many others, worked as though their personal interests were all bound up in the success of John Owens' bequest. They succeeded in filling the Chairs with men of the most brilliant abilities. To mention only some of those whose connection with the College has now ceased, it is evident that an institution which has within a few years commanded the services of men like Sir Henry Roscoe and Professors Frankland, Clifton, Jevons, Jack, and Gamgee, must have deserved the success it has won.

Nor is it uninstructive, regarding the Owens College as the pioneer in a great movement, to observe how largely that movement has been and is being directed by men who themselves owe much to the Manchester institution. By glancing only at the list of those who have held the office of demonstrator in the physical or chemical laboratories, or of lecturer on mathematics, we observe that the Professorships of Physics in the Mason College, Birmingham; of Chemistry in Anderson's College, Glasgow, the Yorkshire College, Leeds, the College of Physical Science at Newcastle-upon-Tyne, and the Firth College, Sheffield; and the Professorships both of Chemistry and Physics in the Normal School of Science, South Kensington, and in University College, Dundee, are or have been held by *alumni* of the Owens College.

When once the College began to grow, it grew rapidly. The change wrought in fifteen years was remarkable. Besides the establishment of numerous new professorships, the Manchester Natural History and Geological Societies handed over their collections to the College as the recognised centre of scientific learning in Manchester. The College and the Medical School were fused into one institution. The handsome buildings in Oxford Road were erected upon land, and partly also with funds, furnished by an Extension Committee, which numbered among its members many of the best-known men in the town, and of which Dr. Watts, whose death Manchester has recently had to deplore, was secretary.

When this was accomplished, the College proceeded to claim the status and powers, as it had already proved its capacity for doing the work, of a University. This question affected interests other than those of Manchester itself. The Yorkshire College, Leeds, then very recently founded, and immature, had sufficient faith in its own future to claim a share in determining the conditions on which a new University was to be established in the North of England. This claim was at first enforced by a formal opposition to the Owens College scheme, on certain specified grounds. Whether a Leeds historian would agree with Mr. Thompson that the opposition "was not based upon accurate knowledge" may be open to question. It may be that the mistake was on the other side, and that the Owens College authorities had not as yet fully recognised the magnitude of the movement to which they themselves had given so great an impulse. However this may be, the controversy seems to have been conducted with fairness and good temper, and to have resulted in an agreement which left none but kindly feelings behind. The Council of the Owens College received satisfactory assurances that their Leeds friends did not desire to share the advantages to be conferred by the Charter of the University till they had made their College worthy of representing it in Yorkshire. On the other hand, they conceded the demand of Yorkshire that the name of the University should not be that "of a town or of any person whose claims to such distinction are merely local." A compromise was arrived at on the other point to which importance was attached. Leeds desired that the Governing Body of the University should be separate and distinct from that of the Owens College, and that it should have power "to incorporate the Owens College and such other institutions as may now or hereafter be able to fulfil the conditions of incorporation laid down in the Charter." This condition was agreed to, with the modification that the Owens College should be named in the Charter as the first College of the University, and that thus its incorporation should be simultaneous with and not posterior to the foundation of the University itself. Finally, a joint deputation from Lancashire and Yorkshire petitioned the Crown in favour of the establishment of the new University. The Charter was granted in 1880. The Owens College was constituted the first College of the University, and though the Yorkshire College has not yet joined it, University College, Liverpool, has recently been admitted as the second member of the federation.

Mr. Thompson's work appropriately ends with the flattering tribute paid by his fellow-citizens to Sir Henry Roscoe by his election as Member of Parliament for one of the divisions of Manchester, and with the expression of the regret of the Council at the severance of his connection with the College. The success of the Owens College is due to no one man, but to no one man more than to Sir Henry Roscoe. His withdrawal may fitly mark the termination of the period of struggle with initial difficulties. The main work of organisation is over. The chief outlines of the scheme for bringing industry into contact with culture and with technical education are drawn. It remains for the Owens and her sister Colleges to fulfil the task on which they are now fairly embarked.

We believe it is not unlikely that in carrying on their work the authorities of the Victoria University may find it necessary to appeal to the Government for a contribution towards the University funds. It will of course be easy to say that as Manchester and Liverpool have done so much they may be left unaided to do more. In forming an opinion upon this question it will be well for the public to remember that, whereas the Universities or Colleges in Edinburgh, Glasgow, Aberdeen, St. Andrews, Aberystwith, Bangor, Cardiff, and the Queen's Colleges in Ireland, receive subventions from the State which amount in all to between 40,000*l.* and 50,000*l.* per annum, English higher education in provincial towns has been entirely provided by unselfish private enterprise, with some assistance in Newcastle from the University of Durham, and elsewhere from the Clothworkers' Company and others of the City Guilds. As far as help from Parliament is concerned, England as usual has to find its share of the money and reaps none of the advantage. It is surely not too much to hope that, if 8000*l.* a year is allotted from the public funds to Colleges which supply the wants of Aberystwith and Bangor, it will not be considered impolitic to help from the National Exchequer the magnificent and national work which has been and is being done in the North of England.

But to return to the book before us. It is fortunate that while the memory of the men who initiated the undertaking is still fresh, and while most of those who carried it out are still with us, an historian such as Mr. Thompson has been found for the Owens College. He has given, not merely the public story of the institution, but short histories of many of those who were closely connected with it and who have now passed away. He has evidently had access to authentic documents and other sources of accurate information, and he has produced a work which will be read with interest by many who have in the past known but little of the Owens College and its founders.

ANDERSON ON HEAT AND WORK

On the Conversion of Heat into Work. By W. Anderson, M.Inst.C.E. (London: Whittaker and Co., and George Bell and Sons, 1887.)

VERY few modern books on Engineering contain what can truly be called accurate science; one of whose special characteristics is the use of each term *in one definite sense only.* In other words, take at random a work on any branch of Engineering, and you find, in every page, more than one sentence which, if it be read as a scientific statement, is simply inaccurate. Of the exceptional works the majority consist of those written by the late Prof. Rankine. He seems to have left no successor, so far as this department of applied science is concerned; and the book before us strongly supports the notion. It gives, in a succinct but comprehensive form, an introduction to the modern Dynamical Theory of Heat, treated almost entirely from the practical Engineer's point of view. It is obviously written by a man who knows his subject, and it is therefore presumably written in terms intelligible to those for whom it is designed. It thus affords a good opportunity of making some further remarks upon the strange line of separation which has unfortunately been drawn between the vocabularies (or, rather, the dictionaries) of Pure and of Applied Science. In using this opportunity, for the purpose stated, we do not attack the present work in particular; we attack the mass of works on Engineering, of which it is a high-class specimen.

From the purely scientific point of view there are two prominent faults in the majority of such works as that before us. The first is the habitual use of a special "vernacular"; not so outrageous, perhaps, as "pidgin" English, but quite on a par with a "wire," a "cable," an "aniline," and such-like monstrosities of recent American origin. Were the words of this vernacular different from those of strict science, our only complaint against their use would be that we should have to learn what would be practically a new language before we could read an Engineering book. But they are, in the main, the same words; and yet each stands for other than the usually accepted meaning. Thus we constantly find pressure given as so many tons per square inch (sometimes the word "square" is omitted). Now, tons per square inch, or pounds per square foot, refer to matter and not to force. They measure, in fact, what is called surface-density. This is altogether "most tolerable, and not to be endured."

The second fault is more grave. It consists in the fundamental misuse of well-settled scientific terms, which the author of an Engineering book usually perpetrates whenever (for a moment) he deserts his vernacular and passes from the applied to the pure part of his subject. We remark in passing that, in the very first page, our author speaks of Mayer's EXPERIMENTAL demonstration of the equivalence of heat and work! This shows how deep a root has been taken by the extravagant laudations of Mayer, which were so common twenty years ago, but which have long since been thoroughly exploded.

Now, to faults of the first class mentioned above. We quote only a few of the more racy passages we had marked; and here, as in the subsequent examples, we introduce (to save comment) Italics where they seem desirable.

"Accelerating forces, *that is* forces acting steadily for a time." This may be the Engineer's vernacular, but it has no necessary connection with the use, in English, of the term "accelerating force."

"Dividing (3,942,400 *foot-pounds* per minute) by 33,000 *foot-pounds*, we get 119·4 *horse-power!*" Put this in the form "dividing 500*l.* a year by 50*l.* we get 10*l.* a year," which contains essentially the same absurdity, and we can scarcely fancy that our author would have let it stand; although in its above form it is put as Engineers too commonly put it.

"The heavenly bodies, *moving at uniform velocities for ever* are instances of *potential* energy." This is the Engineer's way of saying that since there is no change of kinetic, there can be no change of potential, energy.

"When we speak of perfectly elastic substances, we do not mean those which, like india-rubber, have a great range of elasticity." But, though this is true of Engineers, it is not true of purely scientific men. Think of air, for instance.

"Endowed with energy competent to produce the *sensation* of 100° Fahr. of *heat.*" Here the Engineers pick a quarrel with the Physiologist as well as with the Physicist.

As explained above, all this is merely the licence which practical men take with scientific terms. As the book is written for such men, perhaps we ought not to complain. But the faults of the second class, some of which we proceed to give, can only be explained by the practical men's using scientific words in a wrong sense. From the following, and others too numerous to be quoted, a new science (!) could be founded, having nothing in common with that which Galilei and Newton have handed down to us, (of course on the supposition that all the words employed are to be taken as they are understood in pure science.)

"Hence the *potential energy* of each gallon of water is

1/330 of a *horse-power!*" Our author would surely have thought twice before writing "the *distance* from London to York is 200 *miles per hour.*" But this, to which we invite his careful attention, would have involved no greater blunder.

"If the bodies are elastic . . . , the *whole* of the *energy* of the striking body is expended in producing *motion* in the body *struck.*" After this it will not, perhaps, surprise the reader to find that we are furnished with a calculation of "the total *heat from absolute zero* resident in exploded powder, at an atmospheric temperature of 50°, or 510° absolute."

The work may be made, even as a whole, thoroughly useful to those habituated to the persistent inaccuracies of the "vernacular":—but, to effect this, it must be carefully purged of statements analogous to the three last-made quotations. P. G. T.

A FIELD NATURALIST IN EASTERN BENGAL

Letters on Sport in Eastern Bengal. By Frank B. Simson, Bengal Civil Service, retired. (London: R. H. Porter, 1886.)

THIS book is essentially a record of sporting scenes, and the author has ostensibly written it for the purpose of giving instruction in the art of shooting and hunting wild birds and beasts of various kinds, from quail and snipe to tigers and rhinoceroses. Yet it contains so many good observations on the haunts and habits of wild animals, and the author shows himself so capable a field naturalist, that a reader who looks for zoological information will probably be disappointed at not finding more novelty. The scene of Mr. Simson's principal adventures, Eastern Bengal, a vast plain traversed by mighty rivers, a country of rice fields and cane brakes, and great grass jungles, of "bheels," or marshes, and "churs," or temporary islands and sand-banks in rivers, has by no means been rendered too familiar by description. Fertile and peaceable, with never-failing rains and magnificent water communication, it furnishes few sensational paragraphs for newspaper correspondents or other manufacturers of periodical literature. The region is as little known to Anglo-Indians in general as the Highlands of Central India, so vividly described by Forsyth, or the wild Mysore country, of which the elephants, tigers, and other wild beasts found an historian in Sanderson. Why is it that the additions to our zoological knowledge made by Mr. Simson are so much less important than those made by Sanderson and Forsyth?

The explanation is probably twofold, if not threefold. All the three writers named were enthusiastic sportsmen and good observers, but Forsyth and Sanderson related events of more recent date, the details of which were naturally more vivid, whilst the present work is a series of reminiscences, written out long after the incidents described took place. The avocations of the different writers, too, were very dissimilar. Those of the two authors first named led them to pass weeks and months amongst the haunts of wild animals, whilst Mr. Simson, a Bengal civilian, could only spend an occasional holiday at a distance from his office, or avail himself of a few hours at a time during the cold season's tour. Another reason, perhaps of even more importance, is the great difference in the nature of the country, and the different system of hunting rendered necessary. The great grasses of the Gangetic plain, even when reduced to patches by the fires of the spring, conceal the movements of their inhabitants, from rhinoceroses and buffaloes downwards, far more than do the jungles of Central and Southern India, especially after their much less luxuriant grasses have been burnt. The process of beating out a patch of thick grass 10 to 20 feet high with a line of elephants differs widely in the opportunities afforded for observation, from the tracking, chiefly on foot, of the animal sought after, through the burnt glades of the Satpura hills or the comparatively thin undergrowth of the Sahyadri forests.

It must not be supposed that Mr. Simson's work contains no novel observations. A very large proportion of our acquaintance with the habits of animals, especially of the larger Mammalia, is due to sportsmen, but the value of their observations varies. A few sportsmen are deliberately untruthful,—these are easily detected; but many more are unqualified for accurate observation. There is no better test of a writer's truthfulness and capacity than his snake stories. In America it is commonly said that there is no subject on which ordinary mortals are so prone to what may euphemistically be termed "romancing." Indian experience corresponds to American, and whatever may be the deficiencies of the Bengali peasant, no one ever credited him with want of imaginative power. The Europeans in India, as a rule, know nothing about snakes. In the work under review, two of the best letters (the whole is written in epistolary form) deal with snakes, and the account of the poisonous species, all of which are correctly named and described, is excellent. To have picked out the grains of truth, and disregarded the chaff, shows judicial acumen worthy of one who has, in the administration of the law, had much experience of conflicting evidence. One of the most interesting facts mentioned is the use made of cobra venom in poisoning arrows used for the destruction of wild animals.

Another interesting observation may be noted: the shooting of a tiger "whose paunch was crammed full of grasshoppers or locusts." Hitherto, although tigers were not thought to be very particular, they were supposed to draw a line at frogs, and were not suspected of condescending to devour insects.

The plates are good on the whole, the elephants excellent, and the lithograph entitled "A scrimmage with a tiger," is one of the best representations of the animals and men depicted to be found in any Indian sporting work. But the pigs—with one exception, in which the animal looks as if he had been shaved—are far too shaggy, and resemble the European boar, *Sus scrofa* rather than the Indian *S. cristatus.* W. T. B.

THE MEASURE OF THE METRE

La Mesure du Mètre. By W. de Fonvielle. (Paris: Hachette, 1886.)

M. DE FONVIELLE'S little volume is truly national. From one end to the other it rings with applause for those brave men of France who, in 1792 and the following years, under extraordinary difficulties—political, social, and geographical—determined the measure of the arc of the meridian from Dunkirk to Barcelona; from the 1/10,000,000th part of which arc the measure of the metre was then derived.

The author in stirring language recounts the dangers and disappointments of the scientific men engaged in this work during the Revolution—Méchain, Delambre, Berthemie, Biot, Arago, Lenoir, and Lavoisier. He endeavours to awaken a warm and genuine admiration for their labours, and to show that the love of science is in some way natural to France. In pathetic words he recounts the dangers in the field: Méchain's work in Spain, his troubles at home, his recall, and return to Spain; his fears that the great measurement might never be accomplished; and at last the sad end—Méchain's death in 1807 at Plana, a victim to yellow fever. Then follows the appointment of Biot and Arago, and the account of their doubts and difficulties in completing the measurements, of the capture and imprisonment of Arago and Berthemie, of their detention in Algiers, and of their ultimate ransom and release.

M. de Fonvielle traces the development of the new system of weights and measures from the proposal of Buffon in 1790 to take as a unit the length of the seconds pendulum, to the report of the completion of the measurement of the metre in 1809. He refers to the invitation given by France in 1790 to our country, to join in an international effort to adopt one weight and one measure for all nations. This invitation, as experience has shown, ought not to have been declined, but even now, owing to the reluctance of English-speaking nations to abandon their traditional units, a similar proposal might possibly not be warmly received.

M. de Fonvielle reminds his readers that the French metric system must not be altogether regarded as a French innovation, for the Chinese long ago adopted a decimal system. It is to Shun, the sage, when Regent of the Chinese Empire, B.C. 2287, that China owes its decimal system, based on a so-called natural constant, the length of the musical standard lü, or bamboo pitch-pipe.

Of course this little volume is intended for popular reading, particularly in France. For the true account of the circumstances and results of the measurement of the arc of the meridian which passes through Paris, we must go to the "Mémoires" published by Méchain and Delambre in 1806, and to the observations of Biot and Arago issued in 1821.

OUR BOOK SHELF

Histoire Générale des Races Humaines. Introduction à l'Étude des Races Humaines—Questions Générales. Par A. de Quatrefages, Membre de l'Institut. (Paris: A. Hennuyer, 1887.)

PROF. DE QUATREFAGES and M. E. T. Hamy propose to edit a general history of the human race, and the present volume, by Prof. de Quatrefages, is intended for an introduction to a series of monographs by various authors. The dark races will be described by M. E. T. Hamy; the yellow races by M. J. Montana; and the red races by M. Lucien Biart. These volumes are in course of publication, and the first volume of the series, on the Aztecs, by M. L. Bert, has already appeared. There will be a volume on the Mongols, by M. J. Deniker, and one on the Foulahs, by Dr. Tautain.

In the present volume the general questions of ethnology are treated of, and the subject of the classification of the human race is passed in review. With that charming style which characterises the writings of this author, and which has for long made him one of the most popular writers on scientific subjects in France, he here gives a *précis* of the chief works treating on ethnology, and decides that the human race must not be placed in the same category with the animal race, because it exhibits the presence of two additional phenomena, those of morality and religion.

On the question of the unity of the human species, too often one of mere words, the *pros* and *cons* are placed before the reader in a tabular form. In the chapter on the first appearance of man, the various transformistic theories are passed in review, and the views of Darwin, Huxley, Vogt, and Haeckel are alluded to; but the author for himself believes that any certain knowledge on this point is beyond our actual powers. In other chapters, the antiquity and geographical origin of the race are treated of, as well as the subject of the peopling of the globe and the acclimatisation of the species. Primitive man is regarded as of distinct ethnic types, and from these the races took their rise. Lastly, the physical, the intellectual, and the moral and religious characters of the races are discussed in some detail. The work is supplied with numerous and excellent illustrations; it is printed in clear type on royal octavo paper, and forms a handsome volume of nearly 300 pages.

Grundzüge einer Theorie der kosmischen Atmosphären mit Berücksichtigung der irdischen Atmosphäre. Von Wilhelm Schlemüller. (Prague.)

IN this pamphlet the author introduces a modification into the ordinarily accepted dynamical theory of gases by assuming that the molecules of a gas at uniform temperature are all affected with absolutely the same linear velocity as regards magnitude, instead of the temperature being dependent on the mean or average velocity. This of course greatly simplifies the labour of deducing the fundamental relations between pressure, density, temperature, and the potential of external forces; and he claims to be able to deduce the relation, which for the terrestrial atmosphere gives Bessel's refractions to 90° (*sic*) zenith distance; agreeing with the formulæ found by Bauernfeind in 1862-64. We may remark that the convertible equations are reproduced in some cases with almost wearisome frequency, and that Joule is twice called Jonle.

Manual of Physical Geography of Australia. By H. Beresford de la Poer Wall, M.A. (Melbourne: Robertson.)

THIS little manual is written for Australian schools, and may be accepted as a fair and trustworthy account of the physical geography of Australia. For an exhaustive treatment of the subject the material is still wanting for a large section of the continent; on others, again, there is abundance of material, and of these Mr. Wall has made creditable use. It is a pity the book should be burdened with such terrible lists of names as those on pp. 9 and 10: the author would have done much better had he shown the relations of the leading capes to the general relief of the land.

An Intermediate Physical and Descriptive Geography, abridged from the Physical, Historical, and Descriptive Geography of the late Keith Johnston. (London: Stanford, 1886.)

THE late Keith Johnston's larger geography is on the whole the best general text-book of the subject in English. The present abridgment for middle-classes in schools seems to us judiciously done.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Mr. Wallace on Physiological Selection

SEEING that Mr. Wallace has now changed front with regard to some of the points at issue between us, I must once again address you upon this subject.

(1) He appears to have forgotten that the whole plan of his original impeachment consisted in representing me as an arrogant heretic. This impeachment was published under the heading "Romanes *versus* Darwin," and point by point it laboured to show that I was deserving of excommunication as a rebel against the highest authority. In my reply, therefore, I was obliged to show that the charge was misdirected; and this I did by simply quoting passages from that highest authority himself. It is needless to say that I am now as much satisfied as surprised to find this charge, not only abandoned, but reversed. Whereas I was previously accused of presumption for disregarding authority, now the remonstrance is—"he appeals to authority against me," and "I decline to accept authority as an infallible guide." So do I. But I quoted my authority merely for the avowed purpose of defending myself from the specific charge of my opponent. It was *he* who appealed to Cæsar, and cannot therefore now complain if to Cæsar he had to go. Truly, if I may employ his own mode of expression, "further discussion of the matter with such an adversary is out of the question."

(2) But, as regards one of the points, he says that my quotations appear to him to support his own views rather than mine. The shortest way of testing the value of this judgment will be to print in succession three passages, which I have selected as serving in each case most concisely and most fairly to embody the opinion of its writer. The point in question is as to whether specific characters are "invariably" adaptive, or "frequently" not so, and the italics are mine.

"When, *from the nature of the organism and of the conditions*, modifications have been induced which are *unimportant* for the welfare of the species, they *may be*, and *apparently often have been*, transmitted in nearly the same state to numerous, otherwise modified, descendants." (Darwin, "Origin of Species," p. 175.)[1]

"I believe, therefore, that the *alleged* inutility of [many] specific characters claimed by Mr. Romanes as one of the foundations of his new theory, *has no other foundation* than our extreme ignorance." (Wallace, *Fortnightly Review.*)

"The matured judgment of Mr. Darwin clearly recognised the distinction between the origin of *species* and the origin of *adaptations*,—a distinction, indeed, which necessarily follows from his repudiation of the doctrine of utility as universal. . . . . Therefore, with him I believe that an incalculable number of specific characters are of an adaptive kind, and that many more which now appear to us (in our ignorance) to be useless, will hereafter be proved to be useful. But with him also I believe that *a large proportional number* of such characters actually are destitute of utility, having been due, as he says, to 'fluctuating variations, which sooner or later became constant through the nature of the organism and of surrounding conditions, as well as through the intercrossing of distinct individuals; *but not through natural selection.*'" (Myself, *Nineteenth Century.*)

(3) "The impossibility of proving a negative is proverbial, but my opponent declares that his negative—the uselessness of specific characters—wants no proving, but must be accepted till in every case the affirmative is proved." Now, I have made no such declaration. My statement was: "It is too large a demand to make upon our faith in natural selection to appeal to the argument from ignorance, when the facts require that this appeal should be made over so large a proportional number of instances." It is really Mr. Wallace who declares that his *affirmative*—the *invariable* usefulness of specific characters—wants no proving, but must be accepted till in every case the negative is proved, notwithstanding that, as he allows, "the impossibility of proving a negative is proverbial." Of course, *if it has been previously assumed* that natural selection is the *only* factor of organic evolution, we are entitled to conclude that the doctrine of utility as universal requires no further proof, since it follows deductively from the assumption. But where the very question in dispute is as to the validity of this assumption, it becomes an almost comical instance of circular reasoning to construct our biological catechism thus:—Why do you believe that natural selection is the only factor of organic evolution? Because I know that in organic Nature utility is universal. But how do you know this, seeing that "our extreme ignorance" renders it impossible to suggest, in a vast number of cases, what the utility can be? Because I have already proved that natural selection has been the only factor at work.

(4) Mr. Wallace imports from the monthly periodicals part of our discussion on the swamping effects of intercrossing. Here therefore, I must follow him. In my Linnean Society paper I had urged that natural selection must be seriously handicapped in its action by the swamping effects of fortuitous variations intercrossing with their parent forms. This statement Mr. Wallace contradicted on the ground that Mr. J. A. Allen had furnished "a complete demonstration of individual and simultaneous variability by a series of minute comparisons and measurements," with the result of showing that, whatever modification might be required, "we *always* (italics his) find a considerable number, say from 10 to 20 per cent. of the whole, varying simultaneously, and to a considerable amount, on either side of the mean value." Now, in my reply I pointed out that all the variations thus recorded by Mr. Allen were of a kind which had "nothing to do with the difficulty," seeing that they had reference only to such features as "size, strength, fleetness, colour, relative proportions of different parts, and so on, all of which—as we well know without going beyond the limits of our own species—are so highly variable as never all to be precisely the same in any two individuals." Then, by way of illustration, I said: suppose "it were required to produce a breed of race-horses with horns upon the frontal bone, . . . or a fighting spur on a duck, clearly it could not be done by natural selection alone" in the latter case, or by artificial selection in the former; the principle of selection would here require to be assisted by "some common cause [of variation] acting on a number of individuals simultaneously." But there was nothing in the use of this illustration to provoke the remark that it indicates "the belief, apparently, that these are a class of characters which are distinctive of closely allied species"—although such does happen to be the case as regards certain allied genera. I merely requested Mr. Wallace to show me his "considerable number of specimens diverging from the mean condition," as regards either of these structures, *however incipient*—or as regards any other structures, save those the general variability of which as to relative size, &c., no one would dream of disputing. And this I still hold he is obviously bound to do, if he is to sustain his sweeping statement that whatever modification of type may be required, we *always* find from 10 to 20 per cent. varying in the needful way. Thus, as a mere matter of dialectic, I confess it appears to me a somewhat unaccountable expedient to affirm that my *reductio ad absurdum* is "preposterous"—such happening to be the very quality which this mode of refutation is ordinarily designed to present.

(5) Lastly, my critic says:—"The argument to show that the supposed physiological variations would be perpetuated, seems to me as weak and unsatisfactory as ever." This may well be. Indeed, I never supposed that anything would be likely to influence the judgment of Mr. Wallace where natural selection is concerned. But I did not write with any such object. I wrote merely to dispose of a particular criticism which he had advanced, and there can be no two opinions as to the result. For I have shown that whatever may be thought about the truth or falsehood of my theory,[1] at least it is certain that it *cannot* be affected by the criticism of Mr. Wallace; and this for the simple reason that he has run a tilt, not against my theory at all, but against a completely different theory, which, like a figure of straw, he had himself set up. Now that he can no longer have any doubt as to what my theory is, I willingly conclude that he must still have some reasons for thinking it improbable that the supposed physiological variations (if they occur) should be perpetuated. But I am free to confess that it passes my powers of conception to divine what these

[1] By a curious and undesigned coincidence, the same issue of NATURE which contains Mr. Wallace's letter also contains my review of Mr. Spencer's essay on the "Factors of Organic Evolution." In that review several other passages are quoted from Mr. Darwin's works to the same effect.

[1] I call it my theory, because I now understand that it differs widely from that of Mr. Catchpool (see NATURE, vol. xxxiv. p. 617).

reasons can be: I only know that they must be of a totally different order from those which constituted the substance of his published criticism.

Of course the question whether or not these physiological varieties *do* occur is quite distinct; and I most heartily agree with Mr. Wallace that this is a question of fact which ought to be decided, before it can be worth anybody's while to attack my suggestion upon any other grounds. If Mr. Wallace had seen this in the first instance, he might have saved both himself and me a good deal of trouble; but at the same time he would have deprived me of no small amount of encouragement. For I am now more than ever satisfied that the suggestion does not admit of being assailed on any grounds of general reasoning; but, on the contrary, that as a theory it is antecedently probable, and can only be refuted—if it is to be refuted—by an appeal to fact in the form of experiment. And as I cordially hope that this may be the last time that I shall have to address you upon this subject, I should like to neutralise the discouraging influence on experimental verification which may have been exercised by premature criticism in your pages. This I hope in some measure to effect by making two remarks. The first is that my own estimate of the antecedent probability of the theory is shared by some of the highest "authorities" on the Continent. The second is that, in all the lines of inquiry hitherto pursued, I find striking evidence of the actual occurrence of the physiological varieties in question. But as this evidence requires to be largely supplemented by experiment, and as every experiment requires at least three years to perform, those biologists who think with Mr. Wallace may be glad to hear that it will be a very long time before I shall have occasion again to trouble them with the theory of physiological selection.

GEORGE J. ROMANES

The Alleged Ancient Red Colour of Sirius

WITH reference to your paragraph last week (p. 378), in the "Astronomical Column," on "The Alleged Ancient Red Colour of Sirius," it does not seem to have been noticed that the early observations of Sirius were made at its heliacal rising. Under these circumstances the sun is a red star. F.R.S.

A Green Light at Sunset

AT sunset to-night I observed a phenomenon which has, I believe, been seen from on board ship, but never probably from a place with such a distant sea-horizon as we have here—some seventy miles. The sky for a short distance above the point where the sun set was perfectly clear of cloud or haze, and I watched carefully the last portion of its disk disappear into the sea. As soon as the last speck of the yellow vanished, a momentary bright green flash shone out. This was quite different from the complementary green seen after looking at the setting sun; brighter and bluer in tint. I have seen it stated that the cause of this green light is the sun shining *through* the water that hides it, and would be glad to know if such is the true explanation. R. T. OMOND

Ben Nevis Observatory, February 12

Sunset Phenomenon

ON February 21, at 5.25 local time, my attention was attracted by a bright red glow reflected from the earth outside a window having an eastern aspect.

On going out of doors to the Observatory, it was evident that this crimson light proceeded from a band of cloud about 10° in width forming a great circle in the heavens, and intersecting the horizon at points, as well as I could estimate, 145° W. and 35° E. of true north, the inclination of this great circle to the horizon being about 15° or 20°.

In less than three minutes, before I could reach the Observatory, the magnificent spectacle had completely vanished, and in the place that it had occupied were merely some streaks of cirrus and cirro-stratus, the latter being nearest to the place where the sun had set, and in half an hour the entire heavens were cloudless.

Will reflection, or refraction, or both, suffice to explain the above? WENTWORTH ERCK

Shankhill, Co. Dublin

Aspects of Clouds

IN Mr. Ruskin's "Modern Painters" (i. Part 2) I have noticed the following passage amongst the author's remarks on the aspects of clouds:—

"I have often seen the white, thin, morning cloud edged with the seven colours of the prism. I am not aware of the cause of this phenomenon; for it takes place not when we stand with our backs to the sun, but in clouds near the sun itself; irregularly and over indefinite spaces, sometimes taking place in the body of the cloud. The colours are distinct and vivid, but have a kind of metallic lustre upon them."

And again, the author describes the "scattered mists rallying in the ravines and floating up towards you along the winding valleys till they couch in quiet masses, *iridescent* with the morning light, upon the broad breasts of the higher hills."

Dr. Johnstone Stoney recently read a paper to the Royal Dublin Society entitled "The Iridescent Phenomena in Clouds," wherein he explains the cause of a somewhat similar appearance which clouds at times present. Their outer portions are suffused with soft shades of colour like those of mother-of-pearl, a lovely green being generally conspicuous. The tints are usually distributed in irregular patches as in mother-of-pearl, but in some cases they form a regular fringe. Dr. Stoney explained that these phenomena are due to particles of ice, in the form of crystals of various sizes and shapes, and according to their position and character the sun's rays are reflected through them in various colours, thus producing the beautiful effect.

Would this be an explanation of the appearances to which Mr. Ruskin refers? ROBERT JAMES REILLY

Boyle, Ireland, February 17

A Recently-Discovered Deposit of Celestine

IT may, perhaps, be worth mentioning that a large and valuable layer of celestine has been lately found at Yate, in Gloucestershire. It lies just below the sub-soil upon a bed of red Triassic marl, which rests unconformably upon the coal-measures, just at the eastern edge of the Bristol coal-field in that district.

The deposit is, for the most part, about half a metre or more in thickness, and consists chiefly of loose nodules which, when broken, are seen to be masses of white, crystalline, nearly pure celestine. Geodes are occasionally found, one of which, about 15 cm. in diameter, lined with fine clear crystals, is now in our school museum. Beautifully transparent, though not well crystallised masses of selenite also occur in the deposit, and in these are sometimes inclosed single detached crystals of celestine. I picked out one crystal (though it seemed almost sacrilege to break up the fine specimen of selenite), which is about $7 \times 4\cdot5 \times 1\cdot5$ cm., doubly terminated, fairly clear, and showing very perfect, well-developed faces. Its density is 3·95, and it shows very perfectly the characteristic light-bluish tinge of celestine.

It would, I think, be quite worth while for any mineralogist who happens to pass near Bristol to pay a visit to the place, which is only about twelve miles distant on the Midland Railway to Gloucester. The extent of the deposit is not known, but when I was there in October last, and again at Christmas, it was being worked in several fields north-east of the church, about a mile and a half from the station. Large quantities are being sent away, of course for the purposes of sugar-refining and adulterating white-lead paint. H. G. MADAN

Eton College, February 21

"Culminating Sauropsida"

IT is with satisfaction that I note in NATURE of February 3 (p. 331), that Prof. W. K. Parker finds it more and more impossible "to conceive of birds as arising *direct* from the Dinosaurians, or indeed from any other order or group of reptiles." The sentence, no doubt, suggests an indirect origin of birds from reptiles; but, further on, Prof. Parker explains that if proto-vertebrate forms existed it is quite supposable that a metamorphosis may "have taken place of this and that *quasi*-larval form into archaic reptile, ancestral bird, or primitive mammal." We must therefore conclude, either that there were two kinds of protovertebrates, namely, piscine and reptilian—or ichthyopsidan and sauropsidan, as Prof. Parker would probably prefer to call them—fundamentally distinct or preceded by common ancestors, and in neither case themselves entitled to be called protovertebrates, or else that the protovertebrates referred to were ichthyopsida, that is to say, more simply, allied to the amphibia. I do not object to that latter supposition. I suggested it myself in 1884 (*Journal of Anatomy and Physiology*, xviii. p. 356), as perhaps Prof. Parker is aware. But if birds are developed from amphibians or pre-amphibians, and if Prof. Huxley is right, as I believe he is, in supposing that the connection of mammals with amphibians is neither through reptiles nor birds, we come to this: that amphibians or pre-amphibians have furnished the common stem whence reptiles, birds, and mammals have diverged. In that case there is an end of that group, "Sauropsida," which the birds are alleged by Prof. Parker to "culminate."

But, further, amphibians are certainly more closely allied to reptiles than to either birds or mammals. Cuvier's system may therefore be justly reverted to, and the Amphibia or Batrachia be considered as the lowest division of the Reptilia, which I do not for one moment doubt is the true classification.

University, Glasgow, February 8 JOHN CLELAND

The West Indian Seal (*Monachus tropicalis*)

IT will probably be of interest to the zoological portion of your readers to learn of the re-discovery—or the full discovery—of the West Indian seal (*Monachus tropicalis*). The history of this pinniped is in brief as follows.

It was first noticed by Columbus in his account of his second voyage (1494) as having been found in some numbers on the rocky isle of Alta Vela, off the southern shore of Hispaniola, where his sailors killed eight of them for food. Later—in 1675—Dampier found this seal in abundance on the Alacram reefs, about 80 miles north of Yucatan. At that time it was killed there in great numbers for its oil.

The seal then remained unnoticed for over a century and a half, having no place whatever in the writings of zoologists until 1843. Then Mr. Richard Hill published an account of it in the "Jamaica Almanac," calling it the Pedro seal, from the Pedro Keys, some 60 miles south of Kingston, Jamaica, where he had found it. A few years later Mr. P. H. Gosse obtained an imperfect skin (without skull) which he sent to the British Museum, where it was described by Dr. Gray in the Proceedings of the Zoological Society of London, 1849. Dr. Gray gave it then no name, probably by reason of its imperfect characters. Later—in 1850—(Catalogue of Mammals in the British Museum) he described this same specimen as *Phoca tropicalis*, and afterwards (Catalogue of Seals and Whales, 1866) as *Monachus tropicalis*. But so imperfect was the specimen on which the description was founded, and the animal itself was so little known, that even its generic relations were in doubt, and its reference to the genus Monachus was considered provisional. From thence on to the present, rumours of the existence of this seal have been not unfrequent, but nothing seemed trustworthy and positive, and no specimens were obtained, if we except a young skin, without bones or skull, which came from Cuba to the National Museum at Washington, in 1884, without any indication as to locality.

It has long seemed to the writer—as, doubtless, to many others—that the certain presence in our waters of so important a mammal lying *perdu* in regions which our naturalist collectors are yearly visiting, was the opprobrium of American zoologists. We made inquiries, and collected notes from many sources, which showed clearly that this seal existed at isolated points—on small islands and keys—not only in the Caribbean and among the Bahamas, but also in the Gulf of Mexico. Last summer, while on a visit to the western shore of the Gulf of Mexico, we were so fortunate as to *locate* this seal with much certainty. This was upon the Triangles (Los Triangulos), three little keys, hardly above the water-level at high tide, and lying some 100 miles north-west off the Campeachy coast, in latitude N. 20° 50′, and longitude W. 92° 10′. Following this clue, my son, Mr. Henry L. Ward, last December visited the Triangles in company and partnership with Señor F. Ferrari Perez, naturalist of the Mexican Geographical and Exploring Expedition. His hunt was highly successful, and he has during the present month returned with nearly twenty specimens—skeletons and skins of all ages, from a suckling to the fully adult male, 7 feet in length. This ample material has just been carefully studied by Prof. J. A. Allen, the well-known zoologist, and author of the "Monograph of North American Pinnipeds." Prof. Allen has given a preliminary notice of the specimens in *Science*, January 14, 1887, and promises an elaborate account, with plates, in an early issue of the Bulletin of the American Museum of Natural History, New York.

It is a fact of rather peculiar interest that this, the first large mammal ever discovered in America, should, by the strange mishaps of natural history collecting, be the very last one to become known satisfactorily to science. HENRY A. WARD

Rochester, N.Y., January 30

An Abnormal *Hirudo medicinalis*

WHILST dissecting the leech in the class of practical zoology, one of my students directed my attention to an apparent abnormality in the specimen which it fell to his lot to dissect. On careful examination it was found that the vesicula seminalis of the right side had moved forwards into the fifth somite, and there opened into the base of a second and fully-developed penis, which opened to the exterior on the second annulus of the fifth somite. From the vas deferens, however, there passed off to the normal penis a duct which had on it a swelling corresponding in position to the vesicula seminalis, which had been moved forwards. The various parts on the left side, as well as the female organs, were quite normal.

Biological Laboratory, University College, Liverpool, February 14

Instinctive Action

SOME years ago I was about to drown a terrier pup of about a month old. I held it across the palm of my open hand over a large tub of water. It lay quite still on my hand as I gently lowered it. When within 4 inches of the surface, but not yet touching the water, it deliberately began, and continued as long as I held it there, the paddling motion with its feet peculiar to dogs when swimming, and quite unlike that of walking, although I am perfectly certain this puppy had never seen or touched water before. We know almost all animals swim when first placed in water, but how could this puppy know before it touched the water that this peculiar action would be necessary? Has a similar case been observed by any of your readers?

Birmingham, February 17 D. W. C.

THE RELATIONS BETWEEN GEOLOGY AND THE MINERALOGICAL SCIENCES[1]

I.

THE realm of Nature has been recognised from time immemorial as consisting of three kingdoms: dealing with the affairs of these three kingdoms, respectively, there have grown up side by side three departments of natural knowledge—zoology, botany, and mineralogy. But in recent years new and, I cannot help thinking, regrettable relations have sprung up between these sister sciences. Zoology and botany, having developed a method, a classification, and a nomenclature, based on common principles, have been drawn together by bonds so close and firm that many regard them as indissolubly one—the science of biology. Mineralogy, thus isolated, has been driven to seek new and unnatural alliances—with chemistry, with physics, or with the mathematical sciences. For my own part I confess that I regard this threatened "Repeal of the Union" of the natural sciences as alike a misfortune and a mistake.

It is sometimes assumed that the objects dealt with by zoology and botany are so different in their essential characters from those treated of by mineralogy, that the science of "organic" Nature must always follow a different path from that pursued by the science of "inorganic" Nature. The structures commonly known as *organic*, and the processes usually called *vital*, are asserted to be so entirely different, alike in their origin and in their essence,

[1] Address to the Geological Society at the Anniversary Meeting on February 18, by the President, Prof. John W. Judd, F.R.S.

from anything existing in the mineral kingdom, as to warrant the establishment and perpetuation of a fundamental distinction between the sciences dealing with "living" and "non-living" matter respectively.

In the year 1854 a very acute thinker, who at one time occupied this chair, made a serious attempt to formulate the distinctions which are supposed to divide living from non-living matter; but at a subsequent date, admitting with characteristic candour that he had altogether outgrown these ideas, Prof. Huxley argued, with great skill and cogency, that "vitality" is merely a general term for a set of purely physical processes, differing only in their complexity from those to which "inorganic" matter is subject.

It is a circumstance of no small significance that no definition of *life* which has yet been proposed will exclude the kind of processes which we can now show to be continually going on in mineral bodies. "Life," said the late George Henry Lewes, "is a series of definite and successive changes, both of structure and composition, which take place in an individual without changing its identity." Mr. Herbert Spencer prefers to define life as "the definite combination of heterogeneous changes, both simultaneous and successive, in correspondence with external co-existences and sequences."

If either or both of these definitions of life be accepted as satisfactory, then, as I hope to demonstrate to you, the minerals which build up the crust of our globe unquestionably live. At all events I am confident of being able to show that "in correspondence with external co-existences and sequences," or, in other words, as the conditions to which they are subjected vary, they undergo "a series of definite and successive changes, both in structure and composition, without losing their identity."

It may seem paradoxical, but it is nevertheless true, that the "vitality" of minerals—I really do not know what other term to use to convey my meaning—is much greater than that of plants, and, *a fortiori*, than that of animals; and this is the direct and necessary consequence of their less complex and more stable chemical constitution.

The zoologist regards as a case of remarkable vitality the recovery of snails which had been long affixed to a museum-tablet, upon their immersion in warm water. The botanist cites the germination of seeds taken from ancient Egyptian tombs as a striking illustration of how long life may remain dormant in the vegetable world. Let us now turn to the mineral kingdom. A quartz-crystal develops to certain dimensions, in accordance with the natural laws of its being, and when the necessary conditions of growth cease to environ it, its increase is arrested. But the crystal still retains its "vitality," that is, the power of further development which is dependent on its particular "organisation" or molecular structure. We may destroy that "organisation" and the "vitality" which is dependent upon it in a single instant, by subjecting the crystal to the action of hydrofluoric acid or of an oxyhydrogen flame. But unless its "organisation" and "vitality" be thus brutally stamped out, the crystal and, indeed, every fragment of it retains, not the "promise" only, but the very "potency of life." It may be worn by wind and wave into a rounded and polished sand-grain; it may be washed from the beds of one formation, to form part of the materials of a new one, and this process may be repeated again and again; but after countless wanderings and unnumbered "accidents by flood and field," extending over millions on millions of years, let but the necessary conditions of growth again environ it, and the battered and worn fragment will re-develop, in all their exquisite symmetry, its polished facets, it will assume once more the form of a quartz-crystal, having at least as much claim to *identity* with the original one, as a man has with the baby from which he has grown.

"Life!" "Vitality!" These terms are but convenient cloaks of our ignorance of the somewhat complicated series of purely physical processes going on within plants and animals. "Organisation!" Why should the term be applied to the molecular structure of an *Amœba* or a yeast-cell, and refused to that of a crystal? But even if we choose to insist on such distinctions as these, must we also make them a basis on which to establish our classification of the sciences?

Unquestionably there are differences between the cycles of change which take place in animals, plants, and minerals respectively. As the animal differs from the plant in not being able to build up its tissues from the simple compounds of the mineral kingdom, so both animals and plants differ from minerals in their power of growth by intussusception.

But perhaps the most striking difference of all between the "vital" processes in animals, plants, and minerals, is found in the *rate* at which they take place. Animals, in consequence of the instability of their chemical constitution, are distinguished by an almost ceaseless activity and a consequent brevity of existence. Plants, in the slower rate at which their vital processes take place, bridge over to some extent the tremendous gap between animals and minerals. In these last the vital processes are so prolonged in their manifestations, owing to the stability of their chemical composition, and they are not unfrequently interrupted by such enormous intervals of time, that they are only recognised by the geologist.

The cycles of change which take place in an ephemera are rapid indeed as compared with those going on in the oak-tree, among the branches of which it lives; but in the rocks among which the oak thrusts its rootlets, other processes are going on compared with which the life of the oak-tree is as "fast" as that of the ephemera compared with its own.

Nevertheless the three forms of life seem to start pretty much on a level. A solution of nitre in which crystallites are uniting, in obedience to the laws of polarity, to build up crystals, with their regular forms, their molecular structure, and their powers of further development; a solution of sugar, in which the cell of a yeast-plant is living and growing; and a third liquid with floating vegetable particles, in which an *Amœba* is increasing and multiplying;—these three may surely be compared with one another, however unlike may appear to be the higher developments in the three kingdoms to which they respectively belong.

I do not, of course, for one moment wish to suggest that it is practicable, or even desirable, to attempt an extension of the conventional use of the terms "life" and "organisation." But I do think that it is of the first importance that we should clearly recognise the fact that the distinctions between living and non-living matter are not essential and fundamental ones, that cycles of change exactly similar in almost every respect to those occurring in the animal and vegetable kingdoms are equally characteristic of the mineral kingdom; though, in the latter, they are more difficult to follow on account of the extreme slowness with which they take place.

When this great truth is fully recognised, the separation of the biological and the mineralogical sciences will be at an end, and mineralogy will begin to profit by that revolution in thought and in method which has already done so much for her sister sciences.

The temporary divorce between biology and mineralogy has arisen, not from any inherent differences between their aims, their methods, or the objects of which they treat, but from the circumstance that, while the former has in the last half century advanced with the stride of a giant, the latter has during the same period tottered on with the feeble steps of infancy. Mineralogy is still in the "pupa-stage" of its development; it is a classificatory science, with its methods imperfect, its taxonomy undeveloped, and its very notation undefined. Its cultivators, absorbed in the Sisyphean task of establishing new species and varieties, too often treat their science, with all its glorious possibilities, as though it were but akin to postage-stamp lore!

How is it, we may profitably ask, that the biological sciences have made such prodigious advances, while the mineralogical ones have lagged so far behind? We must ascribe the result, I believe, to two causes:—

In the first place, improvements in the construction of the microscope, and more especially the perfecting of methods of study by means of thin sections, have immeasurably enlarged the biologist's field of observation; histology and the cell-theory, embryology with all its suggestiveness, and many important branches of physiological research, must have languished, if, indeed, they could ever have seen the light, but for aid afforded by the microscopical methods of inquiry.

In the second place, the growth of geological and palæontological knowledge has been the leading factor in that profound revolution in biological ideas which, sweeping before it the superstition of fixity of species, has endowed this branch of natural science with the transforming conception of evolution.

Now these two causes, which have done so much for biology, are already working out the regeneration of mineralogy; and I doubt not that the fruits brought forth by the latter science will be equally satisfactory with those of the former.

The application of the microscope to the study of minerals has proved less easy than in the case of animal and vegetable structures. More than a century ago, it is true, several French geologists employed the method of crushing a rock, and of picking out from its powder the several minerals of which it was composed, for microscopic study; and in 1816, Cordier endeavoured, by systematising the methods followed by his predecessors, Daubenton, Dolomieu, Fleurian, and others, to elaborate a scheme for the mineralogical analysis of rocks by the aid of the microscope. In recent years the French geologists, with MM. Fouqué and Michel Lévy at their head, have shown how, by the employment of the electro-magnet, of fluids of high density, and of various chemical reagents, this work of isolating the several minerals of a rock for microscopic study or chemical analysis may be greatly facilitated.

But the great drawback to this method of microscopic study of rocks, as devised in France, was found in the circumstance that it began by destroying the rock as a whole, and hopelessly obliterating the relations of its mineralogical constituents. Delesse and other observers, it is true, succeeded in obviating this difficulty, to some extent, by studying the structure of rocks as seen in polished surfaces under the microscope by reflected light.

The greatest step in advance in connection with the microscopic study of rocks was undoubtedly made, however, when it was shown that transparent sections of minerals, rocks, and fossils can be prepared, comparable to those so constantly employed by biologists in their researches. William Nicol, of Edinburgh, was the first to discover, in the year 1827, how the mechanical difficulties in the way of the preparation of such sections could best be surmounted; while Mr. Sorby, in a memorable communication to this Society, in 1858, showed us the first-fruits of the wonderful harvest of results to be obtained by the employment of this method.

But if the birthplace of the one method of microscopic study of rocks was France, and of the other Britain, it must be confessed that a large part of the merit of developing and improving these methods of inquiry is due to the Germans. To the labours of the numerous, patient, and accurate students in that country must be ascribed much of the perfection to which the methods of microscopic mineralogy have now attained; though we must not forget in this connection many most valuable contributions to the study from Scandinavia, Holland, Italy, and the United States.

As in the case of biology the results attained by the geologist have been the means of awakening new interests and inspiring a new philosophy, so in the case of mineralogy other problems have been suggested, and entirely fresh conceptions of the scope of the science have followed from the development of geological thought. We are thus led to regard minerals, not simply as a set of curious illustrations of mathematical and chemical laws, but as important factors in the evolution of the globe. Mineral collections in the past have resembled greenhouses, wherein only beautiful, though often abnormal growths are admitted; but in the future they will be like the herbaria of the botanist, where mere beauties of form and colouring are subordinated to the illustration of natural relationships and to the elucidation of the great problems of origin and development. Far be it from me to undervalue those wonderful crystals, the choice flowers of the mineral kingdom, which adorn our museums; but as there are many plants of extreme scientific interest which happen to possess only inconspicuous flowers, so there are not a few microscopic minerals, the study of which may lead us to the recognition of some of the most important laws of the mineral world.

I believe that what geology has already done for biology she is now accomplishing for mineralogy; it may, indeed, be instructive to point out how, in every one of its departments, the employment of microscopic methods and the suggestion of new lines of thought is causing mineralogy to develop in just the same directions as biology has already taken before her. In this way we may perhaps best convince ourselves that mineralogy is once more asserting her position in the family of the natural sciences.

Every natural-history science presents us with four distinct classes of problems. With respect to the objects of our study, we may make inquiries concerning their forms, their actions, their relations, and their origin. The answers to the first class of questions constitute *Morphology*, to the second *Physiology*, to the third *Chorology* or *Distribution*, and to the fourth *Ætiology*. The great problems of the mineral world, as I shall proceed to show, fall under precisely the same categories; and we may perhaps gather some useful hints by a comparison between the immature results of the mineralogist in each of these departments and those more perfect ones which have been attained by the botanist and zoologist.

The morphology of minerals was for a long time studied to the exclusion of all other branches of the science; for the problems connected with form and structure were those which naturally first attracted the students of the "inorganic" world.

Few generalisations of science are so beautiful, and at at the same time so suggestive, as those which have been arrived at by a discussion of the accurate measurements of crystal-angles. The constancy, within certain narrow limits, of corresponding angles, amid the almost infinite diversity of form assumed by crystals of the same mineral, is not less striking than the simplicity of the mathematical laws by which all these varied forms can be shown to be related to one another.

But the study of the morphology of minerals, which cannot be carried beyond a certain point by the aid of the goniometer, is capable of being pushed infinitely farther when we investigate the internal structure of their crystals, as illustrated by their optical and other physical properties. Not only do we find the minutest details of their external form to be correlated with peculiarities of molecular structure, as revealed by their action on a beam of polarised light, but delicate differences in internal organisation which the goniometer is powerless to detect, become clearly manifested under the searching tests of optical analysis. For the mineralogist, indeed, the polariscope with its accessories has supplemented the goniometer, in the same way as the spectroscope has the balance of the chemist.

What has been stated concerning the optical characters of minerals is equally true of their other physical properties; for the researches of recent years have shown all these properties to be intimately related to the symmetry of the crystal in which they are displayed. In every crystal, the faces of each group bearing the same relations to its axes exhibit characteristic peculiarities in their lustre, in their hardness, and in the manner in which they are acted upon by solvents; and these serve to distinguish such groups of faces from others in the same crystal having different relations to its axes. The elasticity of crystals, their power of conducting heat and electricity, and their phosphorescent, electric, or magnetic properties, whether natural or induced, are all manifested in varying degrees along certain directions which can be shown to be related to the particular symmetry of the crystal. And the more carefully we study both the forms and the physical properties of minerals, the more are we impressed by the conviction that the most intimate relations exist between these characters and the chemical composition of the minerals.

The phenomenon of "plesiomorphism," as Miller proposed to call it, that is, the slight variation in the angular measurements of crystals in the same species or group, when any of the constituents are replaced by vicarious or isomorphous representatives, very strikingly illustrates this conclusion. And the exact study of the optical properties of minerals shows that the slightest variation in the relative proportions of these vicarious constituents makes its influence felt by changes in their colour, in their pleochroism, in the nature and amount of their double refraction, in the position of their optic axes, and, indeed, in the whole assemblage of the properties of the crystal.

To the admirable investigations of Tschermak on the feldspars, the amphiboles and pyroxenes, the micas, and other groups of minerals, we are largely indebted for the establishment of this conclusion; while Doelter, Max Schuster, and other mineralogists, have contributed many striking observations which serve to extend and fortify it.

The application of the microscope to the study of the internal structure of minerals—their histology—has led to the recognition of many beautiful and unsuspected phenomena. Examined in this way, the seemingly homogeneous masses exhibit many interesting intergrowths and inclosures; and the study of these, as shown by Sorby, Vogelsang, Renard, and Noel Hartley, may serve to throw new and important light upon the conditions under which the crystals were originally developed. Cavities containing carbonic acid and other liquids, with bubbles in constant and, seemingly, spontaneous movement, serve to awaken the interest of the naturalist not less powerfully than the mysterious creeping of protoplasm in the hair of a nettle, or the dance of blood-corpuscles in the foot of a frog!

Others among these histological peculiarities of crystals must be regarded as having a pathological significance; they are abnormal developments resulting from unfavourable conditions to which the crystals may have been subjected during their growth, or in the course of their long and chequered existence.

The variability exhibited in crystals of the same mineral is sometimes very startling. In addition to the varieties due to the combinations of many different forms, or to the excessive development of certain phases at the expense of others, we have the complicated and diversified structures built up by twinning according to different laws. Again, by oscillatory tendencies in the same crystal towards the assumption of different forms, or by the existence of causes calculated to interfere with the free action of the crystallising forces, we may obtain varieties with curiously curved or striated faces. Not unfrequently large quantities of extraneous materials, solid, liquid, or gaseous, may be caught up in the crystal during its growth, and these foreign substances may be so far affected by the polar forces operating around them as to be made to assume definite and symmetrical positions within the crystal.

Even in the case of minerals of identical chemical composition and similar crystalline form, marked variations in physical properties may result from differences in the conditions under which they have originated. In lustre, density, and other characters, adularia differs from sanidine, and elæolite from nepheline. Dr. Arthur Becker has shown that quartz exhibits marked variations in its specific gravity, according to the particular conditions under which it has been formed.

There is one kind of morphological variability in minerals which has during recent years attracted a great amount of attention, and excited much discussion among mineralogists. Soon after his memorable discovery of the relations between the crystalline forms of minerals and their optical properties, Brewster detected certain apparent exceptions to his important generalisation; and since his day many additions to these curious anomalies in the optical behaviour of minerals have been made by other observers. So greatly, indeed, have these been multiplied in recent years, that it is doubtful whether any mineral crystallising in the cubic, the tetragonal, or the hexagonal system could be cited in which the optical properties are precisely what they ought to be according to theory; and similar anomalies are also found in crystals possessing lower degrees of symmetry.

The attempts which have been made by some crystallographers to account for these optical anomalies in crystals, by assuming that they possess only a pseudo-symmetry, the result of very complicated twinning, ingenious as they undoubtedly are, remind one of the wonderful addition of eccentrics and epicycles by which astronomers so long sought to maintain the credit of the Ptolemaic theory. But as, in the latter case, complexities and difficulties alike vanished when the centre of the system was shifted from the earth to the sun, so have the discoveries of Klein, Rosenbusch, and others removed the necessity for the painfully elaborate crystallographic hypotheses to which we have referred.

Most mineralogists will now be prepared to admit, as the result of these researches, that the perfection alike of form and of optical properties which characterises a crystal when first formed, is liable to slight modification, as the conditions of temperature and pressure under which it exists vary. In consequence of this, almost all natural crystals are found, when we study them with sufficient care, to exhibit slight but very striking and significant differences in form and optical behaviour from what they ought theoretically to possess.

While our knowledge of the ordinary mineral varieties promises to be vastly extended by the improvements which have been made in the methods of optical and chemical diagnosis under the microscope, there is, at the same time, reason to hope that the relationship of these numerous varieties will, by the same means, be made more clearly apparent. As the existence of well-defined natural groups of minerals becomes more clearly established, through the study of interesting though inconspicuous links, we shall obtain a basis for a much-needed reform in mineral taxonomy and nomenclature.

The more carefully we pursue our researches among the diversified forms of the mineral world, the more are we impressed by the conviction that each mineral, like each plant or animal, possesses its own individuality. Nature does not make *facsimiles* in the mineral, any more than in the vegetable or the animal kingdoms. All the sciences of Nature must be content to recognise individuals as the only real entities, and to accept species, like genera, families, and orders, as convenient but purely artificial conceptions.

The geological study of minerals leads us to regard each specimen that we examine as possessing a distinguishing combination of properties, some of which are impressed upon it by causes operating when it came into being, while others are no less clearly the result of the long series of vicissitudes through which it has since passed.

Of all the branches of mineral morphology there is none from the study of which the geologist has gained more in the past, or from which he has greater reason to look for future aid, than that of the embryology of crystals.

In the year 1840 Link showed that the first step in the formation of crystals in a solution consists in the separation of minute spherules of supersaturated liquid in the mass; and subsequently Harting in Holland, and Rainey and Ord in this country, obtained a number of interesting experimental results, by allowing crystallisation to take place slowly in mixtures of crystalloids and colloids.

Valuable contributions to the same subject were made by Frankenheim, Leydolt, and others; but it is to Hermann Vogelsang that we owe the greatest and most important contributions to mineral-embryology. By the ingenious device of adding viscous substances to solutions in which crystallisation was going on, he succeeded in so far retarding the rate at which the operation took place as to be able to study its several stages. He thus showed how the minute "globulites," gathering themselves into nebulous masses or ranging themselves according to mathematical laws, gradually build up skeleton-crystals, by the clothing of which the perfect structures arise.

Since the early and regretted death of Vogelsang, the subject of the development of crystals from their embryos, the so-called *crystallites*, has been successfully prosecuted by Behrens, Otto Lehmann, Wichman, and other investigators.

Now in all glasses—whether of natural or artificial origin—in which the process of primary devitrification is going on, we have examples of the growth of crystals in a viscous and retarding mass, and in these, as Leydolt, Zirkel, and Vogelsang clearly saw, admirable opportunities are afforded to us for studying the formation of crystallites, and the laws which govern the union and growth of these into crystals. Two years ago, my predecessor in this chair submitted to you the interesting results of his own researches upon the devitrification of artificial glasses and slags; and the subject has since been pursued by Velain in France, and by Hermann and Rutley in this country.

The igneous rocks supply us with admirable opportunities for studying mineral embryology. In the same rock-mass we may sometimes find every possible graduation, from an almost perfect glass to a holocrystalline aggregate. By the study with the microscope of the several transitions in different parts of the mass, we obtain data for the most important conclusions concerning the phenomena of crystal-development.

There is another line of research in connection with mineral-embryology, which appears to be full of promise, and which has not yet received all the attention it deserves. In the "contact-zones" around great igneous intrusions, we find the curious so-called "spotted slates," which under the microscope are seen to contain nebulous patches, the mere ghostly presentments of crystals, struggling into being in the amorphous mass. The development of these nebulous masses into perfect crystals, exhibiting the characteristic external forms and optical properties of andalusite and kyanite, of garnet and epidote, of hornblende and mica, may be traced in some cases with the greatest facility.

More complicated still are the phenomena exhibited along the foliation-planes of the rocks, which have been made to flow in the act of mountain-making. There, as the old minerals are destroyed, new ones build themselves up from their elements. The study of all the steps of this process is an undoubtedly difficult one, but the results already obtained by Reusch, Lossen, Heim, and Lehmann, by Lapworth, Teall, Roland Irving, and Williams, lead us to look hopefully forward to the full solution of the grand but complicated problems of regional metamorphism.

The field of mineral-embryology is indeed a promising one, and its diligent cultivators may hope to gather a harvest no less rich than that which has been reaped by the workers in the same department of the biological sciences.

(*To be continued.*)

TABASHEER

I HAVE often wondered that this curious substance has never attracted more attention. But scanty references to it are to be found in books, and yet it seems to me that few more singular things are to be met with in the vegetable kingdom.

In Watts's "Dictionary of Chemistry" (vol. v. p. 653), exactly six lines are devoted to it. It is defined to be: "Hydrated silica, occurring in stony concretions in the joints of the bamboo. It resembles hydrophane, and when thrown upon water does not sink till completely saturated therewith." It is further stated to be the least refractive of all known solids, and an analysis by Rost von Tonningen of a specimen from Java gives a composition of 86·39 per cent. silica soluble in potash, 4·81 potash, 7·63 water, with traces of ferric oxide (to which I suppose its occasional yellowish colour to be due), lime, and organic matter.

There are several specimens in the Kew Museums, partly derived from the India Museum. All consist of small irregular angular fragments, varying from the size of a pea downwards, and opaque white in colour. It is obvious that these fragments are the debris of large masses.

Now, the presence of considerable solid masses of so inert a substance as hydrated silica in the plant-body is a striking fact. At first sight, one might compare it do the masses of calcium phosphate which form the endo-skeleton in the higher animals. These, however, serve an obvious mechanical purpose, which cannot be attributed to the lumps of tabasheer in the hollow joints of a bamboo. The presence of silica may sometimes serve an adaptive purpose, as in the beautiful enamelled surface of canes. And according to Dr. Vines ("Physiology of Plants," p. 21), "Struve found that it constitutes 99 per cent. of the dry epidermis of *Calamus Rotang*."[1]

In a few other groups of plants, such as *Equisetum* and the *Diatomaceæ*, it is a characteristic constituent. In all cases it principally occurs in the cell-wall (Vines, *l.c.* p. 137. This has suggested the highly ingenious speculation that, seeing the intimate chemical relationship which obtains between silicon and carbon, there might be a silicon-cellulose. I notice that Count Castracane, in his Report on the *Diatomaceæ* collected by the *Challenger*, speaks of its "having been already shown that silica is sometimes substituted for carbon in the formation of cellulose" (p. 7). Judging from ash-analyses it might be supposed that silica was an essential constituent of gramineous plants. But by the method of water-culture Sachs has found that maize, for example, will grow with only a trace of silica. I must confess to ignorance of all that may have been done in the matter recently. But Ladenburg thought, and I think with reason, that the indifference of the plant to silica was a

[1] Sachs remarks ("Text-book," second edition, p. 700) that silica accumulates chiefly in the tissues exposed to evaporation, though this clearly does not apply to the case of diatoms.

strong argument for a silicon-cellulose in which silicon might or might not with equal physiological convenience play the part of one or more atoms of carbon. Fascinating as this hypothesis is, I am bound to say that the prolonged investigation which he devoted to the question is on the whole adverse to the idea of silicon playing any part of the kind.

It still remains then an unsolved problem why, when no adaptive end is involved, plants should take up such relatively enormous quantities of silica. The case of the frustules of *Diatomaceæ* is peculiar, as there the silicious wall is apparently a continuous plate of inorganic matter capable of resisting without impairment treatment by the most destructive and disintegrating agencies known Yet Castracane adduces evidence to show that such walls can grow; and as this can only be by interstitial growth, a molecular constitution is implied quite different from anything physical, and precisely similar to that of a cellulose membrane. He quotes, indeed, von Mohl for the opinion that the wall is not simply inorganic, "but only an organic membrane which is impregnated with silex."

Now, in the case of tabasheer, it is quite evident that the plant takes up an amount of silica beyond its powers to use, and so it is exuded into the hollow cavities of the bamboo stem. I do not mind confessing that, in so far as I had reflected on the matter at all, I had pictured to myself this as taking place by some process of secretion, so that the mass of tabasheer ultimately accumulated from successive portions of thrown-off silica. I was obliged, however, to give a little more serious thought to the matter when Prof. Cohn, of Breslau, wrote to me that he proposed to investigate the whole subject, and asked for help in the way of specimens and information. It then struck me what a very singular thing the phenomenon of the occurrence of tabasheer really was. I set to work to hunt up in the literature of Indian botany some rational account of the matter. The only ray of light I got was from the "Forest Flora of North-West and Central India," by Dr. Brandis, late Inspector-General of Forests to the Government of India. Everyone who knows Dr. Brandis knows that he gave to administration the energy he would more willingly have devoted to scientific pursuits. I was not at all surprised to find, therefore, modestly hidden in his book (p. 566) the key to the riddle. He says: It is not at all impossible that the well-known silicious deposit (*tabasheer*) which is found in the joints of this and other species [*Bambusa arundinacea*] may be the residuum of the fluid which often fills the joints." I communicated this to Prof. Cohn, and he was good enough to tell me that he quite agreed that this was the correct explanation. I at the same time wrote to Dr. King, the distinguished Superintendent of the Royal Botanic Garden, Calcutta, to know if it were possible to procure specimens of tabasheer *in situ*, as we possessed in our Museum nothing but broken fragments. I extract from several letters he has written me the following particulars:—"January 11. I have inquired of several old workers as to the situation tabasheer occupies. They all say it is found either on the *floor* of the joint, or if (as is so often the case in *B. Tulda*) the stem leans over, it is also found on the lower wall. It is never found on the roof of a joint. . . . . Tabasheer is not common in bamboo grown near Calcutta. And, besides, it is apt to be forced out of its natural position by the forced used in breaking a joint open. There is no external mark by which a tabasheer-bearing joint can be recognised prior to being opened." "January 18. I have got a specimen of tabasheer *in situ* for you. It concretes *as a jelly*, and is now being carefully dried off."

I think that these extracts (in which the italics are mine) fully confirm the explanation as far as I know first put out by Dr. Brandis. The rapidity of growth of a bamboo shoot is well known to be enormous. The root-pressure is probably equally great. The joints, at first solid, become hollow by the rending apart of the internal tissues, and water containing silica in solution is poured out into the cavities so formed. When the foliage is developed, transpiration is active: the water taken up from the ground is rapidly got rid of; not merely is the root-pressure compensated, but the water poured out into the joints is re-absorbed. It is not easy to see why the silica should not be always taken with it, as in the vast majority of cases it no doubt is. But in the cases in which it is left behind it has apparently simply undergone a process of dialysis. The determining causes of the occasional deposit of tabasheer are, I think, still obscure. But, as Prof. Cohn intends to investigate the subject, I think we may pretty confidently look forward to an exhaustive explanation.

It is a well-known fact that a large proportion of the ash-constituents of plants may have but little significance in their nutrition. The chemical constitution of plants, as far as their ash is concerned, to a large extent varies with the nature of the soil in which they are grown. It is quite certain that they will in consequence take up a vastly larger proportion of certain constituents than they can turn to any physiological account. Tabasheer is a striking instance of one such case. The calcareous masses found in the wood of many Indian trees mentioned in NATURE, vol. xxi. p. 376, affords another.

W. T. THISELTON DYER

ON THE EARLIER TRIPOS OF THE UNIVERSITY OF CAMBRIDGE

I HAVE read with great interest the papers by Mr. Glaisher in NATURE of December 2, 18, and 30, 1886 (pp. 101, 153, and 199), entitled "The Mathematical Tripos." Through the period common to Mr. Glaisher's notes and my recollections, I believe that we are strictly in agreement. I am able, however, to supply some little histories (I wish these had been more numerous and more certain) relating to transactions several years earlier than those known, personally, to Mr. Glaisher, and I am desirous that their memory should not be totally lost. There are now few persons, perhaps none, whose recollections of the University of Cambridge and of Trinity College go so far back as my own.

I first advert to the official course of undergraduates' life.

Shortly after introduction to the College in the October Term of 1819, I attended, with all other freshmen, in the Senate House or in the College Hall (I believe the latter) to take the oaths of allegiance and supremacy. With great ardour I renounced the "damnable doctrine" that the Pope of Rome could absolve subjects from their allegiance, with several similar declarations; and I also disclaimed all connection with other Universities and Colleges, and in particular with Wolsey's College at Ipswich. I believe (but have no certain knowledge) that these puerilities terminated a few years afterwards.

The undergraduates were arranged in "sides," divided under the official tutors under whom they were entered in the College Lists. There were then two "sides"; subsequently there were three. The lectures on each side were held in the College rooms of the tutor or his assistant tutor. The lectures consisted, naturally, in proposals of theorems and problems (in writing) and oral discussion of the answers in a friendly style.

The annual College examinations of the undergraduates of all sides (collected), of each year of undergraduateship, were held in the College Hall at the practical termination of the May Term. The order of merit in each year, as determined by these examinations, was published by lists of names suspended in the College Hall. Small sums of money, to be expended in honorary prizes, were assigned to the First Class of each year.

In the third year of undergraduateship arrived the time of "keeping Acts and Opponencies." These, as Mr. Glaisher has explained, were formerly the only public exhibitions of students' merits in the University; and, possibly, were still considered in the University as more important than would be gathered from Mr. Glaisher's account. The three Opponents met to take tea and to arrange their arguments; the Act also was invited, with an intimation that he was not to stop long. I have seen the "Schools," in which the disputations were held, quite filled with undergraduates of all Colleges, who came to listen to the disputations, or rather quibbles, held in the Latin language, of the argumentative quarrel. If my memory is correct, each of the undergraduates (selected, I believe, by the Moderators) appeared twice in the character of "Act" (asserting the correctness of some doctrine in the printed books), and twice or more in the character of "Opponent" (denying that correctness). The President of the School was one of the Moderators. The assertion of the Moderator that the argument failed was given by the words "Probes aliter." The discussion was usually closed by a complimentary address of the Moderator, as, for instance, "Magno ingenio argumenta tua et construxisti et defendisti." I do not think that the form lasted many years after this time.

At length came the October Term, the last term (the tenth) for undergraduates, of which I remember only one characteristic, namely, that in the College Hall a separate dinner-table was established for the "Questionists" (as those were called who were to proceed to the B.A. degree in January). To this table all Questionists were removed from whatever tables they previously occupied. Among others, the "Scholars" of the College (Trinity) were removed from their table, where they had formed agreeable acquaintances, to a collection of strangers, naturally disagreeable to the "Scholars." We much disliked this change. I think that in this term the character of the College lectures was changed almost entirely to problems and questions; some of them in the evening, in the College rooms of one of the Fellows.

At length arrived the Monday morning on which the examination for the B.A. degree was to begin. A breakfast was given by the "Father" of the College (one of the Fellows of the College) in the College Combination Room, and then we were all marched in a body to the Senate House and placed in the hands of the Moderators. How the "candidates for honours" were separated from the οἱ πολλοὶ I do not know. I presume that the Acts and Opponencies had something to do with it. The honour-candidates were divided into six groups; and of these Nos. 1 and 2 (united), Nos. 3 and 4 (united), and Nos. 5 and 6 (united), received the questions of one Moderator. No. 1, Nos. 2 and 3 (united), Nos. 4 and 5 (united), and No. 6, received those of the other Moderator. The Moderators were reversed on alternate days. There were no printed question-papers: each examiner had his bound manuscript papers of questions, and he read out his first question; each of the examinees who thought himself able proceeded to write out his answer, and then orally called out "Done." The Moderator, as soon as he thought proper, proceeded with another question. I think there was only one course of questions on each day (terminating before 3 o'clock, for the Hall dinner).

The examination continued to Friday mid-day. On Saturday morning, about 8 o'clock, the list of honours (manuscript) was nailed on the door of the Senate House.

The ceremonies and customs of conferring degrees in the middle of the day, I believe, have not been altered. The Vice-Chancellor was seated in the centre of the Senate House. The Father of that College of which the Senior Wrangler was a member led him to the Vice-Chancellor. The roar of acclamation from the undergraduates in the galleries of the Senate House, to welcome a favourite Senior Wrangler, will not be forgotten by one who has heard it. The Father presented him with the words: "Dignissime Domine, Domine Procancellarie, et tota Universitas, præsento vobis hunc juvenem, quem scio tam moribus quam doctrinâ esse idoneum ad respondendum Quæstioni; idque tibi fide meâ præsto, totique Universitati." The candidate knelt before the Vice-Chancellor, who pressed the candidate's hands between his own, and answered: "Auctoritate mihi commissâ, admitto te ad respondendum Quæstioni, in nomine Patris, et Filii, et Spiritûs Sancti." I am not able to say how much of this was repeated for each candidate. Then followed some petty quibbles with some Master of Arts concerning questions which nobody professed to understand, but which were inessential. The undergraduate gown was then changed for a B.A. gown.

On a certain day following, at a Congregation of the Senate, the list of names of those who were thus admitted was read to the Vice-Chancellor, who (as I understood) solemnly recognised the rights of the first to the privileges of Bachelor of Arts, and to each of those following only repeated the words "et ei," finally declaring that they were "actualiter in Artibus Baccalaureos."

It is evident that there must have been some relation between the various ranks which no longer exists; and, in particular, that the *Quæstio* was once important, and is now totally lost. And connections existed between the Colleges and the University which can scarcely be traced at the present day.

I now advert to the mathematical subjects of study and examination.

In the October Term, 1819, the only books on pure mathematics were: Euclid generally; "Algebra," by Dr. Wood (formerly Tutor, but, in 1819, Master, of St. John's College), Vince's "Fluxions" and Dealtry's "Fluxions," Woodhouse's and other Trigonometries. Not a whisper passed through the University generally on the subject of differential calculus, although some papers (subsequently much valued) on that subject had been written by Mr. Woodhouse, Fellow of Caius College; but their style was repulsive, and they never took hold of the University. Whewell's "Mechanics" (1819) contains a few and easy applications of the differential calculus. The books on applied mathematics were: Wood's "Mechanics," Whewell's "Mechanics," Wood's "Optics," Vince's "Hydrostatics," Vince's "Astronomy," Woodhouse's "Plane Astronomy" (perhaps rather later); the first book of Newton's "Principia." I do not remember any others. These works were undoubtedly able; and I do not conceal my opinion that for the great proportion of University students going into active life books constructed on the principles of those which I have cited were more useful than those exclusively founded on the more modern system. For those students who aimed at the mastery of results—more difficult and (in the intellectual sense) more important—the older books were quite insufficient.

More aspiring students read, and generally with much care, several parts of Newton's "Principia," Book I. and also Book III. (perhaps the noblest example of the geometrical form of cosmical theory that the world has seen). I remember some questions from Book III. proposed in the Senate House Examination, 1823.

In the October Term, 1819, I went up to the University. The works of Wood and Vince, which I have mentioned, still occupied the lecture-rooms. But a great change was in preparation for the University course of mathematics. During the great Continental war, the intercourse between men of science in England and in France had been most insignificant. But in the autumn of 1819 three members of the Senate (John Herschel, George Peacock, and Charles Babbage) had entered into the mathematical society of Paris, and brought away some of the works on pure mathematics (especially those of Lacroix) and on mechanics (principally Poisson's). In 1820 they made a translation of Lacroix's "Differential Calculus," and they prepared a volume of "Examples of the Differential and Integral Calculus." These were extensively studied; but the form of the College examinations or the University examinations was not, I think, influenced by them in the winter 1820-21 or the two following terms. But in the winter 1821-22 Peacock was one of the Moderators; and in the Senate-House Examination, January 1822, he boldly proposed a paper of important questions entirely in the differential calculus. This was considered as establishing the new system in the University. In January 1823 I think the two systems were mingled. Though I was myself subject to that examination, I grieve to say that I have forgotten many of the details, except that I well remember that some of the questions referred to Newton, Book III., on the lunar theory. To these I have already alluded.

No other work occurs to me as worthy of mention, except Woodhouse's "Lunar Theory," entirely founded on the differential calculus. The style of this book was not attractive, and it was very little read.

From this time to the times of which Mr. Glaisher treats, there were successive books on the new system, but none, I think, which can be cited as producing a marked effect in the University. G. B. AIRY

NOTES

THE University of Bologna has decided to celebrate its eight hundredth anniversary in the spring of 1888. The exact date of its foundation cannot, indeed, be determined, but all authorities on the subject agree that an important school was established at Bologna in the eleventh century. Afterwards the University took a great place as the chief centre for the study of jurisprudence, and there also anatomy was for the first time scientifically studied. The foremost Universities of Europe and America will no doubt be glad to take this opportunity of testifying their respect for so ancient and famous an institution.

AT their meeting on February 3 the President and Council of the Royal Society adopted the following resolutions concerning the publication of the Philosophical Transactions:—That the Transactions be published in two independent series, one (*a*) containing those papers which are of a mathematical or physical character, the other (*b*) those of a biological character; that the papers in each series form a yearly volume, paged continuously (though issued in parts if the Secretaries find it convenient), but that each paper be also published separately in paper covers as soon as it is ready for publication; and that Fellows have the option of receiving one or both of the yearly volumes, or, should they prefer it, each separate paper of either or both series, or the whole of one series and any separate paper of the other series, immediately on publication. These resolutions are to take effect with the volume for the present year.

A COMMITTEE, lately appointed by the College of Physicians of Edinburgh, has reported in favour of the establishment and maintenance, by the College, of a laboratory for the prosecution of original research. The Committee proposes that the College shall vote from its capital 1000*l*. for the establishment of this laboratory, and, year by year, a sum not exceeding a third of the clear surplus of annual income over annual expenditure for its maintenance, including the payment of salaries The superintendent, it is thought, should devote his time wholly to the direction and prosecution of scientific research in the laboratory; and it is suggested that an assistant experienced in microscopic work should be engaged to reside on the premises. The Committee is of opinion that the laboratory should be open without fee to Fellows of the College, to members, and to any licentiate, medical man, or investigator who may, by testimonial or otherwise, be able to show that he is a fit person to use the laboratory for purposes of scientific research. Moreover, the Committee recommends that, if there should be sufficient funds after payment of expenses, a medal and money-prize (not exceeding twenty guineas) should be offered for original work. It is understood that this admirable scheme will be adopted, and we may hope that the example set by the Edinburgh College will soon be followed by the English College of Surgeons and College of Physicians.

A CORRESPONDENT writes to us from Tashkend that on November 29 last, at 9.12 a.m., a violent shock of earthquake was felt there, accompanied by a great noise like thunder. The people were much frightened, and the majority of the buildings were more or less injured. Light shocks were felt also on December 3, and on January 9 and 16.

ON the 15th of January last there was in some parts of Japan the most severe earthquake that has been experienced there since February 22, 1880. It fetched down a number of chimneys and parts of roofs in Yokohama, but in Tokio (eighteen miles distant) it only broke a few vases and created alarm. The important and peculiar feature of the disturbance was that it had a long period and large amplitude. At the Imperial Observatory at Tokio, where a number of "Gray-Milne seismographs" are employed, the pointers of the instrument were seen to move for nearly ten minutes. We learn from the *Japan Gazette* that the disturbance was felt at Tokio at 6h. 51m. 59s. p.m., commencing in a series of small waves. The greatest horizontal movement was 19·2 mm. (about $\frac{3}{4}$ inch). The time taken to describe the largest wave was 2·3 seconds. The vertical motion had a range of 5·5 mm. (about $\frac{1}{4}$ inch), and its period was ·8 seconds. Altogether there were 60 distinct waves, and the maximum velocity with which the earth moved to and fro was 26 mm., or about 1 inch per second. At Tokio people felt the motion as if they had been on a slowly-moving floating pier, and in many cases it provoked a sensation of nausea. The general distribution of destruction at Yokohama was similar to that which took place in 1880. The *Japan Gazette*, however, points out that many chimneys standing on ground which in 1880 suffered severely were this time uninjured. This "anomaly," it thinks, may be explained by the fact that the owners of these chimneys took advantage of the experience they gained in 1880, and rebuilt their chimneys with a special view to their safety.

THE Right Hon. G. Sclater Booth, M.P., has accepted the Presidentship of the Congress of the Sanitary Institute of Great Britain, to be held at Bolton in September next.

ON March 6 a century will have elapsed since the birth of the celebrated optician, Joseph von Fraunhofer, at Straubing, in Lower Bavaria. Preparations are being made in Munich for the due celebration of the day.

IN the eleventh annual Report of the President of the Johns Hopkins University, Baltimore, Dr. Gilman is able to give a very satisfactory account of the progress made by the institution since its establishment in 1876. Much of its success, he thinks, is due to the system of Fellowships. Every year twenty young men who have given evidence of their attainments and of intellectual promise are selected by the authorities as Fellows, and are encouraged to devote all their time to the study of some branch of knowledge in which they have already shown proficiency. During the first ten years this honour has been bestowed upon 130 persons. Their names and the stations to which they have been called have been frequently printed, and Dr. Gilman says a scrutiny of the list will show that it contains the names of many excellent scholars. While resident at the University, the Fellows are recognised as holding an intermediate position between the Faculty and the great body of pupils. They are efficient members of the various literary and scientific associations, and occasionally give lectures on topics which they have specially studied.

A NEW quarterly journal, to be entitled the *American Journal of Psychology*, will soon be issued. Dr. G. Stanley Hall, Professor of Psychology and Pedagogics in the Johns Hopkins University, will be the editor. The *Journal* will contain original contributions of a scientific character; and articles of unusual importance will be translated from other languages, or even reprinted from other English and American publications, in full or in abstract, if not generally accessible. An attempt will be made in each number to give a conspectus of the more important psychological literature of the preceding three months, and to review significant books, bad as well as good.

A SCIENTIFIC and industrial Exhibition will be opened at Ekaterineburg in May next. The mining industries of the Ural Mountains will be well represented. Special interest will attach to the department of ethnography, as it has been arranged that there shall be in the Exhibition a number of families belonging to semi-barbarous tribes of the Ural Mountains and Siberia. Their dwellings will be exactly like those in which they usually live, and they will have with them the weapons and implements used by them in hunting and fishing. Another important element will be a collection of ancient objects in stone, bone, clay, and metal, found in Siberia and among the Ural Mountains. These objects have never before been publicly exhibited.

A CAUCASIAN Agricultural Exhibition will be held next year in Tiflis. Products of the animal, vegetable, and mineral kingdoms will be exhibited.

FISH-HATCHING operations have begun at the Buckland Museum, where consignments of trout ova, presented by Sir James Maitland, have been laid down in the incubating apparatus used by the late Mr. Frank Buckland. The system upon which the ova are hatched at the Museum is that known as the "overflow," the water passing over the eggs, which are placed in slate boxes lined with gravel. The new system is called the "underflow," the water passing underneath the eggs, which are deposited in perforated zinc trays without gravel. Much diversity of opinion exists as to the efficacy of the two systems.

THE other day some workmen, while removing brickwork that had surrounded a tank in the late South Kensington Aquarium, found ten eels secreted in a crevice of the masonry, which was perfectly dry. The tank had been removed eighteen days before, when the Aquarium was dismantled, so that the fish must have been without water during the whole of that time. When placed in water they appeared to have been in no way injured by their terrestrial experience.

IN the debate on the appropriations for the support of the U.S. Coast Survey, the Senate, according to *Science*, pared the items down in a parsimonious spirit. Afterwards the Senate Appropriations Committee addressed a letter to the Secretary of the Treasury, inquiring whether the estimates as submitted by the Superintendent of the Coast Survey were satisfactory to that Department. The answer was that they were perfectly satisfactory, and a communication from the Superintendent of the Coast Survey was submitted, showing the reasons for each item of expenditure, and the present condition of the service. "From these communications," wrote the Secretary, "it appears that the estimates made provision for the efficient and economical prosecution of the Survey during the ensuing year; it also appears that the provision made by the House Bill will not secure such results. Consequently the arrangement made is not satisfactory to this Department."

WE learn from Italy that the idea of boring a tunnel between the peninsula and Sicily has been revived. The estimated cost is said to be seventy-one millions of francs, and the time required for completing the work would be from four to six years. It is stated that the depth of the sea is 160 metres.

THE number of foreigners at present residing in France, and settled there, is 1,115,214, against 37,103,689 Frenchmen. The parts of France in which the foreigners are most numerous are of course the frontier departments, those of the Nord, Alpes Maritimes, Var, Bouches du Rhône, &c. In the Seine Department there are 213,529 foreigners; in the Nord 305,524, most of whom are Belgians.

OYSTER-PRODUCTION, although carried on to a large extent in France, is not yet a profitable investment. The reason is that the rates for transportation from the oyster-beds are too high. In Auray, for instance, oysters are worth nine francs per thousand; in Paris they cost more than fifty francs. An attempt is being made to secure transportation at less cost.

A MOVEMENT is on foot in the North Sea towns of Germany for promoting oyster-culture along the coast, supported by Government grants. At present there are fifty-one banks in the North Sea, viz. twenty-six at Fanö, Romö, and Sylt, and twenty-five at Föhr, Amrum, and Hallingerne. In the Baltic, on the other hand, all attempts at oyster-culture have failed. "Holstein" or "Flensburg" oysters—considered the best in Germany—are really English or Dutch. All the German oyster-banks are the property of the State, and leased to private individuals.

WE regret to announce the death of Dr. Walfried Marx, Professor of Descriptive Geometry at the Technical High School at Munich. He died on February 10.

THE first International Horticultural Exhibition will be held at Dresden on May 7.

HERE is a case in which even a little knowledge of physics would not have been out of place. A man was summoned for making use of the communication between passengers and guard without reasonable and sufficient cause. Being in a third-class compartment alone, he was frightened by the singing noise of his foot-warmer, caused by the contraction of metal due to the reduction of temperature. Thinking it an infernal machine, he immediately threw it out of the window, and, not content with this drastic proceeding, he incontinently proceeded to stop the train by using the excellent mode of communicating with the guard and engine-driver which exists on the South-Eastern Railway. A little more science and a little less energy would have saved everybody a little trouble, but as his *bona fides* was as obvious as his ignorance, the magistrate dismissed him with a caution. The magistrate might, perhaps, have done some good if he had told the man what happens when an ordinary kettle is filled with ordinary water and placed on an ordinary fire.

IN a recent number, *Science* referred to a supposition that "it is change of diet which is the most potent remote cause of consumption among the Indians." Mr. H. C. Wyman, of Detroit, writes to that journal that, in his opinion, another cause is change change of dress. "If," says Mr. Wyman, "a live rabbit be dipped in a solution of glue, so as to cover its body with a coating impervious to air, it is surprising how quickly the frequency of the respiratory movements increases, showing that the work of the lungs is increased by depriving the skin of free access to the air. The process of civilisation has a somewhat similar effect upon the Indian, though to a less degree. One of the first lessons in the effort to civilise him teaches him to envelop himself in clothing of a kind that tends to impede and impair the normal action of the skin, the pores of which are organs of excretion—a mechanism by which morbid and waste material may be thrown out of the system. Deprived of the assistance afforded under previous conditions by the skin, the work of the lungs is greatly increased, rendering them peculiarly susceptible to bronchitis and pneumonia—ailments which are commonly the forerunners of consumption. If we accept the theory of Koch, they make the lungs a suitable habitation for the *Bacillus tuberculosis.*" Mr. Wyman contends that, in the case of civilised races, the liability to consumption from overworked lungs has been tempered by hundreds of generations of ancestors habituated to the use of clothing.

IN the Report of the U.S. Geological Survey on the mineral resources of the United States for 1885, it is stated that the total mineral product is valued at 428,521,356 dollars, an increase of 15,306,608 dollars over 1884. Among seventy mineral substances cited, coal is the most important, showing a total value of 159,019,596 dollars. An increase is shown in the production of coke, natural gas, gold, silver, copper, zinc, quicksilver, nickel, aluminium, lime, salt, cement, phosphate rock, manganese, and cobalt oxide, while the production of coal, petroleum, pig-iron, lead, precious stones, and mineral waters decreased. According to the Report, it is probable that the total output of 1886 was much greater than that of 1885, and even larger than that of 1882.

WE have received the *Annuaire* for 1887 of the Académie Royale des Sciences, des Lettres, et des Beaux-Arts de Belgique. It contains a full account of the organisation of the Academy, and of the means by which it seeks to encourage science, literature, and art. Among the biographical notices are articles on the late François Lenormant and Edouard Morren.

AN illustrated work, entitled "Les Civilisations de l'Inde," by Dr. Gustave Le Bon, is being issued in weekly parts by Firmin-Didot et Cie. Dr. Gustave Le Bon is the author of a work on "La Civilisation des Arabes."

THE Calendar of the Imperial University of Japan for the current year, which we have just received, deserves special mention, for it is the first that has been issued since the amalgamation of the well-known College of Engineering and the University of Tokio into the single institution which forms the new University. This incorporation was made the occasion for several organic changes, one of which is the almost total elimination of Europeans from the teaching staff, their places being taken by Japanese. To understand the full extent of the change in this respect, it is necessary to remember that five or six years ago all the professors in the College of Engineering, and nearly all in the University, were Europeans. An examination of the Calendar shows how the new University stands in this respect. By the Imperial decree, which is the charter of the institution, the Council of Professors regulate the studies and generally look after the interests of the University and each of its Colleges. There is not a single Western amongst the nine Councillors. In the Law College, three out of thirteen professors and lecturers are Westerns; in the Medical Faculty, out of thirty-four professors and assistants, there are three Europeans; there are three Europeans amongst twenty-four professors and assistants in the Faculty of Engineering; two in twenty-six in Science; and three in nineteen in Literature. It is probably not too much to say that, where one European is teaching now, there were six Europeans five years ago. It was only to be expected that ultimately the Japanese would have their own men ready to take the places vacated by Europeans. They had at vast expense sent abroad large numbers of youths to be educated for the various professions in Europe and America, who, on their return, were competent to teach their countrymen; and in looking down the lists of the Japanese professors we see that most of them have foreign degrees and other qualifications. They come from almost every German, French, British, and American University, and in some instances have taken high honours. They may therefore be presumed to be competent for the work which they have undertaken, and there is no special reason to believe that the step taken by the Minister of Public Instruction in placing the higher education of the country in the hands of his countrymen is premature. Be this as it may, it is clear that the day of Europeans in Japanese education is past, and this fact is only emphasised by the few familiar names amongst a host of unfamiliar ones in the list of the University. Moreover, even where there are one or two foreign professors, the direction is all in Japanese hands. The Director and the chief Professor in every Faculty are Japanese, so that if the individuals are fewer in number, the functions and status of each one remaining have also diminished. Time alone will show whether the experiment—for undoubtedly the Imperial University is at present in the experimental stage—will be successful or not. He would be a bold man who, for example, prophesied that the Faculty of Engineering in the new University will maintain the high position won for the old Imperial College of Engineering in the world of science by a body of brilliant European professors, some of whom are now in the front rank at home. In the Calendar there is certainly evidence of much activity. An Astronomical Observatory has been fitted up for the instruction of the students; there is also a Seismological Observatory, with horizontal pendulum and vertical-motion seismographs. By the aid of a complete set of these instruments now in the Observatory, it is possible to measure earth-movements of different grades of magnitude. In addition, a system of telegraphic communication with different parts of the city extends the area of observation. A Botanic Garden and a small Marine Biological Laboratory are likewise attached to the Science Department.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus* ♀) from West Africa, presented by Mr. Julius Wilson; a Secretary Vulture (*Serpentarius reptilivorus*) from South Africa, presented by Capt. Larmer, s.s. *Trojan*; a Crowned Hawk Eagle (*Spizaetus coronatus*) from Natal, presented by Colonel H. Bowker, F.Z.S.; a Spotted Eagle Owl (*Bubo maculosa*) from South Africa, presented by Mr. H. Justice; a Brazilian Hangnest (*Icterus jamaicai*) from Brazil, presented by Mr. W. G. Little Gilmour; two Crossbills (*Loxia curvirostris*), British, presented by Mr. W. H. St. Quintin; two White-fronted Lemurs (*Lemur albifrons*) from Madagascar, deposited; a —— Capuchin (*Cebus* ——) from South America; two Chimachima Milvagos (*Milvago chimachima*) from Brazil, purchased.

OUR ASTRONOMICAL COLUMN

THE BINARY STAR δ EQUULEI.—This close and rapid binary, which was discovered in 1852 by M. O. Struve, and measured on a number of nights between that time and 1874, was supposed by its discoverer to have a period of between 6 and 7 years or one of about 13 years. More recently, Mr. Burnham, who observed the star between 1880 and 1883, concluded from an examination of all the measures that the period was about 10·8 years. It is therefore the most rapid binary now known. At the request of Prof. Glasenapp of St. Petersburg, Herr Wrublewsky (*Astron. Nachr.* No. 2771) has computed a set of elements from all the available observations. He finds the time of periastron passage to be 1892·03, with eccentricity = 0·2011, mean distance, = 0″·406 and period = 11·478 years. These elements do not, however, represent the observed position-angles satisfactorily, and it is desirable that the possessors of sufficiently powerful telescopes should pay some attention to this very interesting object, especially at the present time, when the components are about at their maximum distance apart. Herr Wrublewsky's orbit gives, for 1887·24, position-angle = 204°·9, and distance = 0″·48.

THE TEMPLE OBSERVATORY.—From the Report of Mr. Seabroke, honorary Curator of the Temple Observatory, Rugby, we learn that during 1886 Mr. Percy Smith continued the measurement of position-angles and distances of double stars, 88 sets of measures having been secured. These stars have been divided into three categories for future re-measurement, viz. rapid binaries, to be observed every year; slower binaries, to be observed every 4 years; and long-period binaries, to be observed every 10 years. Mr. Seabroke himself has continued the measurement of the motion of stars in the line of sight with the spectroscope on the reflector, and has completed 100 sets of measures. These observations, together with the corresponding ones for previous years, have been published in the January number of the *Monthly Notices*.

DISCOVERY OF A NEW COMET, 1887*d* (BARNARD 2).—A new comet was discovered on February 15 by Mr. E. E. Barnard, Nashville, Tennessee. It was very faint, and was moving rapidly in a north-westerly direction. At midnight (local time) its position was R.A. 8h. 4m., Decl. 16° 10′ S.

PROBABLE NEW VARIABLE.—We learn from Circular No. 15 of the Liverpool Astronomical Society, that Mr. Backhouse finds 28 Andromedæ to be probably variable within small limits. The observations yet obtained are insufficient to fix the period, which must, however, be short. It is possible that the star is of the Algol type.

NAMES OF MINOR PLANETS.—Herr J. Palisa has named Minor Planet No. 256 Walpurga.

BRIGHTNESS AND MASS OF BINARY STARS.—The current number of the *Observatory* contains an article on this subject by Mr. W. H. S. Monck, in which he attempts to deduce the relative brilliancy of those binaries for which the orbits are best determined. Assuming that the mass of the companion-star is very small as compared with that of its primary, he shows that the relative brilliancy of any two pairs of binaries may be found by the following formula:—

$$\frac{k_1}{k_2} = \left(\frac{I_1}{I_2}\right) \cdot \left(\frac{P_1}{P_2}\right)^{\frac{4}{3}} \cdot \left(\frac{a_2}{a_1}\right)^2,$$

where $I_1 \, I_2$ stand for the total amount of light, as determined photometrically, which we receive from the two pairs respectively; $P_1 \, P_2$ for their periods; and $a_1 \, a_2$ for the angular radii of their orbits. By, apparently, a printer's error, the index of $\left(\frac{P_1}{P_2}\right)$ is omitted in the formula in the *Observatory*. Adopting ξ Ursæ Majoris as his unit of comparison, Mr. Monck finds the brilliancy of γ Leonis 93·29; of Castor, 38·24; δ Cygni, 35·52; of Sirius, 7·17; 42 Comæ, 2·79; 6 (*p*) Eridani, 0·20; and 61 Cygni, 0·08. It is noteworthy that Prof. E. C. Pickering, in a paper which appeared in the Proceedings of the American Academy of Arts and Sciences, vol. viii. No. 1, obtained very similar results for many of the same stars, but by a somewhat different process. In both lists γ Leonis figures at the head, followed by Castor and δ Cygni, whilst the smallest values are found for *p* Eridani and 61 Cygni. The weak point in Mr. Monck's computation is the assumption that the mass of the smaller star is comparatively insensible; the near equality in magnitude of many of the binaries selected would seem to indicate that the assumption was not a safe one. Mr. Monck repeats Prof. Pickering's suggestion that series of careful measurements should be made between each component of the binary systems and some neighbouring stars, so that the ratio of the masses of the two components may be determined. It is to be hoped that some double-star observers may be induced to take up this interesting subject, now that attention has again been called to its importance. The research might also possibly supply us in some cases with a determination of the distance of the binary.

THE LIVERPOOL ASTRONOMICAL SOCIETY.—The Pernambuco branch of this Society now numbers more than eighty members, and has been accorded permission to elect a local executive. The Emperor of Brazil has been elected a member of the Society.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *FEBRUARY* 27—*MARCH* 5

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on February 27

Sun rises, 6h. 52m.; souths, 12h. 12m. 56·0s.; sets, 17h. 34m.; decl. on meridian, 8° 21′ S.: Sidereal Time at Sunset, 4h. 3m.

Moon (at First Quarter March 3) rises, 8h. 50m.; souths, 15h. 30m.; sets, 22h. 21m.; decl. on meridian, 7° 9′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury ...	7 17	13 13	19 9	1 36 S.
Venus ...	7 34	13 31	19 28	1 23 S.
Mars ...	7 19	13 1	18 43	4 11 S.
Jupiter ...	22 48*	3 49	8 50	12 8 S.
Saturn ...	12 30	20 39	4 48*	22 25 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

Occultations of Stars by the Moon (visible at Greenwich)

March	Star	Mag.	Disap. h. m.	Reap. h. m.	Corresponding angles from vertex to right for inverted image ° °
2	Aldebaran	1	17 47	18 4	182 210

M signifies maximum; *m* minimum.

Meteor-Showers

Amongst the meteor-showers of the season are the two following:—Near δ Virginis, R.A. 192°, Decl. 1° N.; near ξ Sagittarii, R.A. 280°, Decl. 17° S. The latter radiant gives very swift streak-bearing meteors.

GEOGRAPHICAL NOTES

TWO letters have been received in Vienna from Dr. O. Lenz, dated, one from Lake Tanganyika in September, and the other from the River Shiré in December. This indicates that the Austrian Expedition has taken an unexpected route to the east coast. When Lenz and his companions left Kasonge, on the Upper Congo, on June 30, they made for Tanganyika, arriving at Capt. Hore's station on the west shore on August 7. Crossing to Ujiji, Dr. Lenz found that it was impossible to proceed northwards to the Albert Nyanza and Emin Pasha, on account of the Arab raids and the state of things in Uganda. Instead, therefore, of proceeding eastwards to Zanzibar, he travelled, by land apparently, to the south end of Lake Tanganyika, along the Stevenson road to Lake Nyassa, down that lake to the Shiré, and thence by the Zambesi to Quillimane. The two letters will be published in the next number of the *Mitteilungen* of the Vienna Society, and will doubtless contain a good deal of information of interest.

TIPPOO TIP, about whom we have heard so much recently in connection with the Emin Pasha expedition, seems to be rather an intelligent man, and even finds time in the midst of his ivory raids to attend to the interests of science. He recently came upon a remarkable tribe on the Congo, to the north of Nyangwé, who do a great deal of work in copper, and whose inlaid work in that metal is of a highly artistic character. He sent several specimens to an English friend at Zanzibar, who has brought them with him to this country. Still more interesting is the discovery by Tippoo, among the same people, of what may be regarded as the first steps towards a currency. Spears are naturally among the most valuable articles which such a people possess, and, as a matter of fact, the value of everything is reckoned by them in terms of spears. Not only so, but they have actually reached the stage of a conventional currency. Enormous spear-heads of very thin copper are made, some six feet in length, which are passed from hand to hand, just as bank-notes are with us. These spears, for example, in the purchase of ivory, are valued at £200—their intrinsic value being probably not so many pence. We are glad to know that a specimen is likely to be deposited in the British Museum. Readers of Schweinfurth's "Heart of Africa" will remember that among the Niam-Niams hoes are used for a similar purpose, only after a reverse fashion; tiny hoes, what we should call mere toys, are in common use as money.

THE principal article in the new number of *Petermann's Mitteilungen* is a summary of the journey across Africa from Mossamedes to Quillimane, by the Portuguese travellers, MM. Capello and Ivens in 1884-85. The most valuable geographical work accomplished by the travellers was the exploration of the interesting region lying between the Upper Zambesi and Lake Bangweolo. The important north-east tributary of the Zambesi, the Kabompo, was traced to its source in the closest proximity to the sources of the Lualaba, one of the most important contributories to the Congo. From here a zigzag was made eastwards and southwards, across the head-waters of many affluents of the Zambesi, until that river was reached about 16° S. and 29° E. MM. Capello and Ivens took very numerous astronomical and meteorological observations during their journey, as well as observations for terrestrial magnetism. The complete narrative of the journey, with ample supply of maps and scientific appendixes, has just been published in Portuguese. The same number of the *Mitteilungen* contains a large collection of barometric data on the hypsometry of South America, mainly Peru and Bolivia.

PROF. L. BODIO sends to the *Bollettino* of the Italian Geographical Society for December 1886 an important paper on Italian emigration, which he divides into two categories—permanent and temporary. The latter, which is essentially of a periodical character, varies from 80,000 to 100,000 persons yearly, and consists chiefly of stonemasons, bricklayers, navvies, and other day-labourers from the northern provinces of Piedmont, Lombardy, and Venice, who seek casual employment on the public works in Austria, France, Germany, Switzerland, Corsica, and elsewhere. They generally leave their homes in the spring, returning with their earnings towards the close of autumn, and enjoy the reputation of sober, steady, intelligent workmen. The permanent movement, which alone constitutes emigration properly so called, has already risen during the last twenty years from less than 20,000 to about 80,000 annually, and is directed from the same northern provinces, and from Liguria and parts of Naples, almost exclusively to the Argentine States and some other parts of the New World. The emigrants, who sail either directly from Genoa, Naples, and Palermo, or from the French ports of Marseilles, Bordeaux, and Havre, comprise between 60 and 80 per cent. of male adults, the small minority consisting of women and children. They represent nearly all social conditions, the peasant class, however, largely predominating in South America. For the year 1885 the returns show 57,827 to the Argentine Republic; 15,485 to the United States; 12,311 to Brazil; and 1477 to Uruguay. The chief inducements to leave their native land and settle abroad appear to be poverty, the desire to better their fortunes, and the direct encouragement of friends and relatives who have prospered in their new homes across the Atlantic. Very few ever return to reside permanently in the mother country.

THE Germans are losing no time in making themselves acquainted with the section of New Guinea which they have annexed. The Empress Augusta River, close to the western boundary of the German territory, was recently navigated by Admiral von Schleinitz and Dr. Schrader, in the steamer *Ottilie*, for a distance of 224 miles. It being the dry season, the river was too shallow for further navigation by the steamer. The ship's steam-launch, however, proceeded 112 miles further, to a point situated in 4° 16′ S. and 141° 50′ E.; judging from the quantity of water in the river the voyage could have been continued 50 miles further, but fuel ran short. For over 200 miles from its mouth the river flows through extensive plains; then its course suddenly changes, and it assumes the character of a mountain stream, forcing its way through hills of gneiss, mica-slate, and quartz; but the velocity of its current remains uniform. The settlements on its banks were only found at long intervals.

ON THE CONSTITUTION OF THE NITROGENOUS ORGANIC MATTER OF SOILS

THE organic matter of soils, the residue of the limited oxidation of vegetable and animal matter, has appeared a subject so complex and obscure, and promising the investigator so little of definite result, that it has received but scanty attention. The researches made have been chiefly confined to a study of the non-nitrogenous humic acids, the nitrogenous organic bodies present in soil have been scarcely at all investigated. The agricultural chemist has indeed not unfrequently spoken and written as if such investigation was superfluous, holding that the nitrogenous organic bodies contained in humus were not capable of serving as food for farm crops until they had undergone a further change into ammonia, and finally into nitric acid. A valuable paper, "Sur les principes azotés de la terre végétale," by Berthelot and André, which appeared in the *Comptes rendus* of December 6, has called attention to this neglected subject, and has done much to clear up our ideas respecting the constitution of the nitrogenous organic matter contained in soils. Like many other epoch-making treatises, the paper in question brings forward facts which have, in part, been already established by earlier investigators; but in no earlier investigation, as far as I am aware, have the facts appeared in such a striking aspect, nor have the conclusions which flow from them been clearly set forth.

Berthelot and André conclude that the nitrogenous matter of soils is mainly composed of insoluble amides;[1] these amides are decomposable by the action of acids, alkalies, and to a less extent by water, into ammonia and soluble amides (amido-acids), in the same manner as other bodies of the same class with which the chemist is already quite familiar. The behaviour of soil towards hydrochloric acid furnishes the main facts on which the French chemists base their conclusions. They find that when a soil tolerably rich in nitrogen (0·174 per cent.) is treated with dilute hydrochloric acid, a quantity of ammonia is found in the solution, which is greater as the strength of the acid is increased, as the time of its action is lengthened, and especially as the temperature is raised; two hours' boiling produces, in fact, with various strengths of acid, four, five, and six times as much ammonia as five days' action in the cold. Besides ammonia, there is found in the acid solution a considerable quantity of some nitrogenous organic body, the amount of which rises and falls with the quantity of the ammonia. In cases in which the action of the acid was carried farthest, the nitrogen of the soluble organic body bore to the nitrogen of the ammonia a proportion of about 3 to 1. The extent to which the nitrogenous matter of the soil was attacked by the hydrochloric acid was very considerable; boiling 200 grammes of soil for two hours with 400 cubic centimetres of water, and 100 cubic centimetres of strong hydrochloric acid, resulted in the solution of 31·8 per cent. of the soil nitrogen, and the conversion of 7·1 per cent. of it into ammonia. The nature of the nitrogenous organic matter found in solution in the hydrochloric acid has apparently not been particularly investigated by Berthelot and André, but the whole reaction is so characteristic of the splitting up of an amide that their view of the constitution of this body becomes highly probable.

Investigations earlier than those of Berthelot had shown that hydrochloric acid dissolves nitrogenous matter from the soil. Loges has pointed out that this solution contains a nitrogenous body precipitable by phospho-tungstic acid. The nitrogen and carbon in this precipitate had a relation of about 1 to 6·2. My own experiments show that a nitrogenous body precipitable by phospho-tungstic acid is also extracted from soil by a cold

[1] The presence of amides in soil was long ago inferred by S. W. Johnson ("How Crops Feed," p. 247), from the reactions of soil with which chemists were then acquainted.

solution of potassium carbonate. We may hope that, before long, further light will be thrown on the constitution of these bodies.

The action of alkalies on soil is quite in accordance with the assumption of the amide nature of its nitrogenous compounds. Boussingault long ago showed that the agricultural operation of liming a soil caused the production of ammonia. It has recently been shown by Baumann, and others, that a solution of soda, even in the cold, develops a notable amount of ammonia in soil, while at a high temperature the action becomes very considerable.

Nor are facts wanting which seem to exhibit the actual synthesis of amides from ammonia and humic acids. Knop long ago observed that when peat was treated with ammonia the ammonia disappeared, and could no longer be detected. Joulie found, in his experiments on the changes which take place in farmyard manure, that when finely divided straw, horse-dung, and ammoniacal urine of known composition were mixed, and allowed to ferment, a great disappearance of ammonia took place, accompanied by a gain of 35 to 63 per cent. in the organic nitrogen. The ammonia had in this case clearly united with some of the organic compounds present.

The view of the constitution of the nitrogenous matter of the soil which has been now brought forward will, we think, prove fruitful: it throws much light on the chemical changes within the soil; it has also possibly important bearings on plant-nutrition. That the acid sap contained in roots is capable of rendering soluble, and thus effecting the assimilation of various mineral matters with which they come in contact, is admitted to be a fact by physiologists. May it not equally follow that the insoluble amides of the soil are also attacked by the acid root-sap? We know not yet the properties of the soluble amides which result from the action of acids on the insoluble amides of the soil; but if they are diffusible through a membrane, they must enter the plant, and it is certainly very probable that they would then be found capable of taking part in plant-nutrition. A reaction of the kind we have supposed between the root and the soil would probably take place to a very different extent with different plants, much depending on the character of the root-sap. When the subject has been more fully investigated, it may perhaps be found that we have in this action of the roots an explanation of those obscure cases of plant-nutrition which at present puzzle the agricultural chemist.

R. WARINGTON

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The following is the speech delivered by the Public Orator, Dr. Sandys, in presenting for the honorary degree of Doctor of Science, Prof. Alexander Agassiz, Curator of the Museum of Zoology, Harvard College, Massachusetts:—

Cum Collegio Harvardiano antiquitus consociati, nuper vetera amicitiae iura auspiciis optimis renovavimus; litteris datis acceptisque trans maria lata dextras iunximus; legatis denique insignibus missis, ludis illis saecularibus, etiam absentes, velut praesentes interfuimus. Hodie vero e Collegii illius professoribus unum revera praesentem videmus, virum et suo et patris et Collegii sui nomine nobis dilectum. Donec Alpium inter culmina ingentes illae glaciei moles desuper paullatim descendunt, tam diu patris illius nomen superstes vivet, qui, in Republica non magna natus, Rempublicam maximam gloriae suae fecit participem, expertus scilicet vetera illa verba quam vera essent:—

"Omne solum forti patria est, ut piscibus aequor,
Ut volucri vacuo quicquid in orbe patet."

Filii vero famam patre tanto non indignam, quibus potissimum verbis exsequi potero? Utinam tu mihi hodie adesses:—

O testudinis aureae
Dulcem quae strepitum, Pieri, temperas;
O mutis quoque piscibus
Donatura cycni, si libeat, sonum.

Atqui Musa illa vocata non audit; rogata tacet; virumque praeconio altiore dignum sermone pedestri laudandum relinquit. Ergo, utcunque possumus, virum libenter laudamus, qui, cum ingenii sui ope aeris thesaurum ingentem invenisset, Academiam suam divitiarum suarum amplitudine ornavit, iudice me (insusurrare mihi videtur Horatius) iudice me, "non sordidus auctor naturae verique." Quid autem de vivario illo dicam, aequoris Atlantici prope marginem ulteriorem condito, ubi maris immensi miracula minutissima ab hoc viro accuratissime examinantur, ubi oceani ipsius e penetralibus profundis rerum naturae veritas ipsa audacter extorquetur? Satis erit hodie de veritate illa dicere quod olim de Romanorum virtute dictum est:—

"Merses profundo; pulchrior evenit."

Duco ad vos marinae praesertim zoologiae indagatorem indefessum, ALEXANDRUM AGASSIZ.

SCIENTIFIC SERIALS

THE *Quarterly Journal of Microscopial Science*, January.—The anatomy of the Madreporian coral Fungia, by G. C. Bourne (plates xxiii. to xxv.). During a visit to Diego Garcia (an atoll lying in 7° 13′ S. lat., 72° 23′ E. long.) which extended from the middle of September 1885 to the middle of January 1886, the author was able to collect and preserve a large number of specimens of *Fungia dentata*. These Fungiæ were very abundant within the lagoon, where at low spring tides they could be collected by scores from depths of from three to ten feet: a prolonged search failed to secure any specimens under two inches in diameter, or an example of the nurse-stock. It is suggested that the time of the year was the cause of this; the depth of the water in which the search had to be made was also unfortunate for such investigations. The name "mesoglœa," suggested by Prof. Lankester, is used to denote the supporting lamina of Cœlenterata: the only seeming objection to the name is that it is the name of a well-known genus of Algæ.—On some points in the development of *Petromyzon fluviatilis*, by Arthur E. Shipley (plates xxvi. to xxix.). The material was obtained by fertilising the eggs of the ripe female Lampern, hatching the larvæ out, and rearing them in confinement. The summary is too long for abstracting, but it may be mentioned that the early development of the skeleton is described up to the stage where Prof. Parker commenced his researches.—The ammoniacal decomposition of urine, by Dr. W. R. Smith (plate xxx.). Records a series of observations proving that the ammoniacal decomposition of urine is brought about by the presence of a Micrococcus which differs from that described by Prof. W. Leube, inasmuch as it liquefies gelatine. Though about twenty different organisms were isolated from one sample of healthy urine, only this one acted so.—Notes on Echinoderm morphology, No. 10; on the supposed presence of symbiotic Algæ in *Antedon rosacea*, by P. Herbert Carpenter (plate xxx.). Discusses the views of Vogt and Yung as to the Sacculi of Antedon being symbiotic Algæ, and considers these views as certainly not proven; an opinion which Perrier seems by intuition to have already ascribed to him.—The function of nettle-cells, by Dr. R. von Lendenfeld (plate xxx.). The plasmotic contractile coat of the cnidoblast is incited to action by the cnidocil: the animal can control this action.—Some new methods of using the aniline dyes for staining Bacteria, by E. H. Hankin. Illustrations of the structure and life-history of *Phytophthora infestans*, by Prof. H. Marshall Ward (plates xxxi. and xxxii.).—On the formation and liberation of the zoospores in the Saprolegnieæ, by Dr. Marcus M. Hartog.

THE *Journal of Botany* for January is chiefly occupied by a biographical notice of the late Dr. H. F. Hance, of Whampoa.—In the number for February, Dr. Richard Spruce describes and figures a Hepatica from Killarney new to science, to which he gives the name *Lejeunea Holtii*; Mr. Alfred Fryer continues his notes on the genus *Potamogeton*; and Mr. J. G. Baker commences a synopsis of the six genera *Sodiroa*, *Caraguata*, *Schlumbergeria*, *Guzmannia*, *Catopsis*, and *Tillandsia*, which make up the tribe Tillandsieæ of the natural order Bromeliaceæ.

Bulletin de l'Académie Royale de Belgique, December 1886.—Determination of the parallax relative to the larger member of the double star Σ 1516 of Struve, by L. de Ball. From previous observations the chief star of this group appeared to have a proper movement in a straight line independently of its companion, with which it had no physical connection. By means of a Cointe refractor the author has followed the relative displacements of the two stars, and has determined a periodicity, the effect of the relative parallax, which he finds to be

$$0''{\cdot}091 \pm 0''{\cdot}013,$$

and the distances

$$0''{\cdot}112 \pm 0''{\cdot}010.$$

From these elements he determines an absolute parallax 0″·104, with a mean error 0″·008, corresponding to a distance which light would take 31 years to traverse.—Note on the transparency of platina mirrors, by Edm. Van Aubel. His further researches confirm the author's previous conclusions regarding the false transparency of these mirrors, the light passing, not through the metal itself, but through the interstices left between the particles deposited on the plates as prepared by Paul Lohmann, of Berlin.—On the instability of equilibrium of the surface-layer of a liquid, second part, by G. Van der Mensbrugghe. The points here dealt with are: (1) the existence of a surface-tension proper to each liquid according to a given inner temperature; (2) the existence of a contractile or expansive force on the surface of a liquid in contact with a solid; (3) tension of a surface common to two liquids not intermingling.—On the valency of an atom of carbon, by Louis Henry. A method is proposed for determining the relative value of the four unities of its chemical action.—On the physiology of the heart of the dog, by Léon Fredericq. The author explains the nature of the contraction of the ventricles, the idio-muscular contraction of the cardiac muscle, the nervous system of the heart, its isolated circulation, and the circulation in the pulmonary artery.—The Neanderthal or Canstadt race in Belgium, by MM. Traipont and Lohest. The authors describe what appears to be the most important anthropological find ever made in Belgium. It consists of two more or less perfect human skeletons discovered by them in association with the remains of *Rhinoceros tichorinus*, *Elephas primigenius*, the cave hyæna, and other extinct animals in the undisturbed Lower Quaternary deposits of a limestone cave at Spy, on the banks of the Orneau, in the province of Namur. The human remains, which came to light during the summer of last year, present remarkable points of resemblance with those of the oldest yet discovered Palæolithic race, as represented by the Neanderthal and Canstadt skulls. The relationship is so close that the strikingly simian features of these skulls, hitherto regarded as possibly aberrant or pathological, would appear to be perfectly normal, and characteristic of the oldest known human inhabitants of Western and Central Europe. One of the skulls of the Spy men is decidedly platidolichocephalic (long and low), with cephalic index 70; the other is sub-platidolichocephalic, with index 74·80. The frontal bone is also very low, narrow, and retreating, and the upper alveolar process highly prognathous, while the chin is but slightly developed, receding more rapidly than that of even the lowest Papuan type.

Engler's Botanische Jahrbücher, Achter Band, 1 Heft.—The latest botanical discoveries in the tombs of Egypt, by G. Schweinfurth. This article, with an appendix dated October 1886, contains an enumeration and description of vegetable remains found in tombs at Dra-Abu'n-Negga. Though the specimens were often in bad preservation, the author has been able to recognise some fifty species of plants from tombs dating from various periods, both very ancient and comparatively modern; among others the garlic (*Allium sativum*), which, with leeks and onions, is mentioned in Numbers, chap. xi.—The next two articles by Alfredo Cogniaux and Dr. F. W. Klatt contain descriptions of the Melastomaceæ, Cucurbitaceæ, and Compositæ collected by Lehmann in Guatemala, Costa Rica, and Columbia.—On the family of the Lactoridaceæ, by A. Engler. The genus Lactoris has been placed by various authors in the Magnoliaceæ, Dilleniaceæ, and Piperaceæ (Saururaceæ). On anatomical as well as other grounds the author rejects the affinity to the Saururaceæ and Dilleniaceæ, and concludes that Lactoris is to be regarded as representing a family (Lactoridaceæ) closely allied to the Magnoliaceæ.—On Didymia, a new genus of Cyperaceæ, by Dr. R. A. Philippi (with one plate).—Contributions to the flora of the Congo district collected by Dr. Naumann on the expedition of H.M.S. *Gazelle*, prepared by A. Engler.—Then follow abstracts of papers published elsewhere.—At the conclusion of this number is a formal offer of prizes for monographs of the genera Ranunculus and Draba, and for a critical revision of the fossil forms of Quercus.

Achter Band, 2 Heft.—Dr. R. A. Philippi, on the Chilian species of Polyachyrus, a genus of Compositæ belonging exclusively to Chili and Peru. The author distinguishes the species according to the characters of the leaves, and illustrates his paper with a plate.—Hepaticæ Africanæ, by F. Stephani (one plate). This is a description of two collections of Hepaticæ: the one, made by F. A. Moller, from the Island of St. Thomas, consists of thirty-four species, of which twenty are new; the other, by W. Mönkemeyer, about the mouth of the Niger, consists of sixteen species, of which eight are new.—The Hepaticæ of the Peninsula of Alaska, prepared by F. Stephani, comprise four new species, three of which are figured on plate iii. The fourth (*Frullania chilcootiensis*) is extremely small, only a few millimetres in length, and is found hidden in the roughnesses in the bark of the birch.—Comparative anatomy of the leaf of the family Olacineæ, by E. Edelhoff. This is a laborious investigation of minute details of the anatomy of the leaf, the outcome of which is apparently no new view as to the grouping of the members of the family, but rather the recognition of microscopic diagnostic characters.—Dr. Gürich, on the botanical results of the expedition of Flegel to the Niger-Binué.—Note on a recently disclosed Pliocene flora in the neighbourhood of Frankfurt/a/M., by Dr. H. Th. Geyler.—Abstracts of papers published elsewhere.

Nuovo Giornale Botanico Italiano, January 1887.—Signor A. Piccone continues his observations on the part played by phytophagous fishes in the dissemination of Algæ. The fish which appears to be by far the most effective in this direction in *Box Salpa*, L.—Dr. F. Tassi contributes an elaborate paper on anæsthesia and poisoning in plants. Among the general conclusions at which the author has arrived, the more important are that there exists in certain plants a property analogous to that which in animals is variously denominated irritability, contractility, excitability, &c., but that this property is located in no special organ, but originates in the protoplasm. Some substances which produce anæsthetic or poisonous effects in animals are in no way injurious to plants.

Rendiconti della R. Accademia dei Lincei, December 1886.—Researches on the nature of malaria, carried out by Dr. Bernardo Schiavuzzi in Pola, Istria. The results of these experiments show the constant presence of a Bacillus, morphologically identical with that already described by Klebs and Tommasi-Crudeli, in the malarious districts of Pola, and its absence from the healthy localities. This Bacillus, artificially cultivated and inoculated on rabbits, develops fevers showing all the characteristics of swamp-fever, while in the infected animals the red corpuscles of the blood undergo the same alterations as Marchiafava and Celli have shown to be characteristic of malarious infection. These alterations, however, are attributed by Dr. Schiavuzzi, not to the presence of a parasitic animal which has never yet been detected either in the air or in the soil of the infected districts, but to a deterioration of the blood-corpuscles directly or indirectly caused by the action of a pathological ferment of quite a different nature. He accordingly concludes that the *Bacillus malariæ* described by Klebs and Tommasi-Crudeli in 1879 is the true cause of marsh-fever.—On the objective spectroscope, by L. Respighi. The author claims the honour of having first introduced and applied to stellar spectroscopy the improved form of this instrument, as now generally used by spectroscopists. Although the important modification made by him is commonly attributed to Secchi, he shows conclusively that it had been adopted and successfully employed by him fully nine months before its application by Secchi in November 1869. An account of his first experiments with the perfected instrument appeared in the Atti of the Academy for May 20, 1869. The modification in question consists in replacing the large prism of Fraunhofer's instrument by one with a small refrangent angle, by means of which may be obtained perfectly distinct and well-defined spectra of the smaller stars.

Rendiconti del Reale Istituto Lombardo, January 13.—Annual Report on the progress of the mathematical and natural sciences, presented by the Secretary, S. Ferrini. In this general survey of work done by members of the Istituto, special reference was made to E. G. Cantoni's memoir on the phenomenon of dew, showing that Aitken's observations have been confirmed by the results obtained in Italy by Fusinieri, Melloni, and Cantoni himself, in opposition to the generally admitted hypothesis of Wells; to C. Poloni's experimental researches on the permanent magnetism of steel at various temperatures, formulating the law of variations caused by changes of temperature, and on his new method for measuring the absolute thermic conductivity of metallic wires; and to Giacomo Cattaneo's studies on the formation of gastric and intestinal glands in the embryo of *Salmo salar*.

Rivista Scientifico-Industriale, January 15.—Electricity developed with the formation of fogs and clouds, by Prof. Luigi Palmieri. Some electric phenomena recently observed at the meteorological stations of Naples and Vesuvius are appealed to in confirmation of the author's view that strong electric tensions in clear skies constantly indicate the near approach of clouds fogs, and even rain. Hence the strong tensions of atmospheric electricity so frequently signalled from the New York Observatory some days before the arrival of storms and wet weather on the west coast of Europe. During thirty-six years of constant study, the author has recorded thousands of similar observations, which have been overlooked by physicists dazzled by theories opposed to the natural conditions.—Further remarks on the question whether electricity is developed during the condensation of aqueous vapour, by Prof. Costantino Rovelli. In reply to the statements of Prof. Magrini, the author points out that, although his own experiments may have their weak side, the prolonged and repeated observations of Prof. Palmieri cannot be refuted by merely negative proofs.

SOCIETIES AND ACADEMIES

London

Physical Society, February 12.—Annual General Meeting.—Prof. B. Stewart, F.R.S., President, in the chair.—In opening the proceedings the President regretted that in their Report the Council have to record the loss of one who took a prominent part in the proceedings of the Society, the late Dr. Guthrie. It was, however, satisfactory to learn that the appeal of the Guthrie Memorial Committee, under the presidency of Prof. Huxley, had been generously responded to. The Council also learn with regret from Dr. E. Atkinson that owing to pressure of work he is unable to retain the office of Treasurer to the Society, and desire to express their thanks to him for his past services. Prof. Rücker has consented to be nominated for the office thus rendered vacant, and the Council believe that by his election the connection between the Society and the Normal School of Science (which is so desirable) will be maintained.—The Report of the Council for the year 1886 was read and received, and the following gentlemen were elected Members of the Council for the present year:—President: Dr. Balfour Stewart, F.R.S.; Vice-Presidents: Dr. E. Atkinson, Prof. W. E. Ayrton, F.R.S., Shelford Bidwell, F.R.S., Prof. H. McLeod, F.R.S.; Secretaries: Prof. A. W. Reinold, F.R.S., Walter Baily; Treasurer: Prof. A. W. Rücker, F.R.S.; Demonstrator: C. V. Boys; other Members of Council: R. H. M. Bosanquet, W. H. Coffin, Conrad W. Cooke, Prof. G. Forbes, Prof. F. Fuller, Prof. J. Perry, F.R.S., W. N. Shaw, Prof. S. P. Thompson, C. M. Whipple, C. R. Alder Wright, F.R.S.—The President proposed the following resolution: "That at the end of Clause 11 of the By-laws, which says, 'Every candidate for admission into the Society shall be recommended by not less than three members, to two of whom he must be personally known,' there be added, 'When a candidate living abroad is a member of a recognised scientific Society, such membership may, subject to the approval of the Council, be held equivalent to the personal knowledge aforesaid.'" The resolution was carried, subject to confirmation by a special general meeting to be held on February 26.—A vote of thanks, proposed by Prof. Ayrton and seconded by Prof. McLeod, to the Lords of the Committee of Council on Education, for the use of the rooms and apparatus of the Normal School of Science, was passed unanimously.—The Hon. R. Abercromby proposed a vote of thanks to the officers of the past year for their gratuitous services, which was seconded by Prof. Pickering.—Sir Philip Magnus proposed a vote of thanks to the auditors, Colonel Festing and Prof. Fuller, which was seconded by Mr. Lecky, and passed unanimously.—Mr. J. Brown was elected a Member of the Society.—The following communication was then read:—Note on the tenacity of spun glass, by E. Gibson and R. E. Gregory. The authors have experimented on the tenacity of glass rods and fibres made from the same piece of glass. The fibres varied from 1/25 to 1/50 mm. and the rods from about $\frac{1}{2}$ to 1 mm. in diameter. They find the tenacity per square centimetre of rods increases as the diameter decreases, as in ordinary wires, whereas with fibres this is not shown. Experiments were shown illustrating the method of working, and the highest tenacity recorded was for a fibre of ·0340 mm. diameter, which gave 466×10^7 dynes per square centimetre, a value about half as great as that for steel wires. The authors refer to Quincke's suggestion that the increased tenacity of small wires is due to surface-tension, and may be represented by $W = Ad + Bd^2$, where W is the breaking weight and d the diameter, but their own results with glass do not agree with this formula. Sir Philip Magnus asked if the diameters were measured at the point of rupture, if the elongation was determined, and whether the authors were able to suggest any other formula which would express their results. Mr. C. V. Boys remarked that the tenacity being so much affected by accidental circumstances, such as rate of cooling, no such formula could be expected. Prof. Rücker, referring to Quincke's experiments, said that the surface-tensions of metals calculated from them appear improbable. After some further remarks by the President, Prof. Ayrton, Mr. C. V. Boys, Prof. McLeod, and Mr. Gregory, the proceedings terminated.

Royal Meteorological Society, February 16.—Mr. W. Ellis, President, in the chair.—The adjourned discussion on the Hon. R. Abercromby's paper on the identity of cloud forms all over the world, and on the general principles by which their indications must be read, was resumed; and the following papers were read:—Remarks concerning the nomenclature of clouds for ordinary use, by Prof. H. H. Hildebrandsson; and Suggestions for an international nomenclature of clouds, by by the Hon. R. Abercromby. Both Prof. Hildebrandsson and Mr. Abercromby have paid great attention to the question of the forms of clouds, and having recently conferred together, they have agreed to recommend for international use the following ten principal varieties, viz.:—High-level clouds: cirrus, cirro-stratus, cirro-cumulus; middle-level: strato-cirrus, cumulo-cirrus; and low-level: cumulus, stratus, strato-cumulus, nimbus, cumulo-nimbus.—The influence of weather on the proportion of carbonic acid in the air of plains and mountains, by Dr. W. Marcet, F.R.S., and M. A. Landriset. The authors give an account of some experiments which they have made on the proportion of carbonic acid in the air at Geneva and on the summit of the "Dole," the highest point of the Jura chain, the difference in altitude being 4193 feet. The results of these experiments show: (1) that in fine clear weather on a mountain chain of moderate Alpine altitude, and in the adjoining valley or plain, the atmosphere holds the same mean proportion of carbonic acid at both places; and (2) that when the summit of a mountain chain is in a fog, a circumstance which frequently happens in an Alpine district, the air in the fog contains a smaller proportion of carbonic acid than it would hold in fine clear weather.—The Secretary, Dr. Tripe, read a letter received from Sir F. Abel, Organising Secretary to the proposed Imperial Institute, inviting the Society to draw the attention of the Fellows to the undertaking, with the view of their contributing towards it. The President stated that copies of the letter and of the accompanying paper, explanatory of the scheme, would be forwarded to each Fellow.

Mathematical Society, February 10.—Sir James Cockle, F.R.S., President, in the chair.—The following communications were made:—On the equation of Riccati, by the President (Prof. Hart, Vice-President, taking the chair).—The orthocentroidal circle (*i.e.* the circle whose diameter is the join of the orthocentre and centroid), by R. Tucker.—On polygons inscribed in a quadric and circumscribed about two confocal quadrics, by R. A. Roberts.—On the binomial equation $x^p - 1 = 0$; quinquisection, by Prof. Tanner.—Symmetrical determinant-formulæ in elliptic functions, by L. J. Rogers.—Notes on curves, by H. M. Taylor.—Some generalisations of differential formulæ connected with the change of the independent variable in a differential expression, with application to a new class of reciprocants, by C. Leudesdorf.

Geological Society, February 9.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—Evidence of glacial action in the Carboniferous and Hawkesbury series, New South Wales, by T. W. Edgworth David.—The terraces of Rotomahana, New Zealand, by Josiah Martin.—The eruption of Mount Tarawera, by Capt. F. W. Hutton. The paper began with a description of the country in which the eruption took place. From Tongariro to White Island, in the Bay of Plenty, a distance of 130 miles, there extends a belt, 20 or 30 miles wide, abounding in solfataras, geysers, hot springs, &c., and composed of volcanic rocks, chiefly rhyolite, with some augite-andesite. About the middle of this belt lie the mountain and lake of Tarawera, and two or three miles further south Lake Rotomahana, the spot where the famous Pink and White Terraces existed. Before the recent eruption there were no craters on Mount Tarawera, the form of which was a ridge, apparently due to denudation. Having described the eruption, Capt. Hutton briefly noticed the results of the eruption in the form of fissures on Mount Tarawera, the change of Rotomahana from a lake to a crater of larger dimensions, with precipitous walls, the formation of a new lake between this crater and Tarawera, and the formation of a number of small craters about Okaro. The materials ejected were composed of augite-andesite, and rhyolites, both compact and vesicular. The mineral structure and distribution over the surrounding country of various forms of pumice, scoria, and ash were described, and it was shown that there was a difference in the substances ejected from the mountain craters of Tarawera and those from the craters in the plain at Rotomahana and Okaro, the former comprising pumice and scoria, which were not thrown out from the latter, and but little steam issuing from the higher craters when compared with the enormous volumes emitted from the lower vents. The eruption was ascribed to the reheating of old lava-streams saturated with water. This reheating was apparently not due to crushing—for, had it been so, the preceding earthquakes would have been more violent—but probably to molten rock coming up from below and heating the rocks near the surface. The eruptions from Rotomahana and Okaro were purely hydrothermal.

Chemical Society, February 3.—Dr. Hugo Müller, F.R.S., President, in the chair.—The following papers were read:—The absorption of gases by carbon, by Charles J. Baker.—An explanation of the laws which govern substitution in the case of benzenoid compounds, by Henry E. Armstrong. Certain mono-derivatives of benzene, especially those containing a hydrocarbon radicle, one of the halogens, hydroxyl or amidogen, yield a mixture of the para- and ortho-di-derivatives in proportions which vary both according to the nature of the compound dealt with and of the reagent, and the conditions under which the change is effected; and if produced at all, the meta-derivative is formed in but a small proportion. If, however, the radicle present in the mono-derivative be—

$$NO_2, COH, CO_2H, SO_3H,$$

the meta-di-derivative appears invariably to be the chief product. Hitherto no explanation of this difference in the behaviour of the two series of mono-derivatives has even been suggested. In seeking to arrive at an explanation it is necessary to form a clear conception of the manner in which "substitution" is effected. The author is of opinion that in the first instance an additive compound is formed; and he points out that Kekulé has long since insisted in the plainest terms on this interpretation of those cases of change which are commonly spoken of as "double decompositions." He is inclined to believe that the tendency of negative to attract and combine with negative elements—to which he has of late frequently directed attention—is the effective cause; and that the additive compound is formed from those mono-derivatives which obey the "para-ortho law" by the fixation of the reacting molecule upon the carbon-atom which carries the radicle; separation of water or halogen hydride ensuing thereon, the radicle of the reacting molecule assumes the place either of an ortho- or of a para-hydrogen atom. It is easy to understand the formation of the ortho-di-derivative, as the hydrogen-atom displaced is associated with a carbon-atom contiguous to that to which the reacting molecule attaches itself. The formation of the para-compound is attributed by the author to the tendency towards symmetry, so frequently evidenced in cases of isomeric change and in other ways by benzenoid compounds; and not to the existence of any direct connection between carbon-atoms relatively in the para-position. The formation of meta-derivatives is believed by the author to result from the addition of the reacting molecule, not to the carbon-atom of the benzene-ring, but *to the radicle* which in the mono-derivative is attached to one of the carbon-atoms of the ring; he is, however, of opinion that in order to explain why the additive compound thus constituted yields a meta-di-derivative, it will be necessary to obtain further information regarding the "dynamics" of such changes.—Some derivatives of tetramethylene, by G. H. Calman and Dr. W. H. Perkin, Jun.—Derivatives of pentamethylene, by Dr. W. H. Perkin, Jun.—The decomposition of potassium chlorate and perchlorate by heat, by Dr. Percy F. Frankland and John Dingwall.—The action of chlorine on methyl thiocyanate, by Dr. J. William James.

Paris

Academy of Sciences, February 14.—M. Gosselin, President, in the chair.—On waterspouts and M. Ch. Weyher's recent experiments, by M. Faye. While fully appreciating M. Weyher's novel and interesting essays, the author makes certain reservations, especially as regards the term *trombe marine* ("waterspout") applied by him to one of the results. This, he submits, was not a true waterspout, but only a rotatory movement of a volume of air without any defined limits, and with aspiration towards the axis of the ventilator. But a true waterspout is characterised by a cylindro-conical funnel sharply outlined, descending from the clouds to the ground or to the surface of the sea, without exercising on it any perceptible aspiration.—Note on MM. Paul and Prosper Henry's photograph of the nebula No. 1180 of Herschel's general catalogue, by M. Mouchez. During their photographic operations on Orion on January 27, MM. Henry obtained an image of a nebula of 3′ to 4′ diameter with stars of the 17th magnitude, invisible to the observer with the equatorial of the East Tower. This nebula, which has also since been photographed by Roberts in England, has now been identified with that discovered at the Cape by Herschel, and by him indicated with the number 1180 in his catalogue.—Reply to M. Houzeau's recent note on a method to determine the constant of aberration, by M. Lœwy. It is shown that M. Houzeau's method of determining the constant from the differences in right ascension or in declination as measured at dfferent epochs, is liable to the most serious errors. In virtue of the diurnal movement, the two images are displaced in the field of the telescope at different rates of velocity and in any direction, their relative position changes from instant to instant, and under the given conditions cannot be accurately defined.—On a sandstone of organic origin discovered in the coal-fields of the Loire basin, by MM. Favarcq and Grand'Eury. Notwithstanding their chemical composition these remarkable deposits belong evidently to fresh-water organisms, which cannot at present be further identified. They abound especially in the Rive-de-Gier and Saint-Etienne districts.—The inauguration of railways in France: its true date, by M. Léon Aucoc. It is pointed out that the proposed celebration in 1887 of the fiftieth anniversary of this event rests on an historical error. The first line actually completed was that between Saint-Etienne and Andrezieux, 23 kilometres long, opened on October 1, 1828; that is, nine years before the assumed date 1837.—Remarks on the palæontological researches made in the Lower Tertiary deposits in the neighbourhood of Rheims, by M. V. Lemoine. The author gives the general results of his investigations carried on uninterruptedly for the last fifteen years, and constituting the Rheims district one of the points where the beginning of Tertiary life may be best studied in Europe. The fossil vertebrates alone studied by him now number 94, of which not more than 8 or 10 were previously known. Amongst them are 40 mammals belonging to 23 different genera, of which 8 only had hitherto been observed in later Tertiary beds.—On the mode of formation of the striated Bilobites, by M. Ed. Bureau. The author has obtained plaster casts of most of these Bilobites, from a careful study of which he concludes that they must represent imprints of animals on the sands of shallow Silurian waters.—Combined action of belladonna and opium in a case of acute diabetes, by M. Villemin. After the usual remedies had failed, this treatment was lately tried in an extreme case of diabetes at the Val-de-Grâce Hospital, with complete success.—Determination of the position of the shaft corresponding to a given position of the piston in a steam-engine, by M. H. Léauté. Two remarkably simple graphic constructions designed in 1869 by M. Marcel Deprez are described, by means of which the position of the shaft for each position of the piston may be determined with sufficient accuracy, when the length-ratio of connecting-rod and shaft is greater than 3.—On the application of photography to M. Lœwy's new methods of determining the elements of refraction and aberration, by M. Ch. Trépied. An inquiry is here made into the conditions and means by which M. Lœwy's new and effective method of photographic registration might be utilised in determining the elements of astronomic refraction.—Observations of Barnard's and Brooks's comets made with the 0·38 m. equatorial, Bordeaux Observatory, by MM. G. Rayet and Courty.—On surfaces where the difference of the chief radii of curvature is constant at each point, by M. R. Lipschitz.—On a certain class of recurrent sequences, by M. Maurice d'Ocagne.—On the specific heats of liquids, by M. Marcellin Langlois. By the process here described the author determines the specific heats of water, sulphuret of carbon, chloroform, chloride of carbon, ether, alcohol, and acetone.—Researches on the specific inducting power of liquids, by M. Negreano. The author determines the dielectric constants of a series of homologous and liquid carburets of hydrogen for the purpose of comparing the dielectric constants with the molecular weights and densities. He also determines the index of refraction of these different liquids with a view to the verification of Maxwell's law.—On the variable period of the current in an electro-magnetic system, by M. R. Arnoux.—Physical researches on the isomery of position, by M. Alb. Colson. Having succeeded in transforming orthoxylene and metaxylene into alcohols, glycols, ethers, &c., isomerous with the known compounds of paraxylene, the author here inquires whether bodies so closely related in their chemical properties may not also be connected by some physical relations. The best results have been obtained by the calorimetric process.—Action of the oxide of mercury on some dissolved chlorides, by M. G. André. In this preliminary paper the author deals with the chlorides of barium, calcium, strontium, and magnesium.—On the action of hydrochloric acid on the solubility of the chlorides, by M. R. Engel. His further studies enable the author to generalise the law already announced by him in the *Comptes rendus* for March 1886.—A new process of analysing the carbonic acid emitted, and the oxygen inhaled, in the act of breathing, by MM. M. Hanriot and Ch. Richet. The differential method here described as applicable, with some modifications, to the analysis of various gaseous mixtures, constitutes a simple and rigorous method for the quantitative analysis of those of respiration.—The formic salts, by MM. Gréhant and Quinquaud. The authors here discuss the question as to what becomes of the formic salts introduced into the system, and find that the formiate of soda injected into the digestive organs or into the blood mostly passes unchanged into the urine.—On the properties of colchicine, by MM. A. Mairet and Combemale. Their experiments on dogs and cats satisfy the authors that this substance is an irritant poison which attacks all the organs, but especially the digestive tube and the region of the kidneys.—On the effects of the transfusion of blood into the head of decapitated animals and men, by M. J. V. Laborde. The author refers to his numerous experiments on this subject, which were overlooked in the paper recently presented to the Academy by MM. Hayem and Barrier.—On the comparative morphology of the brain in insects and crustaceans, by M. H. Viallanes.—The males of *Lecanium hesperiaum* and the question of parthenogenesis, by M. R. Moniez.—On the zoological researches carried out during the second scientific expedition of the *Hirondelle*, in 1886, by Prince Albert of Monaco.

BERLIN

Physical Society, January 7.—Prof. von Helmholtz in the chair.—Dr. R. von Helmholtz developed theoretically the formulæ expressing the relations subsisting between vapour-pressure, the melting-point, pressure, and volume, and enabling the vapour-pressures in the fluid and solid state, or the freezing-points and the change of the melting-point with that of the pressure, to be calculated.—Dr. Thiesen, while engaged in working experiments instituted by Schellbach respecting the resistance of air, had found an expression for the force of resistance in accordance with which a medium with less interior friction must necessarily offer a greater resistance than did a medium with more friction. This induced him to carry out experiments of his own with cylindrical rods regarding the resistance of air. On a hardened steel point a brass cylinder open at the bottom and bearing at its lower end externally two conjoined pieces, into which the steel rods 1 metre long and 1 English inch thick could be inserted horizontally and diametrically opposite to one another, was able to rotate. By means of a cord circulation, the cylinder was set rotating, and the abatement of speed consequent on the resistance of the air was noted by each half-revolution being marked electrically. These experiments yielded the same formula for the resistance as had been obtained from the earlier experiments. Another important result was that the method employed for the measurement of the resistance of air had maintained its validity remarkably well. In the discussion following this address, Prof. von Helmholtz took part. He called attention to the formation of whirling surfaces and whirls on the rotating bodies, a matter which in a high degree complicated the phenomenon.—Dr. Thiesen made a further communication respecting the determination of the national standard kilogramme. The cylinders of platinum-iridium, weighing rather more than 1 kilogramme, which were cast in London, were tested in respect of their density, and so often as fissures were detected they were re-cast. They were thereafter polished and again tested. Forty-two such standards were next compared with one another, and their uniformity and non-liability to be affected by transport having been ascertained, they had then to be compared with the kilogramme of the Archives, and after examination by the International Commission were despatched to the different Governments.

BOOKS AND PAMPHLETS RECEIVED

Histoire des Sciences Mathématiques et Physiques, vol. x.: M. Marie (Gauthier-Villars, Paris).—Proceedings of the Linnean Society of New South Wales, 2nd series, vol. i. part 3 (Cunninghame, Sydney).—Nomenclature of Color for Naturalists: R. Ridgway (Little, Brown, and Co.).—Bulletin of the Philosophical Society of Washington, vol. ix. (Washington).—Hourly Readings, 1884, part 2, April to June (Eyre and Spottiswoode).—The Origin of the Fittest: E. D. Cope (Macmillan).—Geographical and Geological Distribution of Animals: A. Heilprin (K. Paul).—Hints for the Solution of Problems of Solid Geometry: P. Frost (Macmillan).—Levelling and its General Application: T. Holloway (Spon).—Observations Météorologiques de Godthaab: A. F. W. Paulsen (Gad, Copenhague).—*Challenger* Expedition Reports—Zoology, vol. xvii.; Botany, vol. ii.—Philosophische Studien, Vierter Band, 1 Heft (Engelmann, Leipzig).—Encyklopædie der Naturwissenschaften, Erste Abth., 50 Lief.; Zweite Abth., 39, 40, 41 Lief. ENDOWMENT OF MEDICAL RESEARCH

OUR readers will probably have seen that a memorial, signed by some of the most able and trusted leaders in science and in medicine, has been presented to the Council of the Royal College of Surgeons, asking it to consider the propriety of establishing a new institution for the prosecution of such branches of science as are most closely connected with the objects of the College. There is no doubt that the memorial will be carefully and maturely considered in a spirit worthy of the eminent men who guide the policy of the College, but it seems fitting that in these columns the excellence of the suggestion should be acknowledged, whatever may be found to be the best method of meeting it.

In the first place, all who care for English biology and English surgery can heartily rejoice that the College which has done so much for both is now in a position not only of dignity but of affluence. Just before the foundation of the present College, the Company of Surgeons which preceded it was almost bankrupt, and, by want of observing a legal formality, well nigh forfeited its charter. But for fifty years past the College has grown in honour and in wealth. Its Membership stands deservedly first among the surgical diplomas which admit to practice. Its Fellowship involves higher training and more thorough examination than most University degrees. It possesses the second Medical Library in the kingdom, and the most complete, extensive, and well-arranged Museum of Anatomy—human, comparative, and pathological—which exists in the world. The original Hunterian Collection which was purchased by the nation after the death of the great anatomist, was intrusted to the care of the College of Surgeons on condition of providing a suitable building and a competent Curator. The trust has been nobly dealt with. The museum left by Hunter, still cherished with reverence and still remarkable in varied aspects, has been many times multiplied by successive additions. Buildings of great size and admirable design have again and again been added. Curators have been appointed who have made their names familiar through Europe—Clift, Quekett, Owen, and Flower. And Hunterian Professors and Lecturers have been appointed who have made the Museum as well known as that of the Jardin des Plantes—Sir Everard Home and Sir Richard Owen, Huxley, Flower, and Parker, among anatomists; and, among surgeons, Abernethy, Cline, Astley Cooper, Laurence, Hilton, Fergusson, and Paget. Far from reserving its theatre for the veterans only, the College has shown a laudable liberality in founding Junior Lectureships; and now some of the most industrious, thoughtful, and brilliant of the younger generation of anatomists and pathologists are describing their new investigations from the Chair of the Hunterian Museum.

Now, however, there seems to be a probability of the College making another and an enduring addition to the benefits which it has conferred on science.

A large bequest has enabled them seriously to consider the foundation of such an institution as is suggested in the memorial above mentioned. With some the impulse to save is stronger than the impulse to spend; and even if it is determined to spend the Wilson bequest, part at least might be safely applied to further extension and improvement of the Museum, fresh buildings, and an increased staff of officials. Still we hope that it may be found possible to meet such current needs by current income, and that the large sum placed at the free disposal of the College will be devoted to some new, useful, and appropriate scientific purpose.

The appropriate purpose is not far to seek. A museum is necessary for the study of anatomy, the one half of the science of living creatures; but for the prosecution of the other half, for the study of physiology, a laboratory is needful, where the physical, chemical, and vital phenomena of man and animals can be observed. Hunter himself was never content with the mere demonstration of a fact in living structures, normal or diseased. His acute and fertile intellect at once inquired: How came it about? What is its use? Of what process is it the evidence? How can that process be either checked or fostered for the relief of suffering and preservation of life?

The progress of knowledge since Hunter's day has vastly increased our power of dealing with these questions: many have been already more or less perfectly answered; more are ripe for solution to anyone who can give time and pains to the work; and most lie still untouched, a rich and virgin field ready to reward the man of thought as well as skill. But the methods of research have become more and more elaborate. The easy things have been done; or rather what was once hard has now become easy, and what once was impossible is now practicable, with greater expenditure of time and money. The change is only what has taken place in navigation, in war, and in engineering. Few scientific investigations can now be carried on except in properly equipped laboratories.

There are many departments in which work is urgently needed, and in which our own country is discreditably behindhand. In Germany and France and America, even in smaller countries like Holland and Sweden, adequate, or something like adequate, provision is made for the investigations of which we speak. Edinburgh has made great strides of late years, and there the University laboratories of physiology and pharmacology are worthy of the place. Cambridge has, since Prof. Foster was called to the University, been known through Europe for the first time as a great school of physiology. Oxford has lately built and furnished a laboratory for Prof. Sanderson. But London is still far behind the three chief Universities of the kingdom, and behind Paris and Lyons, Strassburg, Berlin, Leipzig, Bonn, and a host of petty towns in Germany.

It is true that before he was carried away to Oxford Dr. Burdon Sanderson had established a laboratory at University College which is a credit to London, and where work of the best kind has been and is being done. At King's College, though the accommodation is not what it should be, Prof. Gerald Yeo and his assistants put forth no less excellent results. In two at least of the great medical schools physiological laboratories have long existed, and have contributed to the progress of knowledge, as well as to instruction. Lastly, the titular University of London has, owing to the exertions of two or three of its medical graduates on the Senate, founded an institute for the study of comparative pathology which, under Sanderson, Klein, Greenfield, Roy, and Horsley, has accomplished results of great benefit both to domestic animals and to man.

If, however, physiology and pathology are to some extent provided with means for research, others of the sciences allied to medicine and surgery are absolutely destitute. Physiological chemistry has scarcely existed in England since the days of Prout, and at the present day there is not a single laboratory where this difficult and important branch of knowledge is pursued. When Dr. Gamgee's excellent text-book is completed, the Index Auctorum will scarcely contain an English name.

Pharmacology—the experimental investigation into the action of drugs—is another foreign science. Fraser and Brunton have done much to redeem this country from absolute sterility, but in London there ought to be a laboratory like that of Prof. Schmiedeberg for this most obviously and practically useful of all medical sciences.

A laboratory for the study of Physiology would be the most closely connected with the memory of Hunter, with the Museum, and with the traditions of the College. A laboratory of physiological, pathological, or therapeutical chemistry would perhaps fill the most absolutely vacant space. A laboratory devoted to the direct study of the nature, origin, and propagation of Diseases, to their prevention, and to surgical methods of treatment would be the most directly useful and probably the most immediately fruitful.

So much is needful before England can begin to contribute her fair share to the common sum of knowledge, that it is scarcely possible to go far wrong in deciding what branch of medical science should first be taken up.

The Royal College of Surgeons has a great opportunity, and one that is not likely to return. If the great accession to its resources should be frittered away on a multitude of objects, the opportunity will be missed, and probably for ever. But we cannot doubt that the leading scientific surgeons in the kingdom will decide on using the Wilson bequest for the endowment of some new and urgently needed institution for research, which will be an honour to the College, a credit to the nation, and an instrument for increasing knowledge and diminishing suffering for centuries to come.

THE ELECTRIC MOTOR

The Electric Motor and its Applications. By T. C. Martin and Jos. Wetzler. (New York: Johnson, 1887.)

CONSIDERING the very rapid strides that have been made during the past six years in the industrial application of electric motors, the appearance of this handsome volume, giving the latest information on this topic, is thoroughly timely. It constitutes, though somewhat popular in style, a welcome addition to the library of the electrical engineer. Those who are accustomed only to the slow and steady development of industries in the Old World can hardly appreciate the revolution that is setting in in consequence of the employment, especially in small workshops and factories, of electric motors in place of steam-engines or gas-engines. They win their way because, though the actual cost of power is no cheaper, the expense of the electric motor is less than that of the steam-engine or gas-engine. It is less troublesome to keep in order, takes less room, runs at a more uniform speed, and is more cleanly. What wonder, then, that thousands—literally—of electric motors are already in use in New England, where an invention is welcomed, not sneered at, because it is new.

Much of the volume before us has already seen the light in another form in the pages of our American contemporary, the *Electrical World*, but the matter has been very carefully edited and arranged. It is by no means a scissors-and-paste affair; but a well-considered treatise, abundantly illustrated with drawings of motors and of their various applications. It treats the subject both historically and systematically.

The first chapter is devoted to an exposition of the elementary principles of electric motors. Almost at once we are plunged into the essence of the matter, the development in the armature of the motor of the counter-electromotive force, that *crux* of the untrained electrician. In this connection Jacobi's law, that the electric motor does its greatest possible work when it diminishes the original current to one-half, is given, and correctly given, not as a law of maximum efficiency, for which it has been so often mistaken, but as a law of maximum activity. But the authors have missed the point that Jacobi's law even in this sense is only true when the condition of supply of the electric energy is that of a given constant electromotive force. Jacobi's law would obviously not apply to motors placed in a circuit in which the given condition of supply was that of a constant current. The chapter concludes with some very apposite remarks on the general principles of construction of electric motors, quoted from a paper in the *Philosophical Magazine* by an English electrician, Mr. W. Mordey.

Chapter II. is devoted to early motors and experiments in Europe, from Barlow's wheel and the primitive engines of Jacobi and Froment down to the famous Pacinotti machine. The complement to this narrative is found in Chapter III., which deals with the early motors and experiments in America, beginning with Davenport in 1837. The most celebrated of these was that of Prof. C. G. Page, who succeeded in constructing a motor of 10 horse-power. The authors incidentally mention that, in the period of the Civil War, between 1860 and 1867 not a single patent on electric motors was issued in America.

Chapter IV. deals with the electric transmission of power, as developed successively by Pacinotti, Fontaine, and Marcel Deprez. In this connection the theory of the efficiency of electric transmission is explained by the use of graphic diagrams in which the areas are proportional to the energy transmitted or to the work performed. The experiments of Marcel Deprez are mildly criticised, and rules for calculating the cost are given.

The modern electric railway and tramway in Europe occupy Chapter V. Here several of Siemens's tramways are described, also those at the Giant's Causeway, at Brighton, and at Blackpool. Chapter VI. gives a similar account of the modern electric railway and street-car line in America. From this account it appears that Mr. Stephen D. Field is in America awarded the sole right to use "the combination of an electric motor operated by means of a current from a stationary source of electricity conducted through the rails," which "combination" he patented in 1880. Drawings of the electric locomotives of Field, Edison, Daft, and others, are given. Several electric railroads of some magnitude are at work in the States. Chapter VII. resumes the subject of street railways in which storage batteries are employed for driving the electric motors. The work done in this country by Mr. Reckenzaun receives due recognition, and Mr. Elieson's tramway engine is also described. The industrial application of electric motors in Europe and in America occupies the next two chapters, the special form of motors devised by Profs. Ayrton and Perry being noticed in the one and those of Griscom and Daft in the other. Electrically-propelled boats and balloons are treated by themselves; so also is the subject of telpherage. This subject—the transmission of freight along a wire road by electricity—originated with the late Prof. Fleeming Jenkin, and it has found imitators in America. The twelfth and last chapter is devoted to the latest American motors and motor systems, the motors of Brush, Sprague, Van de Poele, and others, being here described at length.

And here we must pause to point out the one blot on this otherwise excellent work: namely, that the entire theory of the self-regulating motor, which was discovered and worked out in 1882 by Profs. Ayrton and Perry, and which forms the basis of their epoch-making paper read in 1883 before the Society of Telegraph-Engineers, is appropriated *en bloc*, and accredited to Lieut. Sprague. From p. 160 it appears that Sprague's method of securing self-regulation is to use a differential compound winding; but this is exactly Ayrton and Perry's method. Even the equation on p. 161, which is given as the Sprague law of winding, is identical with the equation given on p. 367 of the present writer's book (edition of 1884) on dynamo-electric machinery in the section on the theory of the differential compound winding. Another matter credited to Mr. Sprague by the authors is the discovery of a motor which, when supplied at constant potential, runs faster when the strength of the magnetic field is diminished. But this is no new principle: it is an inherent law of nature, common to all motors old and new, being the simple converse to the equally fundamental fact that a dynamo, if it is to generate a constant electromotive force, must be run faster in a weak field, and may be run slower if the field is strengthened. Lieut. Sprague has done good work in producing motors of excellent design and having points of original merit: this we may freely acknowledge without ascribing to him what was known before his work was begun. The authors will do well to correct these slips in the second edition, which will probably soon be demanded. The book is creditable alike to authors and publisher.

SILVANUS P. THOMPSON

THE FLORA OF LEICESTERSHIRE

The Flora of Leicestershire, including the Cryptogams. With Maps of the County. Issued by the Leicester Literary and Philosophical Society. 372 Pages and 2 Maps. (London and Edinburgh: Williams and Norgate, 1886.)

THE county of Leicestershire covers an area of 800 square miles of the centre of England, at the summit of drainage between three of the great streams, the Trent, the Severn, and the Midland Ouse. Almost the whole of the county is at least 100 feet above sea-level. A large portion of the surface is between 300 and 500 feet, and Charnwood Forest rises at its highest point to 900 feet, so that Leicestershire is very different from such low-lying level Midland counties as Cambridgeshire, Bedfordshire, and Huntingdonshire. Half the area of the county is in grass, about one-quarter is under arable cultivation, and there are 20 square miles of woodlands. In Charnwood Forest there are slate and granite, and the sedimentary rocks are represented in the county from the middle of the Palæozoic to the middle of the Mesozoic series—Carboniferous Limestone, Coal-measures (Permian missed out), Trias, Lias, and Lower Oolite—so that there is every variety of soil.

Competent botanists have resided in the county for the last three generations. The fathers of Leicestershire botany are Dr. R. Pulteney, F.R.S., who was a surgeon at Leicester, and the author of "A General View of the Writings of Linnæus" (1781), and the well-known "Historical Sketches of the Progress of Botany in England up to the date of the general adoption of the Linnæan System" (1790); and the poet Crabbe, who lived at Belvoir from 1782 to 1813, when he removed to Wiltshire. Between 1820 and 1850 Leicestershire was the home of three clergymen, all of whom were enthusiastic botanists. The Rev. Andrew Bloxam lived at Twycross for more than forty years. He is best known as one of the special investigators of the British brambles, and partly, perhaps, because he worked them so thoroughly there is a general idea that Leicestershire is the richest county in England in forms of this complicated genus. He was one of the last survivors who kept up the old tradition of botany as it was in the days of Smith, Hooker, Turner, Dillwyn, and Forster, when a collector swept through the whole vegetable kingdom, from the flowering plants down to the fungi. The Rev. W. H. Coleman was a most energetic and capable botanist. He was for many years one of the masters of the Ashby-de-la-Zouch Grammar School, and it was he who laid the basis of the present work, dividing the county into a dozen districts, and tracing out the distribution of the plants through them as fully as he had opportunity. He died in 1864, and in 1875 his manuscript was handed over by his friend Mr. Edwin Brown, of Burton-on-Trent, to the Leicester Literary and Philosophical Society, which appointed a Committee to amplify and revise it. Of this Committee Mr. Mott, of Leicester, has acted as Chairman, and Mr. Carter, Dr. Finch, and Messrs. E. and C. Cooper are the other members. The other clergyman who worked in conjunction with Messrs. Bloxam and Coleman was the Rev. Churchill Babington, for many years the Disney Professor of Archæology at Cambridge, and now Rector of Cockfield, in Suffolk. In 1850 Miss Mary Kirby (now Mrs. Gregg) published a small flora of the county, which contained a substantially complete list of the flowering plants and ferns of Leicestershire, but no attempt was made to trace out their distribution in detail.

In the present work the number of flowering plants and ferns, native and naturalised, in Britain is estimated at 1546, and of these, 825 are admitted for Leicestershire. This number of 1546 is reached only by counting the subspecies of such variable types as *Ranunculus aquatilis* and

Rubus fruticosus, and by including a large number of plants that have no claim to be considered as really wild, such as *Linaria Cymbalaria*, *Corydalis lutea*, and the wall-flower. Mr. Watson's estimate was 1425, and, as compared with this, the flora of Leicestershire will stand at a little over 700. He worked out carefully in detail the distribution over the island of all these species, and showed that they fall into, broadly speaking, three geographical or climatic groups: that 532 species are spread generally over the whole island; that 606 species represent southern climatic and geographical influences; and that 238 species represent the boreal element in our flora, and are plants that are thoroughly at home only in the north of Scotland, and are found in England and Wales only in mountainous tracts. In any county, or other tract of land, the great mass of the flora always consists of the 532 generally-diffused plants, and the climatic difference between one county and another is shown by the extent to which the characteristically northern and southern types are represented. It adds very much to the interest which any book on local botany has for the non-resident general reader, if the writers keep these three climatic groups distinct in their minds, and give as complete an idea as possible of the way in which, and the extent to which, the austral and boreal types are represented in the area of which they treat. The writers of the present "Flora" have not attempted to give any general summary worked out upon this basis, and they are quite mistaken in supposing that their county includes three out of Watson's six climatic zones. Watson's infer-agrarian zone includes the low-level country south of the Humber and the Dee. Its characteristic types are such plants as *Clematis Vitalba*, *Rubia peregrina*, *Geranium rotundifolium*, *Trifolium subterraneum*, *T. suffocatum*, *Lathyrus Nissolia* and *L. Aphaca*, and *Centaurea Calcitrapa*. Watson's mid-agrarian zone includes the low levels of the north of England, up to a height of 900 feet above sea-level on the mountains of Yorkshire and the Lake District. Its upper limit is marked by the cessation (essential from climatic causes, not accidental) of fruticose Rubi, *Rosa arvensis*, *Pyrus Malus*, *Viburnum Opulus*, and *Alnus glutinosa*. Above this, up to the line of possible arable cultivation, extends the super-agrarian zone, with an average annual temperature of 42° to 45° F. The only county south of the Humber and Trent in which it is represented is Derbyshire. There do not appear to be in Leicestershire more than ten or a dozen out of the 238 boreal plants, such as *Lycopodium Selago*, *Empetrum nigrum*, and *Drosera anglica*, and these are either very rare or quite extinct. There is no saxifrage except *granulata* or *tridactylites*, no wild bird-cherry, no *Andreæa*, no *Polypodium Phegopteris* or *Dryopteris*. To understand their county and its flora in their proper relation to the rest of England, Mr. Mott and his colleagues must revise completely their ideas on this subject. The county would appear to be essentially a mid-agrarian outpost, pushed out from the Pennine Chain into the centre of England; for, out of the 600 austral types, not more than about 150 enter into it, which is fewer than there are either in North Yorkshire or at the Lakes. The limestone types, the occurrence of which is regulated more by soil than climate, appear to be well represented.

For the way in which the details of the flora are worked out, we have nothing to give but commendation. In the identification of the Phanerogamia, great pains has evidently been taken by the Committee. No doubt some of the species, which they admit on the authority of their predecessors, will prove to be blunders, as, for instance, *Tofieldia palustris*, *Carduus heterophyllus*, and *Asplenium viride*. When the members of the county society make their excursions into the different districts, they will be able to see at a glance what plants have been gathered there by their predecessors. The flora includes, not only the Phanerogamia and ferns, but also the mosses, Hepaticæ, lichens, Algæ, and fungi. It is not likely that there are many fresh Phanerogamia or ferns still to find; but as only 4 Characeæ, 179 mosses, 49 Hepaticæ, 177 lichens, and 446 fungi are known, there is ample scope for further work in all these orders. The portion of the book devoted to Algæ, which is ably edited by Mr. F. Bates, of Leicester, contains descriptive notes on many of the less known species. There is an interesting note on p. 344, on the species which have become extinct. They are 30 in number, and are nearly all plants of swamps and heaths, amongst them being *Lycopodium Selago*, *Osmunda regalis*, *Pinguicula vulgaris*, *Drosera anglica*, and *D. rotundifolia*.

The book will be still more interesting when we have good floras of Warwickshire, Nottinghamshire, Derbyshire, and Cheshire to compare it with, and for all these counties "Floras" are in course of preparation.

J. G. BAKER

GEOLOGY OF JERSEY

Géologie de Jersey. Par Le P. Ch. Noury, S.J. (Paris: F. Savy; Jersey: Le Feuvre, 1886.)

CONSIDERING that Jersey became subject to the Crown of England at the time of the Norman Conquest, English geologists may agree with M. de Lapparent's complaint as to the neglect the island has hitherto received. Although the Geological Society of London made it their earliest care to publish in 1811 (not 1817, as quoted in the opening of this little volume) MacCulloch's paper on the Channel Isles, although at the present time more than one worker is engaged in further removing the reproach, M. Noury is even now well to the front in providing in a handy form an account of the structure of Jersey serviceable to inhabitants and visitors alike. The character of this well-printed *brochure* presupposes, however, some general knowledge of geology, and the author is perhaps not so uniformly happy as, let us say, the Rev. W. S. Symonds in placing his facts before the intelligence of the untrained tourist. Some controverted matters, moreover, of purely speculative value are introduced, such as the construction of the primitive crust (p. 126), the succession in time of granite, syenite, and diorite, and the formation from these of schists and gneisses by disintegration in a heated ocean. The description of the prevailing rocks is the work of a close observer in the field; and the careful mention of such materials as have been artificially introduced ("cultivated rocks," one might almost call them) cannot be too highly praised. Future geologists will thus be spared the description of gneissic fragments (p. 6) imported as ballast from Brazil.

The suggested derivation of "pyromeride" (p. 29)—

"*partagée dans le feu*"—is not historic, Haüy's and Monteiro's name referring to the different fusibilities of the two constituents of the spheroids. We doubt also the primary origin assigned to the chalcedony with which the hollows of these old rhyolites are so often filled. Here, as is so frequently the case among Continental writers, the immense importance of secondary changes appears to be overlooked. In one of these lavas M. Noury has found a spherulite measuring 18 inches in diameter. The "sphérolithes," however, of certain diabase veins (p. 41) would appear to correspond to the spheroidal structure of weathered basalt rather than to the contemporaneous volcanic bombs suggested by the author.

The account of the connection between open fissures and the decomposition of dykes, and of the origin of the numerous bays, as well as of the larger inland features, is full of interest to the visitor. In the review of the history of the island the discussion of recent elevation and depression is too lengthy to allow of justice being done to the evidence relied on for the ages assigned to the various types of rock—evidence derived solely from comparison with the mainland of France. The scanty preservation, moreover, of Secondary deposits in the Hebrides makes one cautious in accepting the conclusion (p. 139) that Jersey has remained above water since Permian times. M. de Lapparent has, indeed, recently stated that the final conglomerate may be of Triassic age.

The book is written in the lucid and attractive style that French men of science have taught us to expect. A coloured geological map forms a handsome and valuable addition. G. C.

OUR BOOK SHELF

General Biology. By William T. Sedgwick, Ph.D., and Edmund B. Wilson, Ph.D. Part I. Introductory. (New York: Henry Holt and Co., 1886.)

THIS work has been planned by the authors as an "introductory study" to biological science, after digesting which the learner may proceed to Huxley and Martin's "Practical Biology," Brooks's "Hand-book of Invertebrate Zoology," or to a second part of the present book, which is promised to be ready some time this year.

In the first four chapters of the introductory portion, Messrs. Sedgwick and Wilson deal with the generalities of biology—that is, with the nature and properties of protoplasm and the origin and modification of cellular tissues. In the remaining chapters they discuss at full length the two types selected to illustrate the two principal modifications of life. These are, the common brake (*Pteris*) and the earthworm (*Lumbricus*). The embryology and physiology of the selected types are as fully dealt with as the pure morphology. At the end of each chapter a scheme of practical work is given, which may in some cases be of much value.

On p. 123 it is stated that "all the organs of the body are originally developed from the walls of these chambers"—that is, the chambers of the body-cavity formed by the dissepiments. But it is a well-known fact that, as has been previously stated by the authors themselves (p. 152), the nerve-cords and ganglia are developed from the epiblast, or, as Messrs. Sedgwick and Wilson prefer to call it, the "ectoblast." Such being the case, it is obvious that the nerve-cords are not developed from the mesoblastic chambers.

Another and more serious error will be found on p. 143, where the *vesiculæ seminales* of the earthworm are described as the *testes*. It has been conclusively shown by Bloomfield that the large white bodies which fill up the tenth and eleventh somites of *Lumbricus* are really the *vesiculæ seminales*. The true *testes* are very small bodies, only present at certain periods of the year. There are two pairs of them, in the eleventh and twelfth somites. The *spermatozoa* are not fully matured in the *testes*, but pass into the *vesiculæ seminales* to complete their development.

Notwithstanding these few errors, Messrs. Sedgwick and Wilson's introductory essay is well adapted for the use of junior students in biology. Moreover, it is adequately illustrated by well-drawn woodcuts, far exceeding in clearness of execution the average of those found in American text-books.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Industrial Studentships

I AM directed to request that you will be so good as to allow me, through the medium of your columns, to inform manufacturers and others engaged in industries in which art is more or less concerned, that the Lords of the Committee of Council on Education have decided to make arrangements for the admission of a limited number of persons employed in those industries to study in the South Kensington Museum, Library, and Schools, without the payment of any fees, for periods of from two to nine months according to circumstances.

Detailed rules with regard to these working studentships will be sent on application to the Department. Briefly, the conditions may be stated to be that the designer or workman for whom admission is sought shall show that he has sufficient power of drawing and sketching to be able to profit by the opportunities afforded; that he is actually engaged in some art industry; and that the proprietors of the works in which he is engaged undertake to maintain him while he is studying at South Kensington. When admitted, the working student will be set, under direction, to study in the Museum and Art Library from examples relating to the industry in which he is employed, and he will also receive instruction in drawing and designing in the Art School, suited as far as may be to his special case.

My Lords have taken this step with a view to render the Museum of more speci l and direct use to the country, and they trust that the valuable collection of examples of applied art which has now been brought together may thus be more fully appreciated and taken advantage of by the directors of industry in the country. J. F. D. DONNELLY

Science and Art Department, February 28

Top-shaped Hailstones

IN connection with the abnormal fall of rain which is taking place this cold weather in the North-West Provinces of India, and which has clothed the outer ranges of the Himalaya with snow down to the 5000-feet level, I should like to mention a fall of hailstones which occurred on January 21 near Ramnagar, in the Terai. The hailstones were not very remarkable for size, being generally one-third of an inch across, with here and there a larger one half an inch in diameter. Some peculiarities of shape and structure, however, arrested my attention. Nearly every one that was not deformed by collision was top- or pear-shaped. Owing to their rebounding from the ground, it was impossible to see whether the broad or pointed end fell foremost; but in every case the broad end was composed of perfectly hyaline, amorphous ice, whilst the pointed end was banded crosswise by alternate layers of clear and white ice. In every case this distinction was perfectly well marked.

In some few instances I found hailstones of another, but probably derived form. Instead of being circular in section at right angles to the long axis, they were triangular, so that they bore a strong resemblance to the kernels of a beech-nut. The

broad end in this case also was perfectly transparent, and the sharper end banded as before.

I append three diagrams representing typical forms.

Ramnagar, Terai, January 25 C. S. MIDDLEMISS

Snowflakes

IN your issue of January 20 (p. 271) is an interesting sketch of the snowstorm of January 7, 1887, with mention of snowflakes 3½ inches long. Without vouching for the exact details I send you some statements from a letter in the *New York World* of to-day's issue. The letter is dated Fort Keogh, Montana, U.S., February 13. "The winter of 1886–87 will be long remembered throughout the north-west for the extreme severity of the temperature and the unusual depth of snow. From January 6 to 11 the degree of cold was something frightful. Mercury thermometers were often congealed, and spirit thermometers were kept jumping from 40° to 60° below zero. Half a dozen times has the 60° notch been touched, and once this season 62½° below zero has been scored on the Saskatchewan plains. But the authorities in weather in this country are the Indians. The oldest members of the Crow tribe say there have been few such winters as the present since they settled in the Yellowstone Valley. Curious phenomena sometimes attend a snowstorm. Near Matt. Coleman's ranch on January 28 the flakes were tremendous, some were larger than milk-pans. Some flakes measured 15 inches square and 8 inches thick. For miles the ground was covered with such bunches, and they made a remarkable spectacle while falling. A mail-carrier was caught in the same storm and verifies it." The narrative is one of great suffering, and loss of human lives and cattle. "Miss Maggie Bunn, school-teacher at Highmore, while going from the school to her house was frozen to death. The bodies of three Indians who belonged to Berthold Agency were found frozen near Ashland." And so on, in harrowing detail, for a number of whites perished. SAMUEL LOCKWOOD

Freehold, New Jersey, U.S.A., February 14

"Invisible at Greenwich"

I WRITE to note an apparent oversight which I have detected in the *Nautical Almanac* for 1888. The partial solar eclipse of August 7 is stated to be "invisible at Greenwich," but on applying a rigorous calculation I find that it will be visible there to a small extent, the times of contact being as follows:—

	G.M.T. h. m.	Angle from N. pt.	Angle from vertex
First contact	6 53 ...	11° to E. ...	26° to W.
Greatest phase ...	7 3 ...	·013 (sun's diam. 1)	
Last contact	7 13 ...	30° to E. ...	7° to W.

the angles being for the direct image.

I am aware that this is a very insignificant eclipse, but the greatest attainable accuracy is desirable in our national ephemeris, which, indeed, inserts eclipses much slighter than the above, *e.g.* the lunar eclipse of November 26, 1890, whose magnitude is only ·002. A. C. CROMMELIN

Trinity College, Cambridge, February 15

Lunar Halos

LAST evening (February 8), about a quarter-past eight o'clock (75th meridian time), I saw around the moon a series of coloured rings lying close together. The inner one was two or three diameters of the moon from the moon and *red*, the next was violet, then red, and finally violet again, this last one being very faint. From their proximity to the moon these rings seem to constitute the coronal, but I am puzzled by the fact that the inner ring was red. Do halos ever occur so close to the moon and without an interval between the two pairs of red and violet rings?

February 12.—Since writing to you on the 9th inst. I have found that my colleague here, Prof. W. G. Brown, noticed the rings around the moon about half an hour before I saw them. He says the colour nearest the moon was *yellow*, passing into red outwards, and that immediately following the red was violet, then the colours of the solar spectrum in order from violet to red on the outside. This indicates that the first red was really outside a violet ring which for some reason was invisible, and brings the phenomenon properly under diffraction: in fact, we had a good example of the coronal with the innermost rings wanting. S. T. MORELAND

Washington and Lea University, Lexington, Va., U.S.A.

The Beetle in Motion

IF it can interest Prof. Lloyd Morgan I am in a position to communicate that I have many times observed the progressive movements of insects, spiders, and myriapods. I have not noticed the retardation of hind-legs; it seems to me that this occurs only in the case of bulky and slow-moving beetles, like the larger Melasomata. In general, I find that the mode of progression in articulates does not differ essentially from what we see in vertebrates; the process is only, at first sight, a little obscured by the plurality of the legs. If we consider only the prothoracic ring of a beetle, we find that it walks like all bipeds, alternating one leg with another. Two segments walk in the manner of quadrupeds, which are not amblers. Now the legs of the third segment must necessarily repeat the movements of the legs of the first segment, for the sake of equilibrium. The fourth ring would repeat the movements of the second, and so on.

Tashkend A. WILKINS

A Recently-Discovered Deposit of Celestine

WITH reference to Mr. Madan's letter (p. 391), on "A Recently-Discovered Deposit of Celestine," I beg to inform him that a note was read by me at the last meeting of the Mineralogical Society, describing these crystals as exhibiting a habit and size unknown till then to occur with such crystals of celestine in England. I obtained the crystals at Christmas, from Mr. Henson, of the Strand, and am expecting to receive more material, which I hope to work on at the end of Term; but, unlike Mr. Madan, I have at present been unable to visit the locality where they are found. R. H. SOLLY

Mineralogical Museum, Cambridge, February 28

The Vitality of Seeds

MAY I ask, through the columns of your widely-circulated paper, whether there is any really trustworthy evidence for the following statement made by Prof. Judd in his address to the Geological Association (p. 393 in your last issue): "The botanist cites the germination of seeds, taken from ancient Egyptian tombs, as a striking illustration of how long life may remain dormant in the vegetable world." I know that this is a popular belief, but should like to learn upon what foundation it rests. Probably it would interest other botanists besides.

THE RELATIONS BETWEEN GEOLOGY AND THE MINERALOGICAL SCIENCES[1]

II.

LET us now turn from the statical aspect of minerals, their morphology, to the dynamical aspects, their physiology.

Minerals are not fixed and unchangeable entities, as they are sometimes regarded. On the contrary, they exhibit varying degrees of instability, and pass through very definite series of metamorphoses.

We have already seen that every alteration in the temperature or other conditions which surround a crystal leads to striking modifications of molecular structure, which are at once revealed by the delicate tests of optical analysis. So sensitive, indeed, are some crystals to the action of external forces, that even the passage of the

[1] Address to the Geological Society at the Anniversary Meeting on February 18, by the President, Prof. John W. Judd, F.R.S. Continued from p. 396.

light-waves through their substance leads to permanent molecular rearrangements which are evidenced by marked changes in colour, translucency, and other properties.

Many minerals have their atoms so arranged that the action of external forces causes them to fall readily into new combinations. In this way there are brought about such paramorphic changes as that of aragonite into calcite, and augite into hornblende. Excessively slight manifestations of force are sometimes sufficient to induce such paramorphic changes.

But the most significant fact of all is that every crystal possesses certain peculiarities of molecular structure, and as the result of this internal "organisation," it responds in a definite manner to the action of various external forces, undergoing in this way well-marked series of physical and chemical changes without losing its identity. As the final result of such successive changes, however, the bonds which hold the "organised" structures together are gradually weakened, and at last break down altogether. In this way the separate existence of the mineral comes to an end; but the materials of which it was composed, resolving themselves into new compounds, may go to build up the substance of other "organised" structures. Need I point out that in all these respects minerals behave exactly like plants and animals?

But in the case of plants and animals changes such as these, which are the direct outcome of external forces acting on a special organisation, are called *physiological*, and I know of no valid reason why the same term should not be employed in the case of minerals. It is true that the accomplishment of the cycles of change in minerals often requires periods of time of enormous duration, and that during incalculable intervals they may appear to be wholly suspended; but in these respects the "life" of a mineral differs from that of a plant in just the same manner as the latter does from the life of an animal.

I must ask your attention for a few moments to these peculiarities of internal organisation in minerals, and to the way in which the various physical and chemical forces act and react upon them in consequence of their special organisation.

Recent researches have shown that every crystal possesses a number of planes, all of which are related to its peculiar symmetry, along which the several physical forces operate in a marked manner to produce changes in the physical and chemical properties of the crystal. These planes have been called the "structure-planes" of the crystal.

By far the most obvious of these structure-planes of crystals are those of cleavage. When crystals are subjected to the action of mechanical force they break up along one, two, or three definite planes, with varying degrees of ease. In some cases when this separation cannot be readily effected by percussion or pressure, it may be brought about by the unequal expansion and contraction in a crystal resulting from alternate heating and cooling. We cannot arrive at the limit of this liability of a crystal to separate along its cleavage-planes; if we powder a calcite-crystal and examine the fine dust under a microscope, each minute grain will be seen to have the form of a cleavage-rhomb of the material.

Now the exquisite molecular structure of a crystal, of which this wonderful property of cleavage is the outcome, is borne witness to, not only by the perfection of the cleavage-surfaces—presenting, as they do, a lustre which no artificial polish can imitate—but by the fact that each particular set of cleavage-surfaces presents definite characteristics, analogous to those seen in the actual faces of crystals. Each exhibits striking peculiarities in its mode of reflecting light; each yields in varying degrees to a hard point drawn across it in different directions; and each, when treated with appropriate solvents, is attacked in a characteristic fashion, giving rise to the geometrical forms known as the etching-figures. Wonderful as these cleavage-surfaces are, however, it must be remembered that the power of cleavage is one that, under ordinary circumstances, remains altogether *latent* in crystals.

Cleavage-planes, however, are not the only latent structure-planes in crystals. Long ago it was shown by Brewster, Reusch, and Pfaff, that when minerals are subjected to pressure in certain directions, their molecules appear to glide over one another along certain definite planes within the crystal; and, if we examine optically a crystal which has been treated in this manner, it is actually found to exhibit a series of twin-lamellæ arranged parallel to the so-called "gliding-planes." It thus appears that in the movements set up within a crystal by the application of force from without, certain of the molecules of which the crystal is built up, lying in bands parallel to the gliding-plane, are actually made to rotate through an angle of 180°.

At one time these "gliding-planes" were regarded as being peculiar to a few minerals, such as calcite and rock-salt; but the investigations of Frankenheim, Baumhauer, Foerstner, and especially of Mügge, have shown that they exist in crystals belonging to every group in the mineral kingdom, including all those minerals which occur as common rock-forming constituents, such as the feldspars and pyroxenes.

As is the case with the cleavage-planes, so with the gliding-planes, there may exist one, two, or three in the same crystal. One of these is usually a principal gliding-plane—the slipping movement with its accompanying twin-lamellæ being produced parallel to it with the greatest facility—while the others are subordinate ones.

Strange to say, however, the particular gliding-plane along which a crystal yields appears to be determined, not only by the direction in which the force is applied, but to some extent also by the nature of that force, whether percussive, or a sustained pressure, or a violent stress; in some cases where the application of external force fails to produce the gliding movement with its accompanying lamellar twinning, it may be induced by the strains which result from unequal expansion and contraction during the heating and cooling of a crystal. Some mineralogists have, indeed, proposed to apply distinctive names to the results which follow from the application of different kinds of force—whether a blow (*Schlagfiguren*), pressure (*Reissflachen*), or the effect of heating and cooling (*Contractionrisse*).

The gliding-planes of crystals are quite distinct from the cleavage-planes, though some very curious and interesting relations have in certain cases been shown to exist between them. That the artificial formation of twin-lamellæ, like the production of cleavage, is rendered possible by complicated molecular structures, it is scarcely necessary to point out. The application of external force to such crystals is like the putting of a spark to a train of gunpowder: the molecules lying in parallel bands are in unstable equilibrium, ready, so soon as set in motion, to roll through an angle of 180°.

There is still a third and even more subtle set of structure-planes in crystals to which I must now allude, those, namely, for which the name of *solution-planes* has been proposed.

It was long ago shown by Daniell that when crystals are exposed to the action of solvents they are attacked in such a manner as to give rise to peculiar geometrical forms. The subject has been followed up by Baumhauer, Leydolt, Becke, and others, who have shown what a wonderful variety of "etching-figures" may be produced by operating upon the various faces and cleavage-surfaces of different crystals.

Quite recently, however, it has been shown by Von Ebner, as the result of his studies of calcite and aragonite, that all the complicated phenomena of the etched figures arise from the existence of planes along which solvent or chemical action takes place most readily within a crystal. It thus appears that the complicated etched figures, with their curved and striated surfaces, are indications of the combination or oscillation of tendencies to chemical action along the different solvent-planes of the crystal.

My own experiments have enabled me to show that the chemical action taking place along the solution-planes of crystals leads to the development of cavities, often assuming the forms of negative crystals, which may become wholly or partially filled with the product of the chemical action.

Although the solution-planes are quite distinct, both from the gliding-planes and the cleavage-planes of crystals, I have been able to show that some curious and interesting relations exist between them. If lamellar twinning has been already developed in a crystal, then chemical action takes place along the gliding-planes in preference to the normal solution-planes.

It is only when we study the minerals building up the rock-masses of the globe that we fully realise the importance of these molecular structures, and the wonderful changes which crystals are capable of undergoing, as a consequence of their internal "organisation." Then, and then only, do we begin to understand the significance and the far-reaching consequences of the physiological changes of which minerals are susceptible.

The crystals forming the rock-masses of the globe have been subjected to every variety of mechanical force—violent fracture, long-continued strain, steady but enormous pressure—prolonged over vast intervals of time, to which must be added the potent effects of alternate heating and cooling. Such crystals, moreover, are transfused through their whole substance by various liquids and gases acting under tremendous, and sometimes varying, pressures.

Under such circumstances it is not surprising to find that the crystals have often yielded along their cleavage-planes, and that cleavage-cracks have been produced. These, by affording a ready channel for the passage of solvents, not unfrequently determine the course of various chemical operations going on within the crystal.

Not unfrequently, too, the rock-forming minerals have yielded along their gliding-planes, and the development in them of twin-lamellæ is the result. Every crystal of calcite in an ordinary metamorphic limestone, and many of the plagioclase feldspars in igneous rocks, exhibit the secondary lamellar twinning which has arisen from the action of mechanical forces upon the mass.[1] The microcline structure in orthoclases, with many other similar structures in other minerals, must almost certainly be ascribed to the same cause.

Still more remarkable are the consequences which follow from the existence of the solution-planes in crystals. By the action of various solvents under pressure, augite is made to assume the forms known as diallage and pseudo-hypersthene, the ferriferous enstatite of bronzite or hypersthene, while the feldspars acquire their avanturine, schiller, and chatoyant phenomena. When, in addition to the statical pressures due to thousands of feet of superincumbent rocks, these solvent agencies work with those tremendous dynamical aids afforded by deforming stresses, such as make the rocks to flow during mountain-making, it is not surprising to find the molecules of the original crystals breaking from their old allegiances, and the liberated atoms uniting to form new minerals, the position of which is determined by the lines of flow in the mass.

Not a few of our gems owe their exquisite beauties to these physiological changes which have taken place in them since their first formation. The ardent glow of the sunstone and the pale watery gleam of the moonstone, no less than the lovely play of the azure tints in Labrador-spar and the bronzy sheen of Paulite, are the result of physiological processes taking place in crystals which were originally clear and translucent. In the profound laboratories of our earth's crust slow physical and chemical operations, resulting from the interaction between the crystal, with its wonderful molecular structure, and the external agencies which environ it, have given rise to new structures, too minute, it may be, to be traced by our microscopes, but capable of so playing with the light-waves as to startle us with new beauties, and to add another to

"The fairy tales of science, and the long results of time."

Yes! minerals all have a *life-history*, one which is in part determined by their original constitution, and in part by the long series of slowly-varying conditions to which they have since been subjected. In spite of the circumstance that their cycles of change have extended over periods measured by millions of years, the nature of their metamorphoses and the processes by which these have been brought about are, in all essential respects, analogous to those which take place in a *Sequoia* or a butterfly. In spite, too, of the limitations placed upon us by our brief existence on the globe, it is ours to follow in all its complicated sequence this procession of events, to discover the delicate organisation in which they originate, to determine the varied conditions by which they have been controlled, and to assign to each of them the part which it has played in the wonderful history of our globe during the countless ages of the past.

The subject of distribution, or chorology, is one of no less importance in the study of the mineral than in that of the vegetable and animal kingdoms. The relations of minerals to one another, and the manner in which they make their appearance in respect both to time and place, constitute a most instructive and suggestive field of research.

The older mineralogists paid some attention to the question of the mode of association of minerals with one another, which they described under the term "paragenesis." But this was at a time when only large and freely crystallised specimens received much attention. At the present day this question of the varied distribution of minerals in space and time, and the manner in which they are associated with one another to build up rock-masses, constitutes a most important branch of our science, that to which the name of petrology is given.

Under the name of "petrography" an attempt has been made to establish a branch of natural-history science which shall bear the same relation to mineralogy as that science does to chemistry. As minerals are formed by the union of certain chemical compounds, so rocks, it is argued, may be regarded as being built up of different minerals. But it must be remembered that while minerals possess a distinct individuality—the result of their different chemical constitution and their characteristic crystallographic form—we are quite unable to point to anything analogous to these in the case of rocks.

How is a rock-"species" to be defined? It is not enough to state its ultimate chemical composition; for rocks of the most varied character and origin may agree in this respect. Equally futile is it to take mineralogical constitution as the basis of our classification; for, in the

[1] It has often been asserted that the "striation" on the faces or cleavage-surfaces of crystals is an indication of the existence of polysynthetic twinning. But in the oligoclase of Ytterby and other localities, I have found that many crystals which exhibit striation do not affect polarised light differently in the alternate striæ. But on submitting the crystals to alternate heating and cooling, and sometimes by percussive force, the twinning may be easily developed in them. It appears from these observations that the crystals are built up of lamellæ, in which the molecules are alternately in stable and unstable equilibrium. I have in some cases found that the stresses upon a slice of feldspar which is being heated and cooled and then ground into a thin section, while cemented to a glass plate during the preparation of a microscopic slide, are sufficient to cause the rotation of the molecules in the alternate lamellæ. In some cases, I have no doubt that twin-lamellation, like cleavage-cracks, may be induced in the crystals of our rock-sections during the processes to which they are submitted in their preparation.

same rock-mass, the species of minerals which are present and their proportions to one another may, and, indeed, often do, vary from point to point. Nor does minute structure, though affording admirable criteria for distinguishing certain *types* of rock, supply a sufficiently definite means of diagnosis for all the different varieties which occur. A system of "lithology" may, indeed, be devised, if we confine our attention to the hand-specimens in our museums; but it breaks down the moment that we attempt to apply it in our researches in the field.

I have long felt assured that all attempts at a nomenclature and classification of rocks must, for the reasons just stated, be regarded as tentative and provisional only; but the careful study of rock-types is nevertheless bringing to light a number of facts calculated to profoundly modify mineralogical no less than geological thought and speculation.

Petrology forms the link between mineralogy and geology, just as palæontology does between biology and geology. Mineralogy has justly been styled the alphabet of petrology; but if the orthography and etymology of the language of rocks lie in the province of the mineralogist, its syntax and prosody belong to the realm of the geologist. In that language, of which the letters are mineral species and the words are rock-types, I am persuaded that there is written for us the whole story of terrestrial evolution.

Petrology, it is clear, could make but little progress until the improvement of microscopic methods enabled us to make accurate determinations of the minerals in a rock, even when these are present as the most minute particles. The characteristic peculiarities of the different rock-forming minerals, so carefully studied by Zirkel, their accurate optical diagnosis, at which Rosenbusch has laboured with so much success, these with the microchemical methods of Knop, Bořický, Streng, and Behrens, and the pyro-chemical method of Szabó, have already done much to render exact our methods of recognising the minerals in a rock. The contrivances, for which we are principally indebted to the French petrographers, for effecting the isolation of the minerals in rocks, so that they may be submitted to accurate chemical analysis, enable us in cases of difficulty or doubt to confirm or check the results of our microscopical studies.

But there is at present, perhaps, a tendency to confound the end with the means in such researches as these. When all the varieties of minerals in a rock have been correctly identified, the work of the petrologist is not ended; on the contrary, it is only just begun.

The relationship of the several minerals in a rock to one another, the discrimination between such as are original and those of secondary origin, and the recognition among the former of the essential, as distinguished from those that are accessory or accidental,—these are problems of even greater importance than the exact determination of the species or varieties to which each belongs. In not a few rocks it can be demonstrated that every one of its present mineral constituents is different from those of which it was originally made up; in some cases, indeed, it may be shown that the recombination of the elements of the rock into fresh mineral aggregates has taken place again and again. As well might we try to give a rational account of our English speech without taking into account the series of changes through which it has passed in its evolution from the Anglo-Saxon dialects, as to explain the nature of a rock without studying the influence upon it of the forces by which it has gradually acquired its present characters.

With respect to the geographical distribution of the different mineral species, many suggestive observations have been made. Some, like the feldspars, the pyroxenes and the olivines, appear to be ubiquitous in our earth's crust, and even make their appearance again in those bodies of extra-terrestrial origin—the meteorites. Others, like leucite, nepheline, hauyn, sodalite, and melilite, are exceedingly abundant in certain areas of the earth's surface, while they appear to be wholly wanting in others.

Still more remarkable are the relations which are found to exist between the types of rocks occurring in different geographical areas. The study of this subject is leading us to the recognition of the fact that there are distinct petrological provinces. In closely adjoining areas—such as Hungary and Bohemia, for example—widely different types of rock have been erupted during the same geological period; and this is a fact not less striking and significant than that of the meeting of two perfectly distinct biological provinces along a line which traverses the Malayan archipelago. It cannot be doubted that the prosecution of this hopeful branch of study—the geographical distribution of minerals and rocks—will lead us to results of the highest interest and value.

That there will be shown to be a distribution of rocks in time, as well as in space, I am perfectly prepared to believe. I cannot but think, however, that some of the generalisations on this subject which have been hazarded are somewhat premature. To a geologist (especially one belonging to the school of Lyell) it is equally difficult to conceive that there should be a broad distinction between the metamorphic rocks of Archæan and post-Archæan age respectively, as that the pre-Tertiary volcanic rocks should be altogether different from those of Tertiary and recent times.

The great object of all our studies—concerning the morphology, the physiology, and the chorology—of the mineral kingdom, ought to be to arrive at definite ideas concerning its ætiology; the causes by which the existing forms, capabilities, and positions of minerals and rocks have been determined.

While the *fossils* contained in rock-masses afford us the means for determining the date of their origin, the careful study of the minerals which they include may enable us to unravel the complicated series of changes through which they have passed since their first formation.

Eighteen years ago, when seeking to show how the origin of a particular rock might be elucidated by a combination of studies in the field, in the chemical laboratory, and by the aid of the microscope, I ventured to offer to this Society some general remarks on this subject. As it has been my constant endeavour since that time to apply the principles then enunciated in the case of rocks of more complicated character and more recondite origin, I may perhaps be forgiven for repeating the words I then used. Every rock since its first formation "has undergone and it still is undergoing a constant series of internal changes, the result of the action of different causes, as heat, pressure, solution, the play of many chemical affinities, and of crystallographic and other molecular forces, causes insignificant perhaps in themselves, but capable under the factor *time* of producing the most wonderful transformations. The geologist is called upon to unravel the complicated results, to pronounce what portion of the phenomena presented by a rock is due to the forces by which it was originally formed, and what must be referred to subsequent change; to discriminate the successive stages of the latter and to detect their various causes; in short, to trace the history of a rock from its deposition to the present moment."

Dr. Wadsworth has well characterised the changes which take place in rock-masses as due to the tendency of unstable mineral combinations to pass into stable ones. It must be remembered, however, that stability is a relative term, and that the arrangement of molecules which is stable under one set of conditions becomes unstable under another set. As by the internal movements and the external denudation of the earth's crust, the conditions under which rock-masses exist are undergoing slow but continual change, new adjustments of the molecular structure of the rocks are at once necessitated and brought about.

In attempting to reason as to the *original* conditions under which a rock-mass must have been formed, it is of great importance to avoid those sources of error which exist in rocks that have undergone much secondary alteration. Such rocks abound in, though they are not necessarily confined to, the older geological formations; and it is among the younger and fresher rocks, therefore, that we may most hopefully seek the key to many petrological problems.

If, for example, we concentrate our attention upon the more recent and less altered igneous rocks, it becomes clear that the degree of crystallisation displayed by them has depended on the slowness with which consolidation has taken place, and that this has in turn been determined by the depth from the surface at which they have been formed. In this way, by the study of igneous rock-masses in Scotland and in Hungary, I was able to show that there is a perfect gradation from highly crystalline rocks—granites, diorites, and gabbros—into the ordinary volcanic types—rhyolites, andesites, and basalts, respectively—and from the latter into the various kinds of volcanic glass. These conclusions have been confirmed by subsequent investigations like those of Hague and Iddings in the Comstock region, and of Lotto in Elba. Further and more recent researches have enabled me to show that certain types of structure have been determined in rocks, according to the more or less perfect absence of all movement within them during their consolidation.

Very remarkable, indeed, are the internal changes which take place in rock-masses when they are submitted to those powerful stresses which result from the movements that occur during mountain-making; and the full explanation of these is perhaps the most difficult problem which still confronts the geologist.

It was long ago asserted by Scrope and Darwin that the solid rock-masses of the globe, under such conditions as these, must have actually *flowed*, like the viscous lavas of the rhyolitic series. These geologists were even able to show that the separation and disposition of the crystalline elements in such lavas present the closest analogy with what is seen in the crystalline schists and gneisses of greatly disturbed areas.

Since these early researches, which were principally based on the study of rocks in the field, aided only by the pocket-lens, three classes of researches have served to deepen our insight into the methods by which the schistose and gneissose rocks must have been produced.

In the first place, the experiments of MM. Tresca and Daubreé have shown that solid matter under enormous pressure behaves like a viscous substance, its whole internal structure exhibiting evidence of the flowing movements to which it has been subjected.

In the second place, the studies of M. Spring have established the fact that both paramorphic change and direct chemical reaction may result from simple pressure. Thus the unstable monoclinic form of sulphur, by a pressure of 5000 atmospheres, was at ordinary temperatures converted instantly into the stable rhombic form, a transformation accompanied by change of density and of many other physical properties. Still more striking is the case of the unstable, yellow, rhombic, mercuric-iodide, which, by simple rubbing with a hard substance, passes into its stable, red, tetragonal allomorph. It is instructive to notice that the same change in both instances appears to take place "spontaneously" after a sufficient interval of time; or, in other words, small variations in temperature, pressure, and other surrounding conditions are capable, if sufficient time be allowed, of bringing about the same result as more intense pressure applied suddenly. That the similar paramorphic change of pyroxene into hornblende, which is so frequently exemplified in the earth's crust, is sometimes the result of intense pressure, and at other times follows from the repeated slight alteration of conditions during long periods of time, we have, I believe, abundant evidence.

But the experiments of M. Spring that prove that chemical reactions can result directly from pressure are of even greater interest to the geologist. By submitting mixed powders to intense pressure, he succeeded in producing metallic alloys and various binary compounds, and also in bringing about double decomposition between many salts. That similar reactions between the complicated silicates which form the minerals of rocks have resulted from the enormous pressures to which they have been subjected, we have the most ample proof. Thus in rocks where such pressure has just begun to act, such as the "flaser-gabbros," wherever the unstable olivine is in contact with the almost equally unstable anorthite, chemical reactions have been set up by the pressure, and these have resulted in the formation of zones of enstatite and anthophyllite, hornblende and biotite, which have been so well described by Törnebohm, Bonney, Adams, and Williams. Provided with the clue supplied by these results, we find little difficulty in going one step further. When the pressure has been still more intense, as in mountain-making movements, reactions are set up among all the minerals of the rock-mass; the elements of which it is composed, set free from their old engagements, enter into new alliances, and the result is the formation of a completely new set of crystallised minerals.

The third class of researches, destined, as I believe, to remove our difficulties in explaining the origin of the schistose and gneissose rocks, are those already alluded to as having been undertaken with the microscope. As yet the details of such changes have only been explained in the case of some of the simpler examples; but I am convinced that the persevering application of the same methods in the field and the laboratory will result in the removal of difficulties that now seem to be absolutely insurmountable.

Some observers in this country have been led to infer that the recrystallisation of rock-masses under pressure has in all cases been preceded by their pulverisation. Of this, I confess that I can find no evidence. That near great faults of all kinds, this reduction of rocks to powder does take place, we find abundant proof; but the evidence also points to the conclusion that such *rock-crushing*, as distinct from *rock-flowing*, is in every case local and exceptional.

There is another and totally different series of changes which takes place in rocks, when, brought near to the surface by denudation, they are exposed to the action of water, oxygen, carbonic acid, and other atmospheric agents. The breaking-up of the alkaline silicates and the deposition of secondary silica, the formation of the zeolites, the epidotes, the chlorites, and serpentine, the resolution of crystallised minerals into the isotropic mixtures, and the recrystallisation of these in new forms, all offer problems of the highest interest to the geologist.

I may venture, in drawing these remarks to a close, to indicate another point of analogy between the three natural-history sciences. It is found in the circumstance that experimental verifications of our conclusions are often difficult, if not actually impossible.

We must be content to reason from the proved variability of the existing forms of plants and animals as to the possibility of the production in time of new species. And in the same way, with our limited command of heat, pressure, and especially of time, we can scarcely hope to originate the exact counterparts of the various minerals and rocks of our earth's crust.

We may nevertheless point with satisfaction to what, in spite of such difficulty, has already been accomplished in this interesting field of research. The honour of having pushed these researches to such successful issues belongs chiefly to the chemists, mineralogists, and geologists of France. To the labours of Senarmont, Daubrée, and a host of other workers, we owe the artificial production of a very large number of the minerals of our globe; while the ingenious experiments of Fouqué and Michel Lévy have resulted in the formation of many rocks differing in no essential particulars from those which have been produced by natural agencies.

In the prosecution of his various researches the importance and value of exact mineralogical knowledge to the geologist is becoming every day more apparent. The temporary estrangement between the cultivators of mineralogy and geology is now, we may hope, for ever at an end; very heartily, indeed, do geologists recognise and welcome the aid of their brethren the mineralogists.

But if it be confessed that the benefits, past and prospective, conferred on geological science by mineralogy are vast and even incalculable, it must also be admitted that the debt is amply repaid by the beneficial influence which is being exercised in turn upon mineralogy by geology.

Some time ago a distinguished mineralogist asked me if I did not find the ordinary text-books of his science but little calculated to arouse the interest or excite the enthusiasm of students. I am sure that the energy of my assent must at least have assured my friend of the strength of my convictions on the subject.

Too long, indeed, has the accumulated mass of mineral lore recalled the grim vision of the seer of Chebar. In that gruesome valley the wail of the student, "the bones are very dry," has mingled with the sigh of the teacher, "Can these bones live?" But now from the four winds of heaven come the constructive ideas of many minds—from Scandinavia and from France, from Germany and from the United States—and in obedience to this influence behold "a great shaking" in the formless mass. Scattered facts, isolated observations, imperfect generalisations, and tentative hypotheses are falling together "bone to his bone," and are building up a sound body of mineralogical knowledge; and into this the spirit of geological thought entering, mineralogy shall stand forth a living science.

DR. WILLIAM TRAILL, OF WOODWICK [1]

THE death of this assiduous student of natural history merits more than a passing notice, since there are few surgeons who did more for the advancement of Eastern conchology than he; while his researches on the antiquities of his native county (Orkney) also claim attention. His whole career, indeed, as in the case of many an Eastern surgeon, illustrates the wisdom of placing both natural history and botany on the curriculum of every medical student.

Dr. Traill was the eldest son of Mr. Traill, of Westness, Rousay, Orkney, and he was born in Kirkwall on September 8, 1818. He proceeded to the University of Edinburgh to study medicine at the age of sixteen, and while there he had the advantage of the direction and advice of his uncle, the late Prof. Traill, who held the Chair of Medical Jurisprudence. Young Traill proved an apt student, and showed from the first a strong liking for natural history. This was fostered by his uncle (whose collection of snakes, now in the Museum of Science and Art, was well known to naturalists), as well as by his pursuits during the holidays at the family seat at Westness, in the Island of Rousay. Amongst his fellow-students were Dr. Cleghorn, of Stranthie, late Conservator of Forests in India, Sir Lyon Playfair, and Dr. Halliday Douglas.

After graduating in 1841, he proceeded to India as a surgeon in the East India Company's service. The splendid field thus opened up to the young naturalist stirred all his energies into activity, and he studied and collected various groups, but especially the land-shells of Madras. His early studies on the shores of Orkney had given him a predilection for this department, and he remained faithful to it throughout life. Thus, when shortly afterwards called to serve in China, he began the collection of those beautiful specimens of Eastern shells now so well known in many collections. His opportunities were further extended by a residence of some years at Singapore, and afterwards at Malacca and other stations. He returned to England in 1854, and his collections were much admired, both as regards the beauty of the specimens and the number of examples of each species. His acquaintance with Dr. Knapp, a retired army surgeon, and also well known as a malacologist, gave a great impetus to his studies, as also did his association with Andrew Murray, Robert Gray, Dr. Howden, Wyville Thomson, Foster Heddle, James Cunningham, Patrick Dalnahoy, and R. Greville.

His return-voyage to India in 1856 gave him an opportunity of examining the pteropods and other pelagic mollusks, and his observations, with four plates and a chart, were communicated by Sir Walter Elliott to the *Madras Journal*, then edited by his friend Dr. Cleghorn. His preparations of the delicate glassy shells of the Thecosomatous forms was remarkable. He also described some rare species, observed certain peculiarities in their structure, and made comparisons between the velum of the young Cypræa and the epipodia of the pteropods. His collection of Eastern mollusks was largely increased during his second period of duty, so that it became celebrated for certain rare types, such as *Rostellaria rectirostris*, *Trochus guilfordii*, *Trochus imperialis*, &c. He also added largely to Prof. Traill's collection of snakes formerly alluded to.

On retiring from active duty he settled at St. Andrews, and at once took an active interest in the University Museum and Literary and Philosophical Society, of which latter he was a Vice-President at his death. He spent much of his time in arranging the Mollusca in the Museum, and he enriched the collection by many interesting and rare types. In his annual trips to his estate in Orkney he also made researches on the antiquities and geology of the district, and these he embodied in papers communicated to the Edinburgh Antiquarian Society, and to the Society at St. Andrews. Amongst these papers are the following:—"Results of Excavations at the Broch of Burrian, Orkney," two plates and woodcuts; "Notice of Excavations at Stenabeck, Orkney," with woodcuts; "On Submarine Forests in Orkney"; "On the Picts' Houses of Skerra Broc"; "On the Recurrence of Boulder-Clay in Orkney"; "Notice of the Boulders in North Ronaldshay," &c.

His knowledge of botany also enabled him to acclimatise various plants in Orkney, such as *Phormium tenax*, various Veronicas, the Manuka (Capt. Cook's sea-plant), the Japanese *Euonymus*, and others.

Dr. Traill was a man of refined and cultivated mind, genial but unobtrusive, and had a large circle of friends. He enjoyed good health till eighteen months ago, when the first symptoms of the disease which ultimately proved fatal appeared. W. C. M.

[1] Abstract of Paper read at the Literary and Philosophical Society, St. Andrews, January 21, 1887.

THE EARTHQUAKE

A SERIES of shocks of earthquake has caused much havoc in the Riviera during the last week. Although it is too early to attempt to give a complete account of what has happened, the leading facts, so far as they are of scientific interest, are well summed up in the following report, issued by Father Denza, of the Montcalieri Observatory:—

"(1) The earthquake in our region has had nearly the same effect as those on November 28, 1884, and September 5, 1886. In length it extended to the east along a line leaving the plains of Lombardy at Lomellina, and passing by the district of Alessandria to the Riviera di Levanto, and westward over all the Western Alps, proceeding towards Switzerland as far as Geneva and beyond, and to Paris and Corsica. The telluric movement proceeded from the Lepontine Alps on the north to the Gulfs of Lyons and Genoa on the south, extending, but more feebly, through Tuscany to Rome.

"(2) The movement had its greatest intensity in Liguria, in Southern France, and in Piedmont, where it shook the whole of our plain, and penetrated into all the Maritime, Cottian, Graian, Pennine, and Lepontine Alps.

"(3) This time the centre of the strongest intensity was in the Gulf of Genoa, along the line dividing the place where the Apennines join the Alps, and extending from Savona to Mentone. It was within this space that people lost their lives in several localities, such as Savona, Noli, and Mentone, and everywhere as far as Marseilles there were numerous disasters and buildings thrown down. The movement of the soil, not so violent, but equally disastrous, spread over the mountainous country which extends from the Altare Pass to Millesimo, Mondovi, and the neighbouring regions. The shock was severe, but it did no considerable damage, in a portion of the province of Coni, as also in the provinces of Alessandria and Turin, it being very intense on Mont Cenis. It was slighter in the plains and in the valleys of the province of Novara.

"(4) In the places where the earthquake was most intense the principal shocks were three in number, and with a slight difference, depending probably on the difference of clocks, correspond to the times indicated by the seismic instruments of our Observatory—namely, the first at 6.22 a.m., the second at 6.31, and the third at 8.53. In the places near the centre of motion slight shocks occurred at intervals all through the day. The severest and most terrible shock was the first, which was undulatory in several places, oscillatory, and perhaps rotatory. It was several times prolonged and accentuated. Here at Montcalieri, as at Turin and elsewhere, it had three principal repetitions, plainly evidenced by the courses traced by our registering seismograph. These augmentations of intensity were mistakenly regarded by some as so many distinct shocks.

"(5) The dominant direction of the first undulatory shock was from west to east, with slight deviations at intervals from west and north-west to east and south-east, and with oscillatory and very slight vibrations. The two other shocks were also undulatory, and the last was rather more intense than the second, btt without reaching the intensity of the first. The second and third had about the same direction as the first.

"(6) The earthquake in places where it was severe and very severe was accompanied by rumblings. I may add, in conclusion, that about 2 o'clock this (Thursday) morning our most delicate seismic instruments signalled very slight fresh shocks, undulatory, and from north-west to south-west."

The fullest and most accurate details as to the successive shocks have come from the more important towns in the western Riviera. Mr. W. J. Lewis, writing to us from the Hôtel des Iles Britanniques, Mentone, on Saturday, the 26th of February, says that some slight vibrations seem to have been felt there about midnight and 3 a.m. before the great shock. "This last," he continues, "occurred apparently a few minutes before six, just as day was dawning." He was roused from sleep by being violently jolted in bed, which was being shaken with great violence. At the same instant he heard loud noises of apparently cracking walls and ceilings, and the rattle of falling plaster and breaking glasses. "I did not," says Mr. Lewis, "instantly realise my position, but had time to consider what was going on, and to conclude that, if the house collapsed under the shock, escape was hopeless, and that there was nothing to be done. This may possibly have taken ten seconds. Needless to say, that when the motion ceased and I found myself unharmed, I was up, seized my warmest clothing, and was down in the garden in less than a minute. The daily Press will have sufficiently described the scenes which have occurred throughout the Riviera. The second shock, of considerable, but much less, force, occurred about ten minutes later. I observed, within a few minutes of this that the hall clock marked 6.15, local time, corresponding to 5.54 a.m., so that I should be inclined to place the second shock at 6.10. A third shock of about the same intensity as the second occurred between 8.30 and 8.45. This last threw down bricks, tiles, &c., which had been displaced by the first shock, and raised the panic to the greatest height."

According to Mr. Lewis, the early reports of the disaster at Mentone were much exaggerated, but the truth, he says, is bad enough. "The large hotels, especially those in high situations, seem to have suffered least. The whole of the East Bay and the old town have escaped practically unharmed. The greatest damage has occurred to two-storied buildings placed on the alluvial soil in the comparatively level part lying along the sea, and in the valleys of the Carrei and Borrigo, embracing the main portion of the modern town of the West Bay. Here the relation with the foundation is well marked in the case of two equally well-built houses not more than 300 yards apart, viz. St. John's Parsonage and the House of Rest. The former is in the valley, and the foundations were a source of great trouble at the time of building. It is very much shattered. The other is built on a rock, and has escaped uninjured. Within a radius of a quarter of a mile of the station the main destruction has occurred. But the houses most wrecked—some score or more—show most conclusively bad building. The large hotels in this injured area—the Iles Britanniques, National, Orient, Mediterranée, des Colonies, &c.,—most of which are four to five stories high, have suffered injury to lathe and plaster, but in few places are the main walls seriously damaged. In the case of these high buildings the intention of raising them to such a height necessitated a firm and solid foundation. I have noticed that the walls in a part of this hotel at a height of six stories have on the top floor suffered no visible damage. In the same way Monte Carlo, built on rocky ground, has escaped uninjured."

Writing from Nice, a correspondent of the *Times*, signing himself "Commander, R.N.," says that, on Wednesday morning, about six o'clock, he was awakened by an extraordinary commotion so unaccountable that for a moment he thought an escaped lunatic was shaking the bed in a maniacal outburst of fury. Running to the window, he saw that the shock must have been very severe, "for everywhere the streets were strewn with fragments of cornices, mouldings, chimney-pots; while many houses exhibited dangerous-looking cracks and rents in the walls of the upper stories. Another shock as violent as the first must inevitably have been followed by the downfall of many buildings. Fortunately, however, none of the succeeding shocks at all approached the first in violence." Another correspondent of the *Times*—"C. E. de M."—writes from Nice, that he was awakened shortly after 6 a.m. by "a tremendous vibration, which shook the whole house, a large hotel, from top to basement. The bed rocked and swayed violently to and fro like a hammock set swinging, and great masses of plaster fell from the ceiling and walls in every direction, strewing the room with *débris*, while the paper was literally stripped off the walls, and every second the whole hotel appeared as if it must topple over. . . . At 8.30 a.m. another shock, though of less violence, seemed to complete the reign of terror which had now set in."

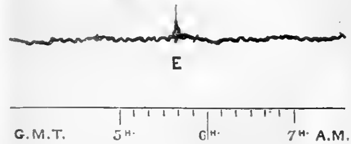
At Cannes Sir Theodore Martin noted that the first of a series of shocks began at five minutes after six (Cannes time). "No premonitory warning was given, and there was none of that rumbling noise which frequently accompanies earthquakes. The sky was without a cloud, and the first 'rose of dawn' had just begun to show itself in the east. The air was still and fresh, and not a leaf stirred on mimosa or eucalyptus. The trembling, beginning somewhat gently at first, like that produced by the passage of a heavy railway train, grew rapidly more and more marked. . . . The convulsion lasted for fully a minute, and the oscillation was from east to west. A second but slight shock, some minutes afterwards, did not tend to diminish the apprehension caused by the first. So far as I can learn, few of the thousands who fill the hotels remained in their rooms, the great majority finding their way, some in the scantiest of raiment, into the adjoining gardens. The first alarm was beginning to pass off when, about half-past eight, a third shock was felt. This did not last above fifteen seconds, but while it lasted it was very severe, shaking the floors and moving the furniture in the same way, but in a less degree than the first shock. The air continued calm as before, and the whole sky was flooded with sunshine."

It will be observed that Sir Theodore Martin describes the direction of the oscillation at Cannes as from east to west. Another correspondent of the *Times* says that at Antibes the undulations were "undoubtedly from west to east." At Toulon, where there were two violent shocks about six o'clock, the undulations were also from west to east. On the other hand, at Turin, where there were three shocks in the space of seventeen seconds, the second shock, which was by far the strongest, had a direction from north-east to south-west.

At Marseilles two smart shocks were felt about 6 a.m., and a third at 8.30 a.m. They lasted about fifteen seconds each, and caused fissures in several houses. At Nîmes some windows were shattered, and the clocks stopped; and like results were produced at Grenoble. At Avignon three shocks were felt between 6 and 8 o'clock a.m., and the first shock was violent enough to awake all the inhabitants. Slight shocks were felt at Lyons.

It was in the towns and villages of the Italian Riviera that the earthquake produced its most desolating effects. Diano Marina was utterly destroyed. At the first shock, about 6 o'clock, the inhabitants of this place rushed into the streets half dressed. Then came a more fearful shock. A frightful cracking noise was heard as far as the beach, and the houses fell in, burying the greater number of those who had lived in them. The results at Diano Castello, a mile and a half off, were also very appalling, and at Bajardo more than 200 persons were killed in the church. The full extent of the calamity which so suddenly overtook these and other places in the same district cannot even yet be accurately determined. The following is the official list of dead and wounded:—Alassio, 3 dead, 8 wounded; Albenga, 30 wounded; Albissola, 3 dead, 12 wounded; Bajardo, 230 dead, 30 wounded; Bussano, 80 dead, 27 wounded; Castellaro, 41 dead, 65 wounded; Ceriana, 5 dead, 12 wounded; Diano Castello, 35 dead, 10 wounded; Diano Marina, 180 dead, 65 wounded; Montalto Ligure, 1 dead, 3 wounded; Noli, 16 dead, 12 wounded; Oneglia, 23 dead, about 150 wounded; Pompeiana, 5 dead, 7 wounded; Porto Maurizio, 1 dead, 10 wounded; Savona, 11 dead; Taggia, 8 dead, 14 wounded; Triora, 4 dead, 9 wounded.

All over Switzerland the earthquake was felt, more or less, and the oscillations are said to have been from north to south. Dr. A. Riggenbach, Assistant Astronomer at the Basle Observatory, writes to us that some shocks occurred there. The two clocks of the Basle Observatory, and the two regulators of the public electric dials, the principal astronomical clock of Knoblich, keeping sidereal time, were stopped at 6h. 42m. 50s. a.m. local mean time, or 5h. 34m. 30s. a.m. Greenwich mean time. Mr. G. M. Whipple, Superintendent of the Kew Observatory, has been good enough to send us a careful tracing, which we reproduce, of the curve given by the bifilar magnetograph at the Kew Observatory, showing that the instrument was affected by the earthquake about 5.40 a.m. Indications of the later shocks were shown on the original photograph, but not with sufficient clearness to enable them to be satisfactorily identified. In the Signal Office at Washington, the Government seismoscope was, on Wednesday morning, disturbed by accurately recorded shocks at 7.33 a.m. This is equivalent to 7.50 a.m. by the standard time of the 75th meridian. If, therefore, these shocks were connected with the earthquakes in Southern Europe, the velocity of their transmission from the Riviera was about 500 miles an hour.



Copy of trace of bifilar magnetograph at the Kew Observatory, Richmond, Surrey, 1887, February 23, 5–7 a.m. Movement produced by earthquake marked E.

The problems connected with the earthquake were discussed at the meeting of the French Academy of Sciences on Monday. M. Mascart stated the contents of a note from M. Fines, of Perpignan, who possesses a magnetometer. A little before the shock his magnetic instruments were shaken by a peculiar jolting motion. At 5.45 a.m. the magnetic registering instruments at the Observatory in the Parc de St. Maur, near Paris, exhibited the same motions. At the Lyons Observatory similar vibrations were observed at 5.55. M. Mascart remarked that these movements were simultaneous. It was not, therefore, an oscillatory movement passing from one point to another with which they had to deal, but a phenomenon which affected a large space simultaneously. He supposed there had been an electric current which had acted on all the instruments placed within its sphere of action. The form of the curves recorded was very distinct from those given by magnetic instruments when affected by storms or auroras. M. Mascart suggested that means might yet be found of predicting the approach of a seismic storm. He added that if the cause of the effects that had been observed was an electric flux, it was easy to understand why their intensity was everywhere nearly the same. A commission was appointed to examine documents which may be transmitted with reference to the earthquakes.

NOTES

A CIRCULAR to Great Britain and the other European States, and to the United States, has been forwarded by the Executive Commissioners of the Melbourne Centennial International Exhibition. The Exhibition will be opened on August 1, 1888, in order to celebrate the centenary of the founding of the colony of New South Wales, and will remain open for six months. The Commission invites the British, foreign, and colonial Governments to participate in the undertaking, and trusts that steps will promptly be taken by them for the completest possible representative display. It is pointed out that the population of Australasia is 3,500,000, that the imports of British goods annually amount in value to 32,000,000*l*., and that 7700 miles of railway are open for traffic, while over 2000 miles of line are in course of construction. Applications for space must be made before the end of August this year. The Commission desires to make the Exhibition specially interesting in manufacturing processes, machinery, &c., in motion, and objects of manual labour. There will also be a picture gallery lighted by electricity. Further information may be obtained from the Agent-General in London, or from the Executive Commissioners in Melbourne.

Mr. Robert Etheridge, Jun., of the Geological Department of the British Museum, has received the combined appointments of Palæontologist to the Department of Mines, and to the Australian Museum, Sydney, and will shortly proceed to Australia to take up the duties of the two offices. His extensive palæontological knowledge will be much missed in the British Museum.

Some days ago the Medical School of Paris elected M. Brouardel as Dean, in the place of M. Béclard, recently deceased. M. Brouardel is Professor of Forensic Medicine.

On Saturday last Mr. John Morley delivered, in the Egyptian Hall of the Mansion House, the annual address to the students of the London Society for the Extension of University Teaching. His subject was "The Study of Literature," and we need scarcely say that he set forth his ideas with his usual vigour and lucidity. But what did Mr. Morley mean by the following sentence: "I, for one, am not prepared to accept the rather enormous pretensions that are nowadays made sometimes for physical science as the be-all and end-all of education"? By whom are these "rather enormous pretensions" made? Men of science, no doubt, claim for the study of physical science a high place in education; but we have never heard that they feel disposed, on that account, to exclude the study of art and literature.

The University of St. Petersburg lately celebrated its sixty-eighth anniversary. It has 64 professors, 47 fellows, 8 lecturers, and 39 laboratory assistants. There are 2627 students, who are grouped as follows:—For Oriental languages, 87; for law, 1170; for natural science, 426; for mathematics, 618; for history and philology, 224.

We have received the four February sections of "Studies in Microscopical Science," edited by Mr. Arthur C. Cole. The text, which is finely illustrated, relates to Haustoria, the ovary and ova in birds, fatty degeneration of the kidney, and microbes.

Prof. Otto Struve's jubilee was celebrated some days ago at the Pulkowa Observatory. A great number of delegates from learned societies and scientific institutions were present.

The new journal edited by Prof. Grancher is called the *Bulletin Médical*. It appears in Paris twice a week, on Thursdays and Sundays.

In the February number of the Journal of the Anthropological Institute there is an interesting paper by Mr. Bloxam, describing eight specimens of Aroko or symbolic-letters, which have actually been used by the tribe of Jebu in West Africa. These Aroko were sent to Mr. R. N. Cust by Mr. J. A. Otonba Payne, Registrar of the Supreme Court at Lagos, who himself belongs to the tribe of Jebu. The paper is carefully illustrated. One of the figures represents a message from a native prince of Jebu, Ode, to his brother residing abroad. It consists of six cowries, all turned in the same direction. The quill of a feather is passed through them from front to back, and the shaft is turned towards the end of the quill and fixed to the side of the cowries. The significance of this symbolic group of objects depends upon the facts that, in the Jebu language, six is "E-fà," from the verb "fà," to draw, and that Africans are in the habit of cleansing their ears with a feather, and look upon it as the only instrument by which this can be effectually done. The meaning is: "By these six cowries I do draw you to myself, and you should also draw closely to me; as by the feather only I can reach to your ears, so I am expecting you to come to me, and hoping to see you immediately."

In the *Rendiconti* of the Reale Istituto Lombardo for January, Count Trevisan de Saint-Léon describes some experiments recently carried out by Dr. Bareggi in Milan, for the purpose of showing that it is possible to ascertain, from the state of the blood, whether persons bitten by animals suspected of rabies, or even undoubtedly mad, have really been infected.

The Reports of the Botanist to the New York Agricultural Experiment Station, Geneva, N.Y., Mr. J. C. Arthur, for 1885 and 1886, furnish an admirable illustration of the value of such State appointments. A large portion of both Reports is occupied with an exhaustive history of the pear-blight (*Micrococcus amylovorus*), which is exceedingly destructive to pear-trees in the Northern United States; proofs that the mischief is caused by the specific Bacterium; and suggestions for a remedy. In addition to this, much information is given with regard to the following diseases, among others: the strawberry-mildew (*Sphærotheca Castagnei*), the plum-leaf fungus (*Septoria cerasina*), the lettuce-rust (*Septoria Lactucæ*), and the lettuce-mildew (*Peronospora gangliformis*). Woodcuts are given of these various fungoid parasites, and a very useful summary is appended of the literature of the pear-blight.

An admirable lecture on "Wrought Iron" was delivered by Mr. J. Starkie Gardner at the Society of Arts on Tuesday, February 22. It is printed in the current number of the Journal of the Society of Arts, with illustrations of the exquisite iron-work in the cathedrals of York, Durham, and Winchester. The general artistic superiority of mediæval ironwork to that of later times Mr. Gardner attributes in part to the fact that in the Middle Ages important work of this kind was intrusted only to smiths who had a special aptitude for it. If such a workman was not forthcoming, the work was either not executed, or was made in the simplest form; whilst, if he were forthcoming, the details at least of the design were left to his own fancy. Mediæval smiths were not fettered by estimate or bound by time, but Mr. Gardner is of opinion that they did their work much more quickly than men do now. Otherwise, he thinks, the intricate designs used in Germany, Spain, and Portugal, for ordinary domestic purposes, could not have been produced at any price which would have suited the occupiers.

At a durbar held at Shillong in connection with the Jubilee rejoicings, Mr. Ward, Chief Commissioner of Assam, reviewed the history of the province during the last fifty years. In that time, he said, its population and settled area had been nearly trebled. The first tea plantation had been started about fifty years ago. There were now nearly 200,000 acres under tea, while the land taken up by planters, although not yet actually planted, amounted to about 400,000 acres. Again, fifty years ago the land revenue of five districts, comprising Assam proper, had been about four and a half lakhs of rupees; it had grown to twenty-six lakhs. Then the journey from Gowhatty to Debrooghur had occupied a month or six weeks; now it took three days.

Much interest has been excited by the announcement that Capt. Conder, of the Palestine Exploration Expedition, has succeeded in deciphering and translating the Hittite inscriptions. Ten principal texts are known, and Capt. Conder claims to have intepreted all of them. Three of his translations, which were published in the *Times* of Saturday last, are invocations to the sun and water gods, and, apparently, to the divinity of the moon. Capt. Conder says that not only the words, but the grammar of the inscriptions, can be shown to belong to a well-known tongue. What this tongue is, we are not to learn for some time.

WE regret to announce the death of Dr. Grothe, Professor at the Polytechnical School at Delft, author of "Mechanical Technology," and an excellent monograph on iron. He was born in Westphalia in 1806, and died on February 10 last.

PROF. HAECKEL, of Jena, has just started on a journey to the East, which will be of some months' duration. He will visit the coast of Asia Minor to continue his investigations of lower marine animals.

LIEUT. QUEDENFELDT has just returned from Morocco to Berlin, bringing with him some valuable collections: an ethnological one, which he has presented to the Anthropological Society, a collection of insects, and a large collection of the implements, tools, and instruments of torture of the Hamadjas tribe.

MESSRS. G. PHILIP AND SON have in the press a revised and enlarged edition of "The Geology of England and Wales," by Horace B. Woodward, F.G.S., of the Geological Survey of England. They will also have ready shortly "Philips' Planisphere of the Stars visible from the Countries situated about 35° south of the Equator" (uniform with "Philips' Planisphere for England"); "Rustic Walking Routes within the Twelve-mile Radius from Charing Cross," containing a field-path map of the district, with geographical description, charts, and directions, by W. R. Evans; and "Philips' Handy Volume Atlas of the World," consisting of sixty-four plates, containing upwards of one hundred maps, printed in colours, with statistical notes on each map.

MESSRS. WHITTAKER AND CO. will publish shortly a second and much enlarged edition of "Magnets and Dynamo-Electric Machines," being the first volume of their "Specialist's Series." For the new edition some revisions in the text have been made, and a preface and a chapter on the latest types of generators have been written by Mr. W. B. Esson.

A FRENCH translation has been published of Cæsar Lumbroso's "Uomo Delinquanti," with a fine series of figures to illustrate the learned author's lectures concerning the anthropological features of the professional criminal.

ADMIRAL TEISSERENC DE BORT has just published a map, showing the distribution of fog on the various parts of the earth. It is based upon observations made at 1600 land stations, and 112,000 marine ones.

IN a Report just issued, Mr. S. W. North, Medical Officer of Health, calls attention to the prevalence of typhoid fever in York during the year 1886. For many years York has been liable to outbreaks of this disease, and the fact will not surprise anyone who reads Mr. North's account of the sanitary conditions of the city.

IN a paper entitled "Ueber die Allgemeine Beugungsfigur in Fernröhren" (Mémoires de l'Académie Impériale des Sciences de St. Pétersbourg, viie. série, tome xxxiv., No. 5), Hermann Struve remarks that the old problem of the diffraction of light through a circular aperture, the source being in the axis, has been considered by Airy and others, who have given approximate solutions in special cases; but the general solution has only been made feasible by the discovery of Bessel's functions. He accordingly proceeds to develop it by the straightforward methods with which readers of modern analysis are familiar; showing how his solution accords with those previously given for the axis and for the edge of the geometrical shadow. In this latter case he remarks that the illumination is less than one-fourth that which would be obtained by removing the screen. His results are put into a useful numerical form in tables at the end of the paper.

THE last number of the *Bulletin* of the Belgian Natural History Museum contains a summary of ornithological observations made at various stations throughout Belgium during the year 1885. This is quite a novel feature, which, if carried out systematically, promises excellent results, especially as regards the many obscure questions connected with the migrations of birds of passage. The chief stations are Brussels, Hasselt, Carlsburg, and the Ostend and other lighthouses along the coast. The names of the naturalists who undertake to send in reports are given in all cases. These reports contain the name of the bird in three languages—Latin, French, and Flemish or Walloon according to the locality—followed by the dates of arrival and departure, and any other remarks tending to throw light on the habits and movements of the bird. Thus, under *Ciconia alba*, Bechst., *Cicogne blanche*, *Ooievaar* (white stork), we have, from the Nieuport Lighthouse: "Seven seen, June 18, flying westwards; rare on this coast, where they never nest.—Signed, A. Vermorke." The present summary contains 171 such entries, the value of which, when made by competent observers from year to year, ornithologists will not fail to appreciate.

THE latest advices from Honolulu report that the volcano of Mauna Loa is again in eruption, and that all the craters in the vicinity have become active.

IN the December number of the *Mineralogical Magazine*, Prof. Macadam gives the analysis of a sample of talc used in paper-making. This mineral is obtained from New Jersey. It is very largely employed for paper-making in place of China clay (kaolin), and gives, amongst other advantages, a much more pure effluent, fully 90 per cent. being retained in the paper. From its fibrous nature it appears to attach itself to the smaller paper particles, and retain these also. The very high and beautifully smooth glaze of the American papers is largely due to the use of this substance.

IN the *Mittheilungen* of the Zürich Antiquarian Society (Band xxii. Heft 1) will be found a detailed account of the recently-discovered lake-dwelling at Wallishafen, on the Lake of Zürich. The articles found were mainly bronze, but underneath the existing remains appear to be the charred fragments of an earlier dwelling, the remains of which clearly belong to the Stone Age.

A LARGE canoe, belonging to prehistoric times, was lately dragged from the bottom of the River Cher, near Vierzon, and is now in the Museum of the Society of Antiquaries at Bourges. A part of it had been visible for many years at low water, but no one understood what it was until it happened to be seen by M. Beauchard, who at once perceived its real character. When it was brought to land, fragments which had been torn or cut off by peasants were recovered and pieced together. The canoe is in the form of a trough, and is said to have a general resemblance to the ancient boat found some time ago at Brigg, in Lincolnshire. The present specimen has the special characteristic of being closed at both ends by pieces of wood fixed in vertical grooves. This device seems to have been adopted in consequence of the boat having been injured by some accident.

M. GUILMETH, the French traveller, while on a journey in Australia, discovered some bee-hives in a gigantic eucalyptus-tree, of 120 metres in height. The honey was strongly scented with the perfume of the flowers of the tree. Prof. Thomas Karaman has examined it, and believes it to have beneficial medicinal properties.

LIKE the authorities of the National Museum, Washington, the Curators of the Museum of the Academy of Natural Sciences, Philadelphia, complain that they have not nearly room enough for the display of the collections intrusted to their charge. "It is well within the truth," they state in their Report for 1886, "to say that the existing collections, if properly displayed, would completely fill a building of twice the dimensions of the present one. The large and very valuable collections of the Pennsylvania Geological Survey, contained in upwards of 200 cases, still remain in the cellar, boxed, for want of exhibition space. The types of the greater number of the fossil plants described by Lesquereux in his 'Coal Flora of the United States,' probably one of the most valuable collections of fossil plants in the world, have been added to this collection during the year, but, for similar reasons, still remain boxed. The report of the Professor of Ethnology and Archæology indicates that accessions to this department of the Academy's Museum could readily be had were proper exhibition space provided, but that under present conditions the same is impossible. In view of these facts the necessity for an extension to the Academy's building cannot be too strongly insisted upon." The Curators also urge that a fund should be raised for zoogeographical exploration. The interest derived from 50,000 dollars would, they think, fairly equip an annual expedition to any of the largely-unexplored regions lying about the dominions of the United States, such as Mexico, Central America, the Bahamas, and Labrador.

MR. ARTHUR J. BETHELL has reprinted, with additions and corrections, three articles which lately appeared in the *Field*, on a ride to the Falls of Zambesi. He has added a number of notes which may be of considerable service to men who think of spending some time in hunting in South Africa.

IT was decided some time ago that a number of the Crown diamonds of France should be sold. Others were put aside for the collections of the Paris School of Mines and Museum of Natural History; and these gems were recently given to the delegates appointed by the two Schools. The Regent diamond, a very fine one, will be kept in the Louvre Gallery.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*), a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Miss E. James; a Three-striped Paradoxure (*Paradoxurus trivirgatus*) from India, presented by Mr. Gerald Callinder; a Common Squirrel (*Sciurus vulgaris*), British, presented by Miss May Honrott; a Scop's Owl (*Scops qui*), captured at sea near Aden, presented by Mr. W. M. Holland; a White-fronted Heron (*Ardea novæ-hollandiæ*) from Australia, presented by Mr. J. B. Dyas; a Stanley Parrakeet (*Platycercus icterotis*) from West Australia, a Burmeister's Cariama (*Chunga burmeisteri*) from South-East Brazil, a Black Sternothere (*Sternothærus niger*) from West Africa, received in exchange; two Smews (*Mergus albellus* ♂ ♀), European, purchased.

OUR ASTRONOMICAL COLUMN

COMET 1887 *b* (BROOKS, JANUARY 22).—The following ephemeris for this object is by Dr. R. Spitaler (*Astr. Nach.* No. 2773).

1887 Berlin midnight	R.A. h. m. s.	Decl. ° ′	Brightness
March 4	3 37 51	51 48·5 N.	1·19
6	3 43 32	49 39·6	1·15
8	3 46 11	47 35·1	1·12
10	3 53 33	45 35·2	1·08
12	3 58 3	43 39·9	1·04
14	4 2 17	41 49·3 N.	1·00

The brightness on January 25 is taken as unity.

COMET 1887 *c* (BARNARD, JANUARY 23).—Dr. H. Oppenheim gives (*Astr. Nach.* No. 2773) the following ephemeris for Berlin midnight for this comet:—

1887	R.A. h. m. s.	Decl. ° ′	log *r*	log Δ	Brightness
March 10	21 36 44	51 59·4 N.	0·3182	0·3700	0·6
14	21 52 56	53 51·0	0·3259	0·3775	0·6
18	22 9 39	55 34·6	0·3335	0·3855	0·5
22	22 26 51	57 10·3	0.3411	0·3938	0·5
26	22 44 30	58 37·8	0·3486	0·4025	0·4
30	23 2 32	59 57·2 N.	0·3560	0·4113	0·4

The brightness at discovery is taken as unity.

COMET 1887 *d* (BARNARD, FEBRUARY 15).—Prof. Boss supplies the following elements and ephemeris for this object from observations made on February 16, 18, and 20:—

T = 1887 April 6·77 G.M.T.

$$\left.\begin{array}{l}\pi = 203^\circ\ 13'\\ \Omega = 139\ \ 16\\ \iota = 126\ \ \ 2\end{array}\right\}\text{Mean Eq. 1887·0}$$

$\log q = 9·8892$

Ephemeris for Greenwich Midnight

1887	R.A. h. m.	Decl. ° ′	Brightness
March 2	3 56·7	29 21 N.	0·38
4	3 40·0	31 18	
6	3 26·5	32 48 N.	0·32

The brightness at discovery is taken as unity.

A METHOD FOR THE DETERMINATION OF THE CONSTANT OF ABERRATION.—M. Lœwy, in reply to M. Houzeau's claim to be considered the originator of the method for determination of aberration by measurement of the relative positions of two stars situated in distant parts of the sky (NATURE, vol. xxxv. p. 377) points out, in the *Comptes rendus*, tome civ. No. 7, that the invention of a new method for the determination of the constant of aberration does not consist in a general indication of the effect of aberration on a certain observation or combination of observations, but in furnishing definite rules the following out of which will lead to results of the accuracy demanded by the exigencies of modern science. M. Lœwy maintains that M. Houzeau's researches on the subject come under the former category, whilst his own are entitled to be ranked under the latter.

The same number of the *Comptes rendus* contains a note by M. Trépied pointing out how photography can be applied for the purpose of practically carrying out M. Lœwy's method.

THE HARVARD COLLEGE OBSERVATORY.—From Prof. Pickering's Report, presented on December 7, 1886, we learn that during the past year the east equatorial has been used for the photometric observation of the eclipses of Jupiter's satellites upon the system adopted in 1878. The total number of eclipses thus observed is 358, of which 39 have occurred since the end of October 1885. With the same equatorial the observation of comparison stars for variables with the wedge photometer has been continued, and has formed the principal work of the instrument. The "new" stars in Orion and Andromeda, and comets, have also been observed with the east equatorial throughout the year. The reduction and publication of work already done with the meridian-circle is at present, in Prof. Pickering's opinion, more desirable than the prosecution of new series of observations. This department of the Observatory has sustained a heavy loss in the resignation of Prof. Rogers, who has devoted many years to laborious astronomical work at Harvard College. During the year ending November 1, 1886, 209 series of measures have been made with the meridian-photometer. The total number of separate photometric comparisons is 59,800. The instrument continues to give entire satisfaction as a means of measuring the brightness of stars of the ninth magnitude or brighter. The average deviation of 100 circumpolar stars used as standards, which, with the smaller instrument of the same kind employed in the Harvard photometry, was 0·16 of a magnitude, has been reduced to 0·12 with the present instrument; whilst the average deviation of stars from the fifth to the ninth magnitude but little exceeds 0·1 of a magnitude. And a comparison between the results obtained by Dr. Lindemann, at Pulkowa, with a Zöllner photometer, and at Harvard College, with the meridian-photometer, shows that the average deviation of a measurement of the difference in brightness between two stars observed at both places does not exceed 0·1 of a magnitude. For an account of the interesting and important researches in stellar photography which have recently been carried out at the Harvard College Observatory, see NATURE, vol. xxxv. p. 37.

NEW MINOR PLANET.—A new minor planet, No. 265, was discovered on February 27, by Herr Palisa, at Vienna. This is the fifty-eighth that Herr Palisa has discovered.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *MARCH* 6–12

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 6

Sun rises, 6h. 37m.; souths, 12h. 11m. 28·1s.; sets, 17h. 46m.; decl. on meridian, 5° 40′ S.: Sidereal Time at Sunset, 4h. 43m.

Moon (Full on March 9) rises, 13h. 39m.; souths, 21h. 29m.; sets, 5h. 10m.*; decl. on meridian, 17° 4′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	6 54	13 15	19 36	3 22 N.
Venus	7 20	13 35	19 50	2 16 N.
Mars	7 0	12 54	18 48	1 58 S.
Jupiter	22 19*	3 21	8 23	12 2 S.
Saturn	12 2	20 11	4 20*	22 28 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

Occultations of Stars by the Moon (visible at Greenwich)

March	Star	Mag.	Disap. h. m.	Reap. h. m.	Corresponding angles from vertex to right for inverted image ° °

ON RADIANT-MATTER SPECTROSCOPY:—EXAMINATION OF THE RESIDUAL GLOW[1]

I.

THE duration of phosphorescence after cessation of the exciting cause is known to vary within wide limits of time, from several hours in the case of the phosphorescent sulphides to a minute fraction of a second with uranium glass and sulphate of quinine. In my examinations of the phosphorescent earths glowing under the excitement of the induction discharge *in vacuo*, I have found very great differences in the duration of the residual glow. Some earths continue to phosphoresce for an hour or more after the current is turned off, while others cease to give out the light the moment the current stops. Having succeeded in splitting up yttria into several simpler forms of matter differing in basic power (Roy. Soc. Proc. vol. xl. pp. 502-509, June 10, 1886), and always seeking for further evidence of the separate identity of these bodies, I noticed occasionally that the residual glow was of a somewhat different colour to that it exhibited while the current was passing, and also that the spectrum of this residual glow seemed to show, as far as the faint light enabled me to make out, that some of the lines were missing. This pointed to another difference between the yttrium components, and with a view to examine the question more closely I devised an instrument similar to Becquerel's phosphoroscope, but acting electrically instead of by means of direct light.

The instrument, shown in Fig. 1, A and B, consists of an opaque disk, *a b c*, 20 inches in diameter, and pierced with twelve openings near the edge as shown. By means of a multiplying wheel, *d*, and band, *e f*, the disk can be set in rapid rotation. At each revolution a stationary object behind one of the apertures is alternately exposed and hidden twelve times. A commutator, *g* (shown enlarged at Fig. 1, B), forms part of the axis of the disk. The commutator is formed of a hollow cylinder of brass round a solid wooden cylinder. The brass is cut into two halves by a saw cut running diagonally to and fro round it, so as to form on each half of the cylinder twelve deeply cut teeth interlocking, and insulated from those on the opposing half cylinder by an air space about 2 mm. across. Only one half, *h h h*, of the cylinder is used, the other, *i i i*, being idle; it might have been cut away altogether were it not for some little use that it is in saving the rubbing-spring, *j*, from too great friction when passing rapidly over the serrated edge. To a block beneath the commutator are attached two springs, one, *k*, rubbing permanently against the continuous base of the serrated hemicylinder *h h*, and the other, *j*, rubbing over the points of the teeth of *h h*. By connecting these springs with the wires from a battery it will be seen that rotation of the commutator produces alternate makes and breaks in the current. The spring, *j*, rubbing against the teeth is made with a little adjustment sideways, so that it can be said to touch the points of the teeth only, when the breaks will be much longer than the makes, or it can be set to rub near the base of the teeth, when the current will remain on for a much longer time and the intervals of no current will be very short. By means of a screw, *l l*, attached to the spring, any desired ratio between the makes and the breaks can be obtained. The intermittent primary current is then carried to an induction coil, *m*, the secondary current from which passes through the vacuum tube, *n*, containing the earth under examination. When the commutator, the coil-break, and the position of the vacuum tube are in proper adjustment, no light is seen when looked at from the front if the wheel is turned slowly (supposing a substance like yttria is being examined), as the current does not begin till the tube is obscured by an intercepting segment, and it ends before the earth comes into view. When, however, the wheel is turned more quickly, the residual phosphorescence lasts long enough to bridge over the brief interval of time elapsing between the cessation of the spark and the entry of the earth into the field of view, and the yttria is seen to glow with a faint light, which becomes brighter as the speed of the wheel increases.

To count the revolutions, a projecting stud, *o*, is fastened to the rotating axis, and a piece of quill, *p*, is attached to the fixed support, so that at every revolution a click is produced. With a chronograph watch it is easy in this way to tell the time, to the tenth of a second, occupied in ten revolutions of the wheel.

Under ordinary circumstances it is almost impossible to detect any phosphorescence in an earth until the vacuum is so high that the line spectrum of the residual gas begins to get faint; otherwise the feeble glow of the phosphorescence is drowned by the greater brightness of the glowing gas. In this phosphoroscope, however, the light of glowing gas does not last an appreciable time, whilst that from the phosphorescent earth endures long enough for it to be caught in the instrument. By this means, therefore, I have been able to see the phosphorescence of yttria, for example, when the barometer gauge was 5 or 6 mm. below the barometer.

When the earth under examination in the phosphoroscope is yttria free from samaria, and the residual emitted light is ex-

[1] Paper read before the Royal Society by Mr. William Crookes, F.R.S., on Feb. 17.

amined in the spectroscope, not all the bands appear at the same speed of rotation. At a slow speed the double greenish-blue band of Gβ (545) first comes into view, closely followed by the deep blue band of Gα (482). This is followed, on increasing the speed, by the bright citron band of Gδ (574), and at the highest speed the red band of Gζ (619) is with difficulty seen.

The following are measurements of the time of duration of the phosphorescences of the different constituents of yttrium. The wheel was first rotated slowly, until the first line visible in the spectroscope attached to the phosphoroscope appeared; the speed was counted, and it was then increased until the line next visible was seen. In this way the minimum speed of revolution necessary to bring each line into view was obtained, and from these data the duration of phosphorescence for each constituent

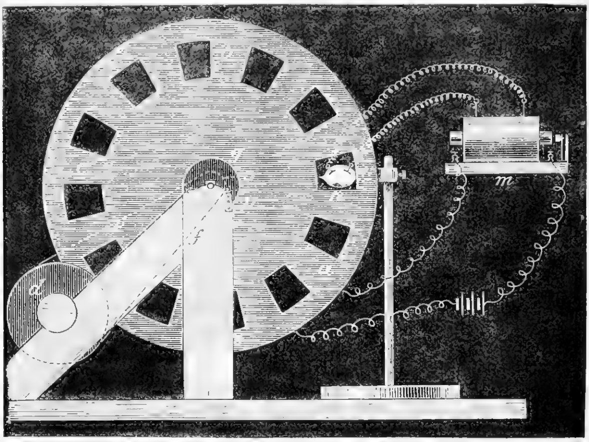

Fig. 1, A.

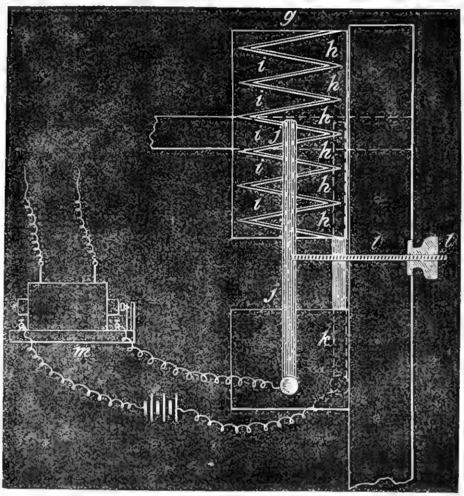

Fig. 1, B.

of yttria was calculated. The time in the following table represents in decimals of a second the time elapsing between the cessation of the induction discharge and the visibility of the residual glow of the earth :—

At 0·00[illegible]5 sec. interval the green and blue lines of Gβ and Gα begin to be visible.

At 0·0032 sec. interval the citron line of Gδ begins to be visible.

At 0·00175 ,, the deep red line of Gζ (647) is just visible.

At 0·00125 ,, the line of Gδ is almost as bright as that of Gβ, and the red line of Gη is visible.

At 0·000875 sec. interval the highest speed the instrument could be revolved with accuracy, the whole of the lines usually seen in the yttria spectrum could be seen of nearly their usual brightness.

I have already recorded (Phil. Trans., 1883, Part III. pp. 914–16), that phosphate of yttria, when phosphoresced *in vacuo*, gives the green lines very strongly whilst the citron band is hazy and faint. The same tube of yttric phosphate was now examined in the phosphoroscope. The green lines of Gβ soon showed themselves on setting the wheel into rapid rotation, but I was unable to detect the citron band of Gδ even at a very high speed.

The effect of calcium on the phosphorescence of yttria and samaria has been frequently referred to in my previous papers. It may save time if I summarise the results here. About 1 per cent. of lime added to a badly phosphorescing body containing yttrium or samarium always causes it to phosphoresce well. It diminishes the sharpness of the citron line of Gδ but increases in brightness. It also renders the deep blue line of Gα extremely bright. The green lines of Gβ are diminished in brightness. Lime also brings out the phosphorescence of samarium, although by itself, or in the presence of a small quantity of yttrium, samarium scarcely phosphoresces at all.

In the phosphoroscope the action of lime on yttrium is seen to entirely alter the order of visibility of the constituents of yttrium. In a mixture of equal parts yttrium and calcium, the citron Gδ line is the first to be seen, then comes the Gα blue line, then the Gβ green line, and finally the Gη red line. This may, I think, be explained somewhat as follows:—Calcium sulphate has a long residual phosphorescence, whilst yttrium sulphate has a comparatively short residual phosphorescence. Now with yttrium, although the green phosphorescence of Gβ lasts longest, it does not last nearly so long as that of calcium sulphate. The long residual vibrations of the calcium compound induce, in a mixture of calcium and yttrium, phosphorescence in those yttric molecules (Gδ) whose vibrations it can assist, in advance of those (Gβ) to which it is antagonistic; the line of Gδ therefore appears earlier in the phosphoroscope than that of Gβ, although were calcium not present the line of Gβ would appear first.

Experiments were now tried with different mixtures of yttria and lime as ignited sulphates, to see where the special influence of lime on Gδ ceased.

Yttrium	Calcium	
Per cent.	Per cent.	
97½	2½	Order of appearance in the phosphoroscope.—Gβ, Gα, Gδ, and Gη. The citron line of Gδ is only to be seen at a high speed, and is then very faint.
95	5	Order of appearance in the phosphoroscope.—Gα, Gβ, and Gδ (citron and blue) together, and lastly Gη (red). At a very high speed the green lines of Gβ become far more luminous than any other line.
90	10	Order of appearance.—Gδ and Gα together, then Gβ, and lastly Gη.
80	20	Order of appearance.—Gδ and Gα simultaneously, then Gβ, and lastly Gη. The residual phosphorescence lasts for 30 seconds after the current stops. The light of this residual glow is entirely that of Gδ. The line of Gβ comes into view at an interval of 0·0015 second. At 0·00175 second the line of Gη is just visible.
60 50 40	40 50 60	Order of appearance.—Gδ and Gα together, then Gβ and Gη together.
30 10 5	70 90 95	Order of appearance.—Gδ, Gα, Gβ.
1	99	Order of appearance.—Gδ, Gα. The green lines of Gβ could not be seen in the phosphoroscope; they would probably be obliterated by the stronger green of the continuous spectrum given by the calcium.

The action of barium on yttrium was now tried. The following mixtures (as ignited sulphates) were made:—

Yttrium	Barium	
Per cent.	Per cent.	
95 90 80	5 10 20	In the phosphoroscope the Gβ line appears earliest, but the blue Gα line is the next to be seen, whilst the red line of Gη is the latest in appearing. As the percentage of yttrium increases the blue line more and more overtakes the red and increases in brightness.
70 60 50 40 30 25	30 40 50 60 70 75	Spectrum similar to the above. As the percentage of yttrium increases the spectrum grows brighter. In the phosphoroscope the earliest line to appear is the Gβ green, then the Gη red, and next closely following it the Gα blue.
20 15 10 5	80 85 90 95	In the radiant-matter tube all these mixtures give similar spectra. The Gβ green is a little brighter and the Gδ citron is a little fainter than in the corresponding mixtures of yttrium and calcium, but the whole of the yttrium lines are seen. In the phosphoroscope the Gβ green is the first to appear, then the Gη red. The Gδ citron is not visible at any speed.
1	99	Red line of Gη is much brighter; Gδ is very faint, and the green of Gβ is stronger. In the phosphoroscope the order of appearance is,—first the line of Gβ, then the red line of Gη.
0·5	99·5	Phosphoresces with difficulty, of a light blue colour, but turns brick-red in the focus of the pole. Spectrum very faint. Order of appearance to phosphoroscope,—Gβ first, the others too faint to be seen.

The next experiments were tried with strontium, to see what modification the addition of this body to yttrium would produce. The following mixtures of ignited sulphates were experimented with:—

Yttrium	Strontium	
Per cent.	Per cent.	
95	5	A very good yttrium spectrum. In the phosphoroscope the order of appearance is,—first the green of Gβ, then the Gα blue, lastly the Gη red. No Gδ citron line could be seen.
80	20	In the phosphoroscope the green of Gβ is very prominent at a low speed, standing out sharply against a black background. With a higher velocity the Gα and Gη lines come into view.
60 40	40 60	The ordinary spectrum of this and the neighbouring mixtures is very rich in the citron line of Gδ, but I entirely fail to see a trace of this line in the phosphoroscope at any speed. The line of Gβ is the first to come, then the blue line of Gα.
35	65	At about this point a change comes over the appearance in the phosphoroscope. The blue line of Gα is now the earliest to appear, and it is followed by the Gη red and Gβ green. No Gδ line is seen.
25 15 5 0·5	75 85 95 99·5	These mixtures are very similar to each other in the phosphoroscope. The line of Gα comes first, next the Gη line, then Gβ line. No Gδ citron line has been seen in any of these mixtures.

In a paper read before the Royal Society, June 18, 1885, (Phil. Trans., 1885, Part II., p. 716), I described the phosphorescence spectrum given by a mixture of 61 parts yttrium and 39 parts of samarium, and illustrated it by a coloured lithograph. Also in a paper read before the Royal Society, February 25, 1886 (Roy. Soc. Proc. vol. xl. p. 236), I described and figured the phosphorescent spectrum of an earth obtained in the fractionation of yttria which was identical, chemically and spectroscopically, with an earth discovered by M. de Marignac, and provisionally called by him Yα. I repeat here these spectra, and the spectrum of yttrium added for comparison. Omitting minor details, it is seen that the Yα spectrum is identical with

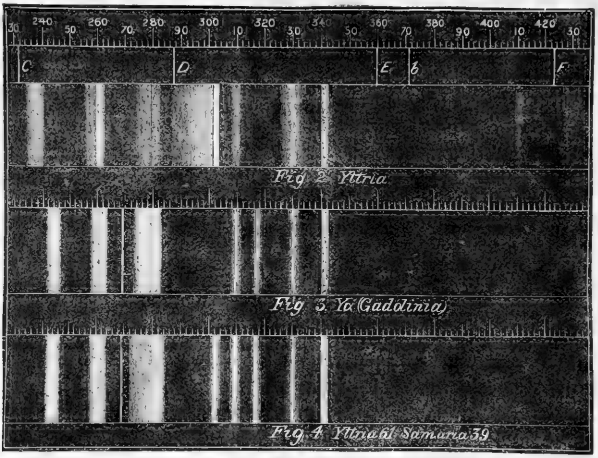

Fig. 2 Yttria

Fig. 3 Yα (Gadolinia)

Fig. 4 Yttria 61 Samaria 39

that of the mixture yttrium 61, samarium 39, with one important exception—the citron line of Gδ in the former spectrum is absent in the latter. Could I by any means remove Gδ from the mixture of yttrium and samarium the residue would be Yα. I have little doubt that this will soon be accomplished, but in the meantime the phosphoroscope enables us to remove the line of Gδ from the mixture. It is only necessary to add strontium to a suitable mixture of yitrium and samarium and view the phosphorescing mixture in the instrument when the wheel is rotating rapidly, to obtain a spectrum which is indistinguishable from that of Yα.

(To be continued.)

PRE-SCIENTIFIC THEORIES OF THE CAUSES OF EARTHQUAKES

IN the course of a lecture delivered recently before the Rigaku Kyôkai, or Science Society of Tokio, on the causes of earthquakes, Prof. Milne classified the theories as to the cause of these phenomena into three kinds—unscientific, *quasi*-scientific, and scientific. In the former class he included the explanations of the Negro preachers at Charleston after the late earthquakes there, that they occurred in consequence of the wickedness of the population. The Mussulmans in Java recently prayed to the volcanoes there to cease their shakings, at the same time promising reformation of life. That earthquakes are the direct result of man's wickedness is an idea that has always been common. About 1750 earthquakes were felt in many parts of Europe, which were widely attributed to this cause, and innumerable sermons were preached inculcating the lesson that if mankind would live better lives there would be no more earthquakes. In 1786, after a shock at Palermo, the people are recorded to have gone about scourging themselves, and looking extremely humble and penitent. An English poem called "The Earthquake," published in 1750, alleged, in somewhat halting verse, that the disturbances were not due to an unknown force, nor to the groanings of the imprisoned vapours, nor yet to the shaking of the shores with fabled Tridents:—

"Ah no! the tread of impious feet
The conscious earth impatient bears
And shuddering with the guilty weight,
One common grave for her bad race prepares."

From this theory, which can scarcely have satisfied the poet himself, Prof. Milne passed on to the myths which attribute earthquakes to a creature living underground. In Japan it is an "earthquake-insect" covered with scales, and having eight legs, or a great fish having a certain rock on his head which helped to keep him quiet. In Mongolia the animal was said to be a frog, in India the world-bearing elephant, in the Celebes a world-supporting hog, in North America a tortoise. In Siberia there was a myth, connected with the great bones found there, that these were the remains of animals that lived underground, the trampling of which made the ground shake. In Kamchatka the legend was connected with a god, Tuil, who went out hunting with his dogs. When these latter stopped to scratch themselves, their movements produced earthquakes. In Scandinavian mythology, Loki, having killed his brother Baldwin, was bound to a rock face upwards, so that the poison of a serpent should drop on his face. Loki's wife, however, intercepted the poison in a vessel, and it was only when she had to go away to empty the dish that a few drops reached him and caused him to writhe and shake the earth. The lecturer had no means of collecting the fables of the southern hemisphere; but they would obviously be worth knowing for purposes of comparison. As to *quasi*-scientific theories, these endeavoured to account for earthquakes as parts of the ordinary operations of Nature. It was supposed, for instance, that they were produced by the action of wind confined inside the earth. The Chinese philosophers said that Yang, the male element, entered the earth and caused it to expand, and to shake the ground in its efforts to escape. Its effects would be more violent beneath the mountains than in the plains, and therefore earthquakes in the north of China, which was mountainous, were said to be more violent than those in the south. It was supposed that when the wind was blowing strongly on the surface of the earth, there was calm beneath, and *vice versâ*. Aristotle and many other classical writers attributed earthquakes to wind in the earth. Shakespeare, in "Henry IV.," speaks of the teeming earth being pinched and vexed with a kind of colic by the imprisoning of unruly wind within her womb. Then came the theory of electrical discharges, which was advocated in 1760 by Dr. Stukely, as well as by Percival and Priestley. They are strongly held in California at the present day, where it was believed that the network of rails protected the State against any dangerous accumulation of electricity. But Prof. Milne showed that the laying down of rails in Japan had no such effect. He thought the electric phenomena which sometimes attended earthquakes were their consequences, not their causes. He had himself experimented with dynamite placed in a hole; an earth-plate was fixed about thirty yards away from the dynamite, and from it a wire was carried some distance to another earth-plate. When the dynamite charge was exploded there was certainly a current produced, as was indicated by a strong deflection of a galvanometer-needle at the end of the wire. He attributed this to chemical action. When the ground was shaken there was always a greater or less action by increase or decrease of pressure in connection with the earth-plate. Earth currents unquestionably accompany earthquakes, but, as has been said, they appear to be the consequences, not the causes, of the latter. Next came the chemical theories, which were very strong in Europe up to the beginning of the present century. It was imagined that underground there were various substances, such as sulphur, nitre, vitriol, which, by their action on each other, resulted in violent changes, giving rise to vapour, the sudden production of which, in certain cases, would shake the ground. It was only in 1760 that Dr. Mitchell, who wrote a good deal on the subject, first threw out the theory that earthquakes were connected in some way with volcanoes, because they were most frequent in volcanic countries. He observed that large quantities of steam were given off from volcanoes, and came to the conclusion that an earthquake was produced at the time that an attempt was made to form a volcano, that steam got in between certain strata, and, as it ran between them, caused pulsations. Prof. Rogers, about the same time, in North America, endeavoured to show that it was not steam, but really lava, that ran along underneath the ground, causing it to rise and fall, thus producing an earthquake. Prof. Milne having thus dealt with unscientific and *quasi*-scientific theories, passed on to those of modern science. It is unnecessary here to follow him into this portion of his subject, although it occupied the main part of the lecture.

ON THE EFFECT OF CERTAIN STIMULI ON VEGETABLE TISSUES[1]

THE object of our paper is to describe the behaviour of turgescent pith when placed in water and treated with certain reagents. If from a growing shoot the external tissues be removed, a well-known result is seen: the pith suddenly lengthens, becoming longer than the specimen was at first. This experiment shows that turgescent pith is normally in a compressed condition—it is always trying to get longer—and when it is freed from the coercion of the unyielding external tissues, it at once does become longer. This tendency to become longer is further manifested by allowing turgescent pith to remain in damp air, or in water, for some time, when a great increase in length takes place. In such a piece of pith we have the essential, active factor in growth, freed from interference, and at liberty to perform its function rapidly and freely. The tendency in turgescent pith to get longer is the very power which calls forth that increase in length which we call growth; so that in studying turgescent pith we are studying the active agent in the production of growth. We do not suppose that our results are necessarily directly applicable to normal growth,[2] but we think that they have a bearing on normal growth sufficiently close to give interest to our experiments.

The pith,[3] after being cut into pieces about 6 inches in length and ⅓ inch in thickness, was ready for use. The lower end of the pith was fixed to a hook at the bottom of a narrow jar, the upper end was attached by a silk thread to the short arm of an auxanometer lever. The jar was then filled with water, and as the pith elongates the short arm of the lever ascends and the long arm rapidly descends. Its movement, read off on a millimetre scale, gives an index of the rate of "growth" of the pith. The lengthening of the pith is, in fact, observed like the normal growth of a plant, the only difference being that the "growth" of the pith is so rapid that the descent of the long arm is clearly visible to the naked eye and is correspondingly easy to measure. It is most striking to see the index travelling down thus quickly and traversing (it may be) 10 mm. (⅖ inch) in a minute. We used a stop-watch to determine the time in which the point of the long arm of the lever travelled over a certain distance, and we could thus estimate the changes in the rate of growth from minute to minute.

The first thing needful to know is the ordinary course of growth of the pith in water. It was found that an interesting phenomenon—an apparent *grand period*—takes place. That is to say, the growth is at first slow, then more rapid, and ultimately becomes slow again, the whole period taking perhaps twenty minutes to complete. This is precisely the series of changes which a growing organ exhibits in the course of days instead of minutes. We do not suppose that our grand period is necessarily of a kindred nature to the grand period of normal growth. For we are aware that purely mechanical processes, such as the moistening of a hygroscopic awn, exhibit the same thing—the awn at first untwists slowly, then more quickly, and then again slowly. But the knowledge of the fact is of great importance to us, since unless we know the normal course of growth we cannot study the effect of reagents.

Warmth.—Before going on to consider the action of reagents, we will say a few words as to the stimulation caused by an increase in the surrounding temperature. If the water in the jar is gradually warmed, the growth of the pith increases in speed in the most striking manner. The increase is fairly steady from, say, 17° C. to about 35°, the rate at this latter temperature being perhaps four times as high as it was at first. It then usually becomes irregular, with some diminution; and, just before a temperature is reached which kills the tissues, a sudden and rapid fall in the rate of growth sets in. This we found usually to occur at about 55° C. This is, no doubt, an unusually high temperature, but not higher than plants are known to be able to survive.

The chief interest in these temperature experiments is this: they show that the phenomena we are considering is a truly vital one. We have always been on our guard in this matter, and have wished to make certain that the observed phenomena are not in some mysterious way mechanical, instead of, as we believe, the response of living tissues *as* living tissues. Therefore, when we find that heat has a normal effect on our material, we are encouraged to believe that our other results—to which we now pass on—are also vital phenomena.

Alcohol.—The pith was attached to the auxanometer, and the jar filled with water. As soon as the rate of growth was found to be steadily diminishing, a small quantity of alcohol was added. The result was an immediate and striking increase in the rate of growth. For instance, when 2 per cent. of spirit was added, the growth was accelerated within two minutes by 50 per cent.

The result is temporary, so that in the course of another two minutes the rate of growth sinks to what it was before stimulation. Similar results were obtained with ether, and here the pith was allowed to grow in damp air, and was subjected to ether in the form of vapour. When the vapour was present in the proportion of 0·27 per cent., the acceleration was 56 per cent.; with 0·4 per cent., the acceleration was 100 per cent. Here, as in the case of alcohol, the result was temporary, the rate falling in a few minutes to what it was before stimulation.

When the ether amounts to 3 per cent. of the atmosphere, the pith is killed, and shows no increase, but, on the contrary, a decrease[1] in length. Elfving has shown that ether has a stimulating effect on respiration, and on the sensitiveness of swarm-spores to light. He also tested its effect on the growth of phycomyces. His results differ from ours, inasmuch as he found no stimulating effect: the ether produced either no effect whatever, or else it retarded, or even stopped, growth.

Ammonia.—We employed the *Liquor Ammoniæ fortior* of the "British Pharmacopœia" for the preparation of our solutions, and we found that various strengths ranging between 0·5 and 2·4 per cent. produced acceleration of growth. Here again, as with ether and alcohol, the acceleration was very temporary.

Acids.—As a rule, acids produced no acceleration, but caused either retardation, or flaccidity and death. Thus, for instance, acetic acid (0·5 and 1 per cent.) produced retardation; 5·4 per cent. produced death.

Hydrocyanic Acid did not cause flaccidity such as we have described in the case of acetic acid. The action of this reagent is comparable rather to that of alcohol, but is not

[1] Abstract of a Paper by Anna Bateson (Newnham College) and Francis Darwin (Cambridge), read before the Linnean Society, January 20, 1887.

[2] For the sake of convenience we shall nevertheless use the word "growth" to mean the elongation of the pith under observation.

[3] Sunflower and Jerusalem Artichoke.

[1] This contraction is simply a symptom of flaccidity, and usually of death.

identically the same. It produces either a temporary acceleration, such as is due to alcohol, or else a remarkably steady and high rate of growth. On the action of this reagent we hope to make further observations.

Quinine Chloride.—Extremely dilute solutions acted poisonously, and produced a shortening of the tissues. When contraction took place it was manifested within a remarkably short time. In one case contraction seemed to begin simultaneously with the exposure to the poison, and was certainly well marked in less than one minute.

Conclusion.—The most interesting fact which we have established is the possibility of stimulating turgescent tissues to increased elongation by such reagents as alcohol, ether, and hydrocyanic acid. And we incline to think that our results may help to direct attention to a factor in the problem of cell-mechanism—namely, the protoplasmic element, rather than the purely osmotic side of the question.

SOCIETIES AND ACADEMIES

London

Royal Society, February 24.—"On the Relation between Tropical and Extra-Tropical Cyclones." By the Hon. Ralph Abercromby. Communicated by Mr. R. H. Scott, F.R.S.

All cyclones have a tendency to assume an oval form; the longer diameter may lie in any direction, but has a decided tendency to range itself nearly in a line with the direction of propagation. Tropical cyclones have less tendency to split into two, or to develop secondaries than those in higher latitudes. A typhoon which has come from the tropics can combine with a cyclone that has been formed outside the tropics, and form a single new, and perhaps more intense, depression. There is much less difference in the temperature and humidity before and after a tropical cyclone than in higher latitudes. The quality of the heat in front is always distressing in every part of the world.

The wind rotates counter-clockwise round every cyclone in the northern hemisphere, and everywhere as an ingoing spiral. The amount of incurvature for the same quadrant may vary during the course of the same cyclone; but in most tropical hurricanes the incurvature is least in front, and greatest in rear; whereas in England the greatest incurvature is usually found in the right front. Some observers think that broadly speaking the incurvature of the wind decreases as we recede from the equator. The velocity of the wind always increases as we approach the centre in a tropical cyclone; whereas in higher latitudes the strongest winds and steepest gradients are often some way from the centre. In this peculiarity tropical cyclones approximate more to the type of a tornado; but the author does not think that a cyclone is only a highly developed whirlwind, as there are no transitional forms of rotating air.

The general circulation of a cyclone, as shown by the motion of the clouds, appears to be the same everywhere. All over the world, unusual coloration of the sky at sunrise and sunset is observed, not only before the barometer has begun to fall at any place, but before the existence of any depression can be traced in the neighbourhood. Cirrus appears all round the cloud area of a tropical cyclone, instead of only round the front semicircle, as in higher latitudes. The alignments of the stripes of cirrus appear to be more radial from the centre in the tropics, than tangential, as indicated by the researches of Ley and Hildebrandsson in England and Sweden respectively. Everywhere the rain of a cyclone extends farther in front than in rear. Cyclone rain has a specific character, quite different from that of showers or thunderstorms; and this character is more pronounced in tropical than in extra-tropical cyclones.

Squalls are one of the most characteristic features of a tropical cyclone, where they surround the centre on all sides; whereas in Great Britain, squalls are almost exclusively formed along that portion of the line of the trough which is south of the centre, and in the right rear of the depression. As, however, we find that the front of a British cyclone tends to form squalls when the intensity is very great, the inference seems justifiable that this feature of tropical hurricanes is simply due to their exceptional intensity.

A patch of blue sky, commonly known as the "bull's-eye," is almost universal in the tropics, and apparently unknown in higher latitudes. The author's researches show that in middle latitudes the formation of a "bull's-eye" does not take place when the motion of translation is rapid; but as this blue space is not observed in British cyclones when they are moving slowly, it would appear that a certain intensity of rotation is necessary to develop this phenomenon.

The trough phenomena,—such as a squall, a sudden shift of wind, and change of cloud character and temperature, just as the barometer turns to rise, even far from the centre—which are such a prominent feature in British cyclones,—have not been even noticed by many meteorologists in the tropics. The author, however, shows that there are slight indications of these phenomena everywhere; and he has collated their existence and intensity with the velocity of propagation of the whole mass of the cyclone.

Every cyclone has a double symmetry. One set of phenomena, such as the oval shape, the general rotation of the wind, the cloud ring, rain area, and central blue space, are more or less related to a central point. Another set, such as temperature, humidity, the general character of the clouds, certain shifts of wind, and a particular line of squalls, are more or less related to the front and rear of the line of the trough of a cyclone. The author's researches show that the first set are strongly marked in the tropics, where the circulating energy of the air is great, and the velocity of propagation small; while the second set are most prominent in extra-tropical cyclones, where the rotational energy is moderate, and the translational velocity great. The first set of characteristics may conveniently be classed together as the rotational, the second set as the translational, phenomena of a cyclone.

Tropical and extra-tropical cyclones are identical in general character, but differ in certain details, due to latitude, surrounding pressure, and to the relative intensity of rotation or translation.

Linnean Society, February 17.—Mr. W. Carruthers, F.R.S., President, in the chair.—The Rev. A. Johnson exhibited drawings of an abnormal *Begonia Veitchii* grown by him the preceding autumn. The peculiarity consisted in the flower having a single, large, flask-shaped, ovarian-like organ (?) placed centrally, and surmounted by a single, simple, straight style; thus, though doubtless a male, indicating an hermaphrodite condition, while presenting resemblances to the normal female organs of *Laurus nobilis*.—Mr. E. M. Holmes exhibited some irregularly-developed lemons, in which the carpels were more or less separated at the apex; the arrest of the normal union of the carpel being attributed to the bite of an insect in the early stage of the growth of the fruit.—There were exhibited, for Mr. J. G. Otto Tepper, a new *Stylidium* (*S. Tepperiana*, F. Muell.), collected in November 1886 on Mount Taylor, Kangaroo Island, Victoria, Australia. It was found in the interstices of a Tertiary limestone. Other trees which grew in the neighbourhood were stunted Eucalypts, Hawkeas, and an Acacia somewhat resembling *A. pycnantha*.—Sir J. Lubbock drew attention to examples of *Peziza coccinea* from Ilfracombe.—A dried specimen of *Primula imperialis*, Jungh., collected by Dr. Sydney Hickson in Java, was exhibited from the Royal Gardens, Kew. This species is a giant form of *Primula*, being over 3 feet in height. Plants of this Himalayan and Malayan species are now under cultivation at Kew, and form an interesting addition to this popular group of garden plants.—Mr. G. Maw showed two rare Narcissi, both known under the name of *N. cernuus*. The daffodil discovered by Mr. Buxton in the Pyrenees at 7000 feet altitude is interesting as the only white form known in a wild habitat. A diminutive, orange-coloured species, flowered by the Rev. C. Wolley Dod from bulbs collected by Dr. Henriques, of Coimbra, appears to be allied to *N. triandrus*.—Sir J. Lubbock read the second part of his paper on phytobiological observations, and on the leaf of *Liriodendron*. In *Œnothera bistorta* the seed-leaves are linear, terminating in a large round expansion. There is nothing to account for it in the seed, nor does it appear to be of any advantage to the young plant. On watching the growth, however, and comparing it with that of other allied species, the explanation appears to be as follows: the cotyledons are at first round, but a growth takes place at the base of the cotyledon, which closely resembles that of the subsequent leaves, hence their peculiar figure in this species. In allied species the seed-leaves consist of two parts, a terminal portion—the true or original cotyledon—and a subsequent growth resembling in each species their true leaves. With reference to seed-leaves in which the stalks are connate, *e.g.* *Smyrnium*, the union seems clearly advantageous as giving additional strength. Other characters in various species, *Plantago*, *Tilia*, *Heliophila*, *Cardamine*, &c., were instanced. As to the tulip-tree (*Lirio-*

dendron), for long a puzzle by the peculiar saddle shape of the leaves, after testing various other suggestions which had proved untenable, Sir John described the structure of the bud and the manner in which the young leaves were packed in it, and showed that the peculiar manner in which the young leaves are arranged, satisfactorily accounts for the well-known and very remarkable form of the leaf.—A paper was read on *Dichelaspis pellucida*, by Dr. Hoek, of Leyden. The cirripede in question was got from the scales of a water-snake in the Mergui Archipelago by Dr. J. Anderson, and this is believed to be the first record of the species since Charles Darwin wrote his classic monograph on the group thirty-five years ago.

Zoological Society, February 15.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of January 1887, and called special attention to two Blakiston's Owls (*Bubo blackistoni*) from Japan, presented by Mr. J. H. Leech; three Hooker's Sea-Lions (*Otaria hookeri*), presented by the Hon. W. J. M. Larnach, Minister of Marine of New Zealand; and a Blue Penguin (*Eudyptula minor*) from Cook's Straits, New Zealand, presented by Mr. Bernard Lawson.—Prof. F. Jeffrey Bell read a report on a collection of Echinodermata made in the Andaman Islands by Colonel Cadell. The collection was stated to contain 100 examples referable to 50 species.—Mr. G. A. Boulenger read a paper on a collection of Reptiles and Batrachians made by Mr. H. Pryer in the Loo Choo Islands. The author observed that exceptional interest attached to this collection, seeing that it was the first herpetological collection that had reached Europe from that group of islands. Two new species were described, viz. *Tachydromus smaragdinus* and *Tropidonotus pryeri*.—Mr. Oldfield Thomas read a paper on the small Mammals collected in British Guiana by Mr. W. L. Sclater. The collection contained thirteen specimens belonging to eight species, of which one was new; this the author proposed to describe as *Hesperomys* (*Rhipidomys*) *sclateri*.—Mr. G. A. Boulenger pointed out the characters of a new Geckoid Lizard from British Guiana. The specimen in question was contained in a small collection of Reptiles made by Mr. W. L. Sclater on the Pomeroon River. The author described it as *Gonatodes annularis*.—A communication was read from Mr. Charles O. Waterhouse, containing an account of a new parasitic Dipterous Insect of the family Hipposcidæ. The author stated that this insect had been found on a species of Swift (*Cypselus melanoleucus*), by Dr. R. W. Shufeldt, at Fort Wingate, New Mexico. It was closely allied to *Anapera pallida*, a European dipterous parasite found on *C. apus*, and was proposed to be named *Anapera fimbriata*.—Mr. John H. Ponsonby communicated, on behalf of Mr. Andrew Garrett, the first part of a paper on the Terrestrial Mollusks of the Viti or Fiji Islands.—Mr. F. E. Beddard read a paper on the structure of a new genus of Lumbricidæ (*Thamnodrilus*) discovered by Mr. W. L. Sclater in British Guiana, which he proposed to characterise as *Thamnodrilus gulielmi*.

Anthropological Institute, Feb. 8.—Mr. Francis Galton, F.R.S., President, in the chair.—A paper was read by Sir Charles Wilson on the tribes of the Nile Valley north of Khartoum. Sir Charles Wilson opened his paper by remarking on the extraordinary way in which the various races inhabiting the Nile Valley—with many of whom he had come in contact in the course of the Nile Expedition—had become mixed up, and how completely the indigenous population had in certain cases lost its nationality while absorbing its Arab conquerors. The tribes of the Nile Valley north of Khartoum might be divided into three groups, the Hamitic, the Semitic, and the Nuba, all alike claiming descent from the Koreish of Mecca. Sir C. Wilson then proceeded to give briefly a history of the different tribes from the earliest times, describing in detail the peculiarities and physical characteristics of each race. A number of Soudanese weapons, lent by Sir Allen Young, were exhibited.

PARIS

Academy of Sciences, February 21.—M. Gosselin, President, in the chair.—Determination of the constant of aberration: first method of observation, by M. Lœwy. In this paper the author proceeds to explain successively the geometrical properties on which depend the various methods of estimating the constant of aberration. The first of the two processes is here dealt with, which, although somewhat less rigorous than the general method, practically yield results of the greatest precision, while also enabling the observer to determine two other physical constants—the variation of refraction caused by change either of temperature or of atmospheric pressure.—Note on M. Faye's recent communication regarding waterspouts, by M. Mascart. M. Faye having again raised this question in connection with M. Weyher's experiments, the author returns to his original contention that the great body of observed phenomena are directly opposed to M. Faye's theory of cyclones.—On the development of the Pennatulæ (*Pennatula grisea*), and on the favourable biological conditions presented by the Arago Laboratory for zoological studies, by M. H. de Lacaze-Duthiers. A visit paid to the Arago station last October suggests some remarks on the flourishing condition of the Alcyonaria and Pennatulæ, which have become thoroughly acclimatised in this district. A general description is given of the laboratory and reservoir at the Fontaulé headland, which has been enlarged to a capacity of 130 cubic metres, offering every facility for the study of sponges, star-fish, tritons, and many other lower forms of marine life.—On the Alpine flora surviving in the Paris district, by M. A. Chatin. The author discusses the various hypotheses which trace this already described flora either to the Scandinavian or Swiss Alps or to the Pyrenees, and concludes generally that the Parisian highland flora is independent of all, and truly aboriginal. It is also contended that most of the present European vegetation goes no further back than the Quaternary formations, and that for plants there has been independent succession and plurality of centres of creation rather than wide-spread diffusion from a single centre.—On the orthobutyrate and isobutyrate of lime, by MM. G. Chancel and F. Parmentier. An exhaustive study of these substances shows that M. le Chatelier's approximate relation—

$$\frac{dx}{x} : \frac{k}{\delta} Q \frac{dt}{T^2},$$

giving the variation of solubility of different bodies, with their heat of solution at saturation, cannot be regarded as the expression of a general law from which fresh deductions may be safely drawn.—On the red fluorescence of alumina (second notice), by M. Lecoq de Boisbaudran. Here are treated two highly calcined aluminas + Cr_2O_3 and + Bi_2O_3, and a moderately calcined alumina + Bi_2O_3.—On the incubation of Phylloxera during the winter season, by M. A. L. Donnadieu. In reply to M. Balbiani, who holds that the Phylloxera of the oak completes the entire cycle of its evolution in a single year, the fertilised eggs hibernating during the ensuing winter, the author's researches lead to the conclusion that the activity of this organism is not interrupted during the period of suspended vegetation of the plant on which it lives. A like conclusion is arrived at as regards the Phylloxera of the vine, which on this plant continues without interruption, but with a somewhat diminished intensity, the biological evolutions of its summer life throughout the winter season.—Observations of Brooks's comet made at the Observatory of Toulouse, by M. Baillaud.—On Gauss's quadrature formula, and on Hermite's formula of interpolation, by M. P. Mansion.—On the orthogonal systems formed by the θ functions, by M. F. Caspary.—On the movements of the air, by M. Ch. Weyher. A series of experiments are described which have been carried out by means of a jet of air or vapour a demi-millimetre in diameter and inclined 45° to the horizon, holding in suspense two spheres, one of cork with a diameter of 20 mm., the other of caoutchouc inflated with air. The centre of gravity of the spheres is below the axis of the jet, which thus causes them to revolve round each other, while their weight is balanced by the attraction produced by the series of little eddies developed along the sides of the jet.—On a method of determining the induction flux traversing an electro-magnetic system, by M. R. Arnoux. A simple method is described, by means of which this quantity may be accurately determined without the aid of the ballistic galvanometer, which is not available for practical purposes.—On the causes determining the phosphorescence of the sulphuret of calcium, by M. A. Verneuil. From the author's researches, which are still in progress, it appears that the violet sulphuret of calcium prepared from shells owes its bright phosphorescence to the salt of bismuth, the carbonate of soda, the sea-salt, and the sulphate of lime formed during the reaction.—Action of some metals on weak solutions of the nitrate of silver, by M. J. B. Senderens. It is shown that by acting on such solutions lead reduces the nitric acid while the silver is precipitated; also that analogous phenomena are presented by zinc, iron, tin, cadmium, antimony, and aluminium.—Action of sulphuric acid on the solubility of the sulphates, by M. R. Engel. Sulphuric acid, acting on solutions of sulphates incapable of combining with it to form acid sulphates, determines a diminution of the solubility of the salt. But this is shown to take place according to a law different from that observed for the chlorides in presence of hydrochloric acid.—On the reproduction of the micas, by MM. P. Hautefeuille and L. Péan de Saint-Gilles. In this preliminary paper the authors confine themselves to some of their researches on the fusion of the elements of the micas with the fluosilicate of potassa.—Remarks on M. Boutroux's note regarding the action of nitric acid on sugar, by M. E. Maumené. M. Boutroux's statement that by the action of sugar and nitric acid he obtained saccharic acid and oxalic acid, but not hexepic acid, is shown to be erroneous.—On the treatment of new wines with sugar, by MM. D. Klein and E. Fréchou. The authors' experiments show the possibility of obtaining with alcohol of about the theoretic quantity right fermentations by means of which poor vintages may henceforth be converted into good wines capable of preservation.—A contribution to the study of the alkaloids, by M. Oechsner de Coninck.—Researches on the mode of action of colchicine taken as a therapeutic, and on the mechanism of this action, by MM. A. Mairet and Combemale. The authors' experiments show that this substance has the same diuretic or purgative action on men as on animals, but the former are three times more sensitive to its action than the latter.—Fresh studies on the embryogeny of the Nematodes, by M. Paul Hallez.—On the development of the Nematodes of the beetroot during the years 1885 and 1886, and on their modes of propagation, by M. Aimé Girard.—On the oscillations produced during the Eocene period in the Laval basin, by M. D. Œhlert.—On the geological constitution of la Montagne-Noire, Castelnaudary district, by M. J. Bergeron.

BERLIN

Physical Society, January 21.—Prof. von Bezold in the chair.—Dr. König spoke of the disadvantages of the hydro-oxygen lamps, and demonstrated a new lamp constructed by Herr Linnemann, in which the unsteadiness in the light, arising from the fact that in the common lamp the flame burned now in the burning tube and now outside of it, was avoided. In the new lamp the coal-gas or the hydrogen issued from a ring-shaped opening in the burner, while the oxygen in the centre was admitted through a capillary tube and did not come into contact with the burning gas till outside of the burner. In the middle of the blue flame was seen a bright point which gave the heat-maximum. Instead of the lime cylinder, Herr Linnemann used in his lamp zircon plates, which, at the place of the bright point, gave a highly intense constant light. The speaker made use of this light in order, with the aid of the optical bench of Prof. Paalzow, to demonstrate by projection a long series of phenomena in connection with the doctrine of the polarisation of light. For all teaching purposes and demonstrations this method of representing the most important optical phenomena could not be surpassed by any other.—Dr. Lummer described the experiments of M. Macé de Lepinay, who by a new method had determined the wave-length of the ray of light D_2, ascertaining, as he had done, by weighing, the volume of a quartz cube, the size of which was determined in units of the wave-lengths, and from the volume of the cube finding the length of the light-wave. The speaker showed a series of inaccuracies in the measurements of M. de Lepinay, and, in view of the fact that the wave-lengths of the rays of light were now measured with a precision of 1/60,000, whereas the determination of the centimetre was affected with an uncertainty of 1/4000, he purposed inversely ascertaining the length of the centimetre from the wave-length. The mode of procedure should be the same as that made use of by M. de Lepinay, yet several improvements in the measuring and weighing were stated, such as the speaker hoped to be able to effect later on.—Dr. Dieterici showed an apparatus designed by Prof. Köppen which enabled one to fill a barometer free of air very rapidly. An upright standing communicating-tube open at one end for the admission of the quicksilver issued at the other end in a capillary tube passing at the bottom into a vessel. The open leg of the siphon was longer than the other. On pouring in the quicksilver it rose uniformly in both legs, forced up the air in the closed leg and through the capillary outwards. When the closed leg was entirely filled with quicksilver, and yet more continued to be poured in, it drained itself off through the capillary, bearing along with it all the air, in the same manner as did the Sprengel pump. The quicksilver became collected in the lower vessel and closed the lower opening of the capillary. The vacuum was thus established, and in the closed leg of the communicating-tube the quicksilver sank to barometer height.

—Prof. H. W. Vogel presented photographs of coloured objects which in the distinctness of their *nuances* perfectly corresponded with the impression conveyed by the objects themselves to the eye. The speaker had, in conjunction with Herr Oberneth, succeeded in finding in eosin-silver a substance rendering the photographic plates most highly sensitive for the yellow-green rays, corresponding with the utmost sensitiveness of the retina for those rays. The photographs of solar spectra and different landscapes attested the excellence of this "sensibilisator."

THE AURORA BOREALIS

L'Aurore Boréale. Étude générale des Phénomènes produits par les Courants électriques de l'Atmosphère. Par M. S. Lemström. (Paris: Gauthier-Villars, 1886.)

Resultate der Polarlicht-Beobachtungen angestellt im Winter 1882 *und* 1883 *auf den Stationen Kingua Fjord und Nain.* Von Dr. K. R. Koch. (Berlin: A. Asher and Co., 1886.)

THE organised and obstinate scientific curiosity of our time has not neglected the beautiful phenomenon of the "Polar Dawn." Yet its investigation is attended by peculiar difficulties and discouragements. It can be profitably conducted only amid scenes of frozen desolation, in the grisly depths of Arctic winter nights, under conditions taxing man's energy and resource to live, to say nothing of observing. The appearances in question are, moreover, as elusive as they are surprising. They promptly kindle the imagination, but leave the understanding, unless prepared by special study to apprehend something of their causes, baffled and helpless. Nevertheless, auroral research, though Nature seem to frown upon it, has been pursued with indefatigable energy during the last half century. It has formed the principal object of some, it has occupied a prominent place in the programmes of all recent Polar expeditions; besides being furthered, with less heroic zeal, by writers and thinkers unequal or averse to the company of thermometers normally below the zero of Fahrenheit. Nor have these labours been thrown away. Much of the mystery long attaching to the evanescent splendours of Arctic skies has been dissipated. There is no longer any doubt as to the *kind* of explanation appropriate to them. Their laws and relationships have been, to a great extent, elucidated; a satisfactory theory of their origin is at hand; some circumstances of their occurrence, long in debate, have been attested on unquestionable authority.

An excellent specimen of the patient laboriousness by which these results have been brought about is afforded in the work of Dr. Koch, cited as one of our authorities. He was in sole charge of the German station of Nain, on the coast of Labrador, during the International Polar term 1882–83, and now presents us with the record of his observations there, together with those made simultaneously at the still more northerly post of Kingua Fjord. Although situated in about the latitude of Dundee—56° 33′—Nain appears to be, in point of climate, one of the grimmest localities accounted habitable on the face of the globe. Frost-bites were a quite common incident of Dr. Koch's daily experience; and furious winds, rendering the use of his meteoroscope impossible, often left him dependent upon the natural features of the solemn but forbidding landscape, for determining the azimuths of auroral bands and arches. As regards these phenomena, indeed, the station is admirably located. It lies close to the southern edge of, if not actually within, the zone of maximum frequency; auroræ are consequently numerous and intense, and appear almost indifferently above the northern or southern horizon. Their varying forms are beautifully delineated in the drawings which lend a greatly increased value to Dr. Koch's publication. Multiple arches, up to the number of eight, were frequently seen; and the incessant movements affecting them, both as a whole and in their parts, the transverse flashing of the rays set side by side to compose some of them, the torrential rushing of light along the paths others seemed to prepare for it, as well as the restless wanderings of the entire luminous structure up and down the sky, gave continual variety and animation to these strange exhibitions, while accentuating their baffling recalcitrance to exact measurement. No estimates of height were attempted at either Nain or Kingua Fjord; but there was a total absence of auroral appearances below the clouds, or otherwise unmistakably very near the earth, such as have been noted by M. Lemström and other observers in high latitudes. Luminous mists were, however, common. At times they suffused the whole sky; and shapeless masses of them constantly succeeded, and (at Kingua Fjord) were often the substitutes for the organised and definite forms of a perfect aurora. A sudden and wide-spread development of cirrus clouds was another curious secondary feature of the Nain polar lights. These were, at both stations, completely mute; not a suspicion of audibility attended their movements.

A no less intrepid observer than Dr. Koch is the author of the work with which we have coupled his in the heading of this article. M. Lemström's auroral researches began in 1868, when he was attached to the Swedish Polar Expedition commanded by Baron Nordenskjöld. They were continued during a sojourn of six weeks in Finnish Lapland in 1871, and were brought to a highly successful issue at Sodankylä in 1882–84. Finland held an honourable place among the eleven nations lately combined for a simultaneous attack upon the secrets of the Arctic circle; and the Professor of Physics in the University of Helsingfors was, by an almost inevitable choice, appointed chief of the Finnish meteorological station established in compliance with the terms of international agreement. Our readers are not unacquainted with the original line of work struck out by him in that capacity. Its upshot was to secure demonstrative evidence as to the *proximate* cause of the aurora borealis.

The book under review derives, then, a particular interest from its authorship. It is the production of a man who has devoted thought and labour without stint to the subject of which it treats, and has pushed the associated problems visibly nearer to solution. He now sums up the present state of knowledge as regards them in a well-arranged, concisely written, and copiously illustrated volume, recapitulating the most significant and surely established facts, fitting them, with the critical judgment bought by long experience, into their proper places, and expounding the theory best adapted to interpret and harmonise them.

Remarkably, as time went on, Halley's conjecture of a magnetic origin for auroræ gathered round it confirmatory circumstances entirely unknown to its author. Celsius and Hiorter noticed, in 1741, spasmodic disturbances of the magnetic needle coincident with the darting movements of northern lights. Wilcke, Ussher, and Dalton, ascertained, towards the end of the century, the close geometrical relations between the terrestrial magnetic system and all the various parts composing a fully developed auroral display: the corona forming in the magnetic zenith, the streamers flitting parallel to the line of the dip, the arch erecting its summit in the magnetic meridian. When Faraday succeeded in obtaining luminous effects through magnetic action, and Rudolf Wolf demonstrated the subjection of auroræ to an identical periodicity with magnetic variations, the case might have appeared complete.

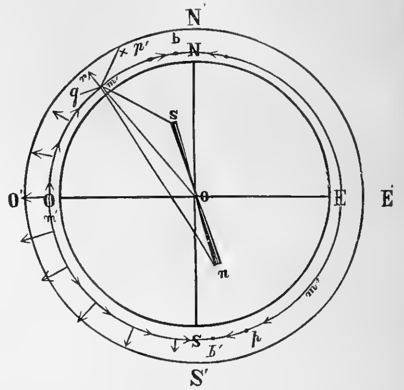
Yet the pure and simple magnetic theory of the aurora borealis, when attempted to be realised, either eluded the grasp of thought, or was found to involve admissions not very easy to make. Dalton, whose propensity towards forming distinct conceptions was a primary quality of his mind, had the courage to give it definite shape in 1793 (in his "Meteorological Observations and Essays"). Compelled, as he supposed, by the exigencies of observation, he conceived an envelope of an elastic fluid partaking of the nature of steel to replace atmospheric air at a height of about a hundred miles, and to supply the material alike of arches and streamers, shown, by their disposition in space, to be of a ferruginous character. It can scarcely be wondered at that the idea, in spite of Biot's adoption and development of it, failed to strike root. More vitality was in Canton's interrogative suggestion forty years earlier: "Is not the aurora borealis the flashing of electrical fire from positive towards negative clouds at a great distance, through the upper part of the atmosphere, where the resistance is least?" (Phil. Trans., vol. xlviii. p. 357.)

It was not, however, until the electrical illumination of rarefied gases came to be studied with detailed attention that the full effect of the visual identity of the two kinds of phenomenon became sensible. The analogy was defined and completed by some experiments made by De la Rive in 1853. They showed that a luminous discharge in an exhausted vessel, when influenced by a powerful electro-magnet, condenses into a ring of light encircling its pole, endowed, moreover, with a rotatory movement such as has frequently been observed to affect a system of auroral streamers. Here, for the first time, their true part in such displays was assigned to the forces emanating from the earth's magnetic poles. It is a directive, not a formative one. The structure, not the occurrence, of auroræ is conditioned by them.

A marked change in scientific opinion resulted, accordingly, from these investigations. The "magnetic effluvium" theory of the aurora borealis finally disappeared, and what we may call the "illuminated vacuum" theory took its place. The change was accompanied by a shifting of the ground of inquiry. What was urgently needed in order to render intelligible the mode of action producing the gorgeous flame-vesture of northern skies, was perceived to be, not so much improved knowledge (however desirable) of the laws of terrestrial magnetism, as a sound doctrine of atmospheric electricity. Here De la Rive broke down. His hypothesis of a polar accumulation, through the agency of the winds, of the positive charge of the air, was obviously untenable.

Nothing better was, however, proposed until 1878, when Prof. Edlund, of Stockholm, applied the principle of "unipolar induction," discovered by Weber in 1841, to explain the phenomena of atmospheric electricity (*Phil. Mag.*, vol. vi. p. 360). The effects thus designated are really derived, as a particular case (in M. Edlund's probable view), from the well-established laws of magnetic action upon electric currents.

Each element of the system of currents formed by the electrified particles of the rotating terrestrial crust and atmosphere is thus urged, by the powerful magnet which the earth may legitimately be regarded as inclosing within it, along a path at right angles to the line drawn from each of its poles to the current-element. The direction and relative strength of the impelling forces are indicated in the accompanying figure, copied from the work before



us (p. 166), where the particle m' is solicited towards × by the south pole (pointing north) of the magnet Sn, and towards g by its south pole. The combined result is to drive the particle upward and poleward along a line everywhere perpendicular to the swing of the dipping-needle. The vertical component, accordingly (represented by the arrows standing erect on the circle m' m'' m'''), attains a maximum at the magnetic equator, where the dip vanishes; the tangential component is there = 0, and attains its highest value in middle latitudes.

Several remarkable effects ensue: first, that atmospheric electricity gains potential with elevation—an observed fact; next, that it is constantly travelling away from the equator towards either pole. The circulatory process, however, thus set on foot, must be carried further; and in its continuance and completion M. Edlund finds the key to the auroral mystery.

At and near the equator, recomposition of the positive electricity of the air with the negative electricity of the earth is opposed by the whole strength of magnetic inductive repulsion, there acting vertically. When effected at all, it can only then be by sudden, violent, disruptive discharges, apparent to our senses as lightning. But the increasing inclination of the magnetic needle in higher latitudes renders the line of no resistance marked by it continually more practicable as an avenue of descent for the accumulating positive fluid. Hence, when it has attained a certain potential, gradual discharges take place over two polar zones, *along the line of the dipping-*

needle. These constitute what we are accustomed in the northern hemisphere to call the aurora borealis.

Auroræ are, in this view, the polar equivalents of lightning. The same office of relieving the electrical tension of the air is fulfilled by them with innocuous tranquillity. Not indeed in absolute silence, though the "eerie din" of their rustling streamers has been caught by very few ears. Major Dawson, however, was fortunate enough to hear once, and once only, during his sojourn at Fort Rae, 1882-83, a sound "like the swishing of a whip, or the noise produced by a sharp squall of wind in the upper rigging of a ship," which accompanied, with its *crescendo* and *diminuendo*, the brightening and fading of an aurora visible at the time. This was the first official confirmation of innumerable less authentic reports to the same effect.

The mutual relations of auroræ and thunderstorms are full of significant interest. In point of geographical distribution, they may be termed complementary. The one kind of phenomenon is not more characteristically of polar than the other is of tropical origin. We take from M. Lemström's pages the following concise table, strongly corroborative of Edlund's theory, showing the dependence upon latitude of storm-frequency:—

Latitude		Mean annual number of storms
Between 0° and 30°	...	52
,, 30 ,, 50	...	20
,, 50 ,, 60	...	15
,, 60 ,, 70	...	10
About 70	...	0

Yet the two kinds of atmospheric luminosity are separated by profound distinctions. Thunderstorms give no sign of systematic magnetic associations. Sometimes, it is true, the needle may be seen to quiver at the instant of a lightning-flash, but by what seems a casual disturbance, quite different from the tumultuous agitation which accompanies or even betrays the darting of northern lights.

Storms are, moreover (so far as is known), completely exempt from the complicated periodicity by which auroral appearances are regulated. Now this, as M. Tromholt discovered in 1882, is exactly inverted in the far north. His discussion of M. Kleinsmidt's observations (1864-80) at Godthaab in North Greenland made it apparent that, on the polar side of the great auroral zone, a sunspot maximum brings with it an auroral minimum, and *vice versâ*; that the two equinoctial peaks of the auroral curve in middle latitudes there coalesce into a single elevation at the winter solstice; and that the evening maximum noted further south is there shifted to the morning. Nor are these curious inversions peculiar to Godthaab.

Their immediate cause is easily understood. The auroral zone swings to and fro in several superposed periods, over the surface of the earth. As the sun's activity augments, it travels slowly towards the equator, and retreats towards the pole as it diminishes, diversifying its progress with minor oscillations, daily, bi-annual, and (perhaps) monthly. The analogy of the closing-in of the solar spot-zones with approach to maximum is striking, but unexplained. Auroral periodicity is thus seen to depend, not upon cessation, but upon removal, and the observed reciprocal relation between auroral frequency in middle and very high latitudes is completely accounted for.

We can even go a step further. By Edlund's theory an increase of atmospheric electricity must be attended by a lowering of the latitude in which recomposition takes place. That is to say, the observed shifting in space of the auroral zone implies, and is explained by, a rise and fall of potential in the upper conducting strata of the air, synchronising with the rise and fall of solar disturbance. This is probably in part an indirect effect of the fluctuations in the sun's activity.

Electricity, in M. Edlund's view, is simply the ether of space, a certain share of which belongs naturally to every ponderable substance. When this normal store is by any means augmented, the body on which the accumulation takes place is positively electrified; when it is diminished, negative electrification ensues. Hence, the expulsion of this so-called "fluid" from the earth by magnetic inductive action leaves it, *ipso facto*, negatively charged, and produces a positive charge in the air.

All this M. Lemström, in the work before us, readily admits; but he supplements the magnetic forces at work in disturbing our planet's electrical equilibrium with evaporation, of which the enormous capabilities for producing high potentials have been indicated by Prof. Tait (NATURE, vol. xxix. p. 517). But evaporation doubtless proceeds most vigorously when the sun's radiative energy is strongest—that is (presumably), at epochs of spot-maximum, so that an obvious link is thus supplied between the solar and auroral periods. The sequence of cause and effect is as follows: the sun's increased power quickens the development of aqueous vapour; this, in its turn, gives rise to a more copious supply of atmospheric electricity; added tension insures more speedy neutralisation; the zone of gradual recomposition descends towards the equator, and auroræ are more frequently visible in middle latitudes.

Yet this is perhaps not the whole truth. Many circumstances speak in favour of a direct electrical inductive action of the sun upon the earth. M. Quet has lately shown (*Comptes rendus*, t. xcviii. p. 1038) that the existence of a magnetic fluctuation corresponding in period with the sun's rotation on its axis is otherwise inexplicable; and the instantaneous response of the terrestrial magnetic system to the solar outburst of September 1, 1859, almost compels the same inference, which is strengthened by the undoubted growth of magnetic intensity with solar activity. Hence, as sunspots become numerous, the circulatory process described by M. Edlund must be quickened and strengthened; atmospheric electrical tension will be heightened; and although the repellent magnetic power is proportionately reinforced, this is more than counterbalanced by the added mutual attraction between the opposite electricities of earth and air. Through this cause also, then, the auroral zone widens its distance from the pole once in eleven years.

The view that auroræ are due to currents of positive electricity illuminating the air on their passage to the earth, has been solidly established by M. Lemström's results at Sodankylä. His "discharging apparatus" served the precise purpose of Franklin's kite. The one experiment was not more decisive than the other. Not only did luminous appearances accompany the setting-in of a current towards the earth from the network of insulated wires spread over the summit of Mount Oratunturi, but the light evoked was distinctively *auroral.* Examined with the spectroscope, it yielded the still enigmatical "citron-line" discovered by Ångström in 1867. This is the invariable and chief constituent of auroral radiations. Besides one fitfully present, detected by Zöllner in the red, it is the only vivid line its spectrum includes. Ten others, more or less dubiously enumerated, are faint, hazy, indeterminate. M. Lemström holds that there is a fair agreement between some of them and lines in the laboratory-spectrum of rarefied air. But this is perhaps a too sanguine opinion. These seeming coincidences are very loose, and have not been drawn closer by careful inquiry. Vogel's conclusion that the spectrum of the aurora is modified from that of atmospheric air is indeed highly probable, but its probability is derived far more from external than from internal evidence.

A. M. CLERKE

THE BUTTERFLIES OF INDIA

The Butterflies of India, Burmah, and Ceylon. A Descriptive Hand-book of all the Known Species of Rhopalocerous Lepidoptera inhabiting that Region, with Notices of Allied Species occurring in the Neighbouring Countries along the Border. With Numerous Illustrations. By Lionel de Nicéville, F.E.S. Vol. II. Royal 8vo. (Calcutta. London: Bernard Quaritch, 1886.)

MORE than four years have elapsed since the first part of this book was published, and one of the authors has been obliged to resign his share in the work. The second volume, which has been written by Mr. de Nicéville alone, is in no way inferior to the first. When we remember that in the trying climate of Calcutta, and only in the leisure hours which can be spared from official work, Mr. de Nicéville has with but very trifling assistance from the Government of India completed a volume of nearly 300 pages, containing over 300 species of butterflies, we must allow that he deserves great praise; and though a volume produced under such difficulties must of necessity contain faults, yet it is in every respect very superior to Mr. Moore's work on the Lepidoptera of Ceylon, which was largely subsidised by Government. There is no doubt that the impetus given to the study of the butterflies of India by the publication of this work will have the best results, and we have every reason to hope and believe that it may be completed in three or four years more at latest. The present volume is devoted almost entirely to the family of Nymphalinæ, and brings up the number of Indian butterflies already described to over 600, all of which are treated in a thoroughly scientific, careful, and painstaking manner.

Though the author has gathered to his assistance a growing band of field workers in various parts of India, among whom Messrs. Möller, Knyvett, Graham-Young, Colonel Swinhoe, and others are conspicuous, and is rapidly accumulating a large quantity of specimens from all parts of the country, he still labours under the difficulty of being unable to see the types of many of the so-called species described by Messrs. Butler and Moore in Europe. Evidence is constantly being brought forward to confirm the opinion of most entomologists, that a large proportion of the names given by these authors represent no fixed or constant varieties, and that the characters described by them cannot be recognised in the insects themselves; but it is impossible to ignore them until this can be proved by comparison of these types with large series of specimens. Under these circumstances, Mr. de Nicéville has acted wisely in printing the descriptions of all these doubtful species, so that the attention of collectors may be called to them, and their existence proved or disproved. His remarks on them have the advantage of being intelligible, which is not always the case with the original descriptions of the authors in question, who have had for some years almost a monopoly in the description of Indian butterflies.

The kind of difficulty which occurs in many instances may be illustrated by the author's final remarks on the numerous varieties of the genus Abisara, described as species by Mr. Moore.

"*A prunosa* is typically the darkest coloured, and in the male most brilliantly purple-shot, of this group of the genus, specimens from Travancore being particularly large and dark. Even among Ceylon specimens, however, I find considerable variation; in some males the inner discal band on the fore-wing is evenly convex, and in others distinctly angled in the middle, and the purple suffusion is also variable; the size and number of the black spots on both sides of the hind-wing is extremely inconstant. In one very abnormal specimen there are two sub-apical spots, only the anal ones being entirely wanting. From an island one would expect to find some distinguishing characters in a species supposed to be peculiar to it, but I have quite failed to discover any. I can only repeat that, in my opinion, the name *echerius* should apply to all the species of this group of the genus Abisara, except perhaps to the Andaman local race, which has been named *bifasciata;* that as, in this case, the geographical range of numerous slight local races is not segregated, and each local race must interbreed with the next on the boundary-line which is supposed to separate them, it can serve no good scientific purpose to pick out a few apparently different specimens from each local race and to describe them, at the same time ignoring the intergrade specimens which exist."

If this opinion had been more generally held, the study of the butterflies of India would have been much simplified, and it is to be hoped that a new edition of "The Butterflies of India," which will certainly be called for almost before the first is complete, will show a large reduction in the number of names. A fixed nomenclature is the first desideratum in this as in other branches of science, and tends more than anything to attract good workers, who are often disgusted by a long list of synonyms and by changes in well-known old names.

The keys to the genera and species have been worked out very carefully, and will be useful to beginners. The literature, geographical distribution, and variation of each species are also well and carefully done. The volume will be indispensable to lepidopterists generally, and ought to interest many in India, who have hitherto looked on the collection of butterflies as rather a pastime than a science.

H. J. ELWES

OUR BOOK SHELF

The Deviation of the Compass in Iron Ships considered Practically. By W. H. Rosser. Second Edition, with considerable additions. (London: James Imray and Son, 1887.)

REMEMBERING the number of books already published treating in a practical form of compasses, their deviations on board iron ships, and the consequent adjustments, some persons may be disposed to ask, "What purpose will be served by an addition to them?" In answer it may be said that this, the second edition of a useful work by an author who bases his knowledge on the teaching of the "Admiralty Manual," and knows from instructing others their many difficulties, can hardly fail to be welcome to those having neither time nor ability to assimilate the subject without a guide at every turn.

Whilst we hope that Mr. Rosser's later edition will be duly appreciated, there is a certain definition which, for the sake of simplicity and accuracy, we would fain see removed from it. At pp. 30 and 31, clear definitions are given of true, magnetic, and compass courses. Why not let well alone, and not complicate the matter by introducing the term "correct" magnetic course? A reference to the later editions of the Admiralty publications on the deviation of the compass shows that the word "correct" in connection with "magnetic course" has been entirely omitted, apparently as no longer serving any purpose.

The concluding paragraph of the preface on patent compasses is hardly fair to Sir William Thomson's. The principles involved in the construction of his compass are not in themselves novelties, but he has done world-wide good by showing in it how that enemy of compasses—friction—may be avoided, whilst at the same time he has produced a card which is almost free from oscillation when the ship rolls heavily.

Travels in the Wilds of Ecuador. By Alfred Simson. (London: Sampson Low, 1886.)

"NO one with the spirit of roaming within him," says the author of this book, "can live long in Ecuador without cherishing a growing desire to explore its unknown parts." Some time ago, accordingly (the exact date is not mentioned), he started with a companion from Guayaquil for Baños, and from Baños they went through the forest to the village of Aguano, on the River Napo, completing the road in eighteen days' actual walking, or forty-five days' foot journey, including necessary stoppages. At Aguano they were obliged to remain forty-two days, which they spent partly in collecting Lepidoptera, partly in making voyages of discovery by land and water in search of provisions. They then made their way in canoes down the Napo to the Amazon, which they reached after a voyage of twenty-five days. At Iquitos the two friends parted, Mr. Simson's companion setting out to explore the Ucayali, while Mr. Simson himself joined a Mr. Reyes in an expedition up the River Putumayo.

The story is very simply and pleasantly told, and those who like to read about distant lands of which little is generally known, will find much to interest them in the author's record of his adventures. The best parts of the book are those in which he describes the Indian tribes of Ecuador, whose habits and modes of thought and feeling he closely observed. He also notes some rather curious facts in natural history. Probably few persons have ever heard of "the roaring of an alligator." "I heard it myself," says Mr. Simson, "on one occasion in the case of a huge beast who appeared to be following a female of his species." The animal was swimming very rapidly, diving and rebounding up to the surface of the water. Mr. Simson was in a small Rob Roy canoe, and remained still to watch his manœuvres. Immediately the alligator saw the canoe, he "came towards it, roaring like a bull at each bound above water." As he was diving, Mr. Simson (who was unarmed) forced the canoe straight over him, and so escaped. "Curiously enough," we are told, "not half an hour after this episode, an alligator jumped from a steep bank over my canoe, and only just cleared it, as I was distractedly paddling along under the shore, and inadvertently startled the reptile above me."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Tabasheer

As I have occasionally found the curious stony plug of which Mr. Thiselton Dyer writes (NATURE, vol. xxxv. p. 396), in the joints of bamboos accidentally broken, and been much exercised as to the nature and origin of the phenomenon, I have been much interested by his paper. May I further suggest that it is to a certain extent pathological—due, that is, to *arrested growth*, either longitudinal or lateral, in the shoot next above the joint in which the stony secretion or sediment is found.

In the onrush of tropical growth in the young shoot, Nature, after flooring the knot, has poured in, as it were, sap and silica sufficient for a normal length and width of stem to the knot next above it. But by some check to the impulse, or irregularity of conditions, the portion of stem thus provided for is shorter or narrower than intended; and the unused silica is left behind as a sediment, compacted by the drying residuum of sap. It is a question only to be settled by close examination of a great number of examples.

Something like it occurs, however, in the case of our own wheat. Larger joints, that is, and stronger walls are commonly found where the length of stem between joint and joint is a short one. As in the bath for electroplating the same amount of silver is deposited in a given time on a single penny as on a tea service of many pieces, so in the case of quick-growing silicated stems it would seem as if the same average amount of material were provided by the mounting sap, and the constructive use actually made of it determined by many accidents. In the wheat stem the silica is differently placed; in the fiercely-growing bamboo shoot the mineral in excess is left behind in a crude form, and disregarded. That is what I should expect to find.

HENRY CECIL

Bregner, Bournemouth, March 1

Temperature and Pressure in Jamaica

THE following table of elevations and averages is not as perfect as might be wished, but as some years mu-t pass before it can be greatly improved, it is here given as one of many results obtained by the Meteorological Service in Jamaica:—

Station	Elevation Feet	Pressure Inches	Max. °	Mean °	Min. °	Range °
Kingston	0	30·00	87·0	78·2	71·0	16·0
Kempshot	1773	28·20	80·5	72·7	68·0	12·5
Cinchona Plantation ...	4907	25·27	68·5	62·6	57·5	11·0
Portland Gap	5477	24·71	69·0	59·7	54·6	14·4
Blue Mountain Peak...	7423	23·14	71·1	55 7	46·3	24·8

In NATURE, vol. viii. p. 200, it was suggested that the fall of temperature, δT was connected with the fall of pressure δP by the equation

$$\delta T = \lambda . \delta P,$$

where λ was taken equal to $3^\circ{\cdot}23$.

We can now correct this expression and take

$$\delta T = \lambda . \delta P + \mu (\delta P)^2,$$

where $\lambda = 2^\circ{\cdot}92$, and $\mu = 0^\circ{\cdot}08$. But these values relate to mean temperatures; for minimum temperatures $\lambda = 0^\circ{\cdot}96$, and $\mu = 0^\circ{\cdot}40$.

These expressions and their connection are important, and it would be interesting to know whether similar results have been found in India and elsewhere within the tropics, or may yet be obtained.

Computing δT by means of these formulæ, and applying the results to the temperatures at Kingston, we have

	Mean	Min.
Kempshot	72°·7	68°·0
Cinchona Plantation	62·6	57·5
Portland Gap	60·5	54·7
Blue Mountain Peak	54·4	45·6

which are fairly satisfactory.

Putting $\delta P = 30$ inches, the minimum formula gives $-311°$ as the temperature of space, the thermometer being shaded from the sun by any spherical body such as the earth or moon.

Putting $\delta P = 30$ inches, the mean formula gives $-81°$ as the mean temperature of a body devoid of atmosphere, such as a meteorite pursuing its course in space, or the moon, at the mean distance of the earth from the sun.

An expression for maximum temperatures cannot be as easily deduced; but if the surface of the meteorite or the moon which is turned from the sun be $-311°$, and if the mean temperature be $-81°$, it follows that the maximum temperature of the surface turned towards the sun must be about $+149°$.

Jamaica, February 12 MAXWELL HALL

Electricity and Clocks

IN addition to the plan pointed out by Prof. Sylvanus Thompson (the correct way to repeat from a striking clock to electric bells), I believe I have seen an arrangement in Dublin whereby a single port or going train only is made to strike the hours on an indefinite number of electric bells. I believe this mechanism is a patent. HORLOGE

Sandymount, March 2

Top-shaped Hailstones

ON August 6, 1885, a hailstorm occurred in this neighbourhood, during which two waterspouts were seen. After one of these had burst, a fall of hailstones, almost exactly similar to those described by Mr. Middlemiss in your issue of March 3 (p. 413), commenced and lasted for some minutes. I do not remember to have noticed that there was a mass of clear ice at the base of the cone, but the banding was very distinct.

Beside the horizontal stratification there was another perpendicular one, giving the hailstone the appearance of being composed of alternate cylinders of clear and white ice. If the hailstones which Mr. Middlemiss saw at Ramnagar showed this peculiarity, he will perhaps be kind enough to communicate the fact through your columns. Sketches of the hailstones which fell in this district were published in the *Meteorological Record* soon after the occurrence, but I cannot give the precise date of the copy. T. SPENCER SMITHSON

Facit, Rochdale, March 7

The Present Southern Comet

EITHER the present brilliant southern comet is periodic, or one of a large family of comets, moving in similar orbits and possessing marked similarities of structure. Its orbit, as far as an orbit can be determined from the approximate positions of a very indefinite nucleus, is similar to those of the 1843 and 1880 comets. In Grant's "History of Astronomy" the following description of the 1668 comet occurs:—"It appeared a little above the western horizon. The tail measured 23° in length, and resembled a huge beam of light. The head was so small as to be scarcely visible. The observations will be represented with sufficient accuracy by the elements of the orbit of the comet of 1843." A fairly accurate description of the present comet. There are other comets—1618, 1689, 1702—which possess this strong family likeness. If these comets be not one and the same, they must all have had a common origin. I do not know if it has been noticed that the aphelia of their orbits lie within a few degrees of Sirius. It may be possible that they have all been ejected from that gigantic sun; at any rate, it is impossible that they could have been attracted from nebulous masses lying beyond Sirius. A. W. R.

Lovedale, South Africa, February 1

The Earthquake

I EXAMINED my magnetograms very carefully on the day of the earthquake in North Italy, and I find no trace of any special disturbance on the H.F. trace similar to that on the Kew curve. It may be well to place this on record, as it may aid in fixing the limits of the disturbance. S. J. PERRY

Stonyhurst College, Blackburn, March 7

CEREBRAL LOCALISATION[1]

I.

IT is rather more than ten years since the first edition of this book came under review in the pages of this journal. And it was intrusted to very able hands, for the reviewer was George Henry Lewes, himself an experimentalist in this branch of physiology, and of the highest distinction as a philosopher and psychologist. The review is courteously but unflinchingly hostile: exception is taken to some of the facts and to most of the deductions of the author; although the value of the work, from its richness in suggestions as well as in facts, is ungrudgingly admitted. Mr. Lewes especially complains that the book "is so deficient in the indispensable correctives of counter facts and arguments, that the reader must be cautioned against accepting any position unless elsewhere verified. . . . From one cause or another there is a disregard of counter evidence, which, in a second edition, I should seriously urge him to rectify. . . . This disregard arises from no unfairness, but simply from the one-sidedness which comes from preoccupation with certain views."

The increased size of the work (498 pages instead of 323) is, no doubt, in part due to an endeavour to carry out this suggestion, although the growth of the subject may of itself, in great measure, account for such increase. Indeed, it must be confessed that the characteristic complained of by Mr. Lewes has not by any means entirely disappeared, and the student who may consult its pages must bear in mind that the book still remains the gospel of the functions of the brain "according to Ferrier."

The pervading idea of the work is expressed by the term "localisation of function." It was against this idea (and especially against certain applications of it) that Mr. Lewes brought to bear the full powers of his criticism.

One serious objection which was urged by him against many of Dr. Ferrier's results (those of localised extirpation) was that he was unable to keep the animals alive long enough to allow the effects of Disturbance of function to subside, so as to leave only the effects of Removal to be estimated. But the use of antiseptics has now permitted this objection to be removed, since there is no longer, in most instances, the same difficulty in preserving the animals, as was the case in Dr. Ferrier's first experiments.

It is further urged by the previous reviewer that "neither the effects of Disturbance nor the effects of Removal are to be taken as conclusive evidence that the function disturbed or removed is the function of the organ operated on." [But although not of themselves conclusive, yet if looked at in conjunction with other evidence they may furnish important indications regarding the function of the organ.] Mr. Lewes further affirms that "whenever a function persists or reappears after the destruction of an organ, this is absolutely conclusive against its being the function of *that* organ," meaning, of course, of that organ alone. That, in the case of recovery or reappearance, partial or complete, of a lost function, another organ previously possessed of a different function has vicariously taken its place, is a scarcely tenable hypothesis. And yet there are well-recorded instances of such reappearance: as in the case of Goltz's dogs, which recovered some of the lost power of voluntary movement; and in that of the visual disturbances which are caused by lesions of the occipital lobe, in which

[1] "The Functions of the Brain." By David Ferrier, M.D., LL.D., F.R.S. Second Edition, re-written and enlarged. (London: Smith, Elder, and Co., 1886.)

I have myself frequently observed recovery, to all appearance complete. It appears to me that the idea expressed by the term "concentration of function" harmonises much more fully with our existing knowledge of the facts relating to this question than the more inflexible phrase "localisation."

It is time, however, to turn to the edition which lies before us. Dr. Ferrier, in his preface, tells us that the book has been almost entirely re-written, and, in point of fact, so much has been added and modified as to constitute this edition, in many respects, a new book. But the principal teachings of the original—those to which the book from the first owed its chief interest—the doctrines, namely, therein advocated regarding the localisation of cerebral functions, are, it is claimed by the author, maintained in all essentials unchanged. Since it is to the exposition of these doctrines, and especially of the experimental facts upon which they rest, that the student of physiology or psychology would naturally first turn, in order to discover what that is new may have been adduced in support of the Ferrierian teachings, and in what manner the hostile attacks which have been directed against them are met by their author, no apology is needed if we devote our attention first and chiefly to those parts of the book which deal with this important question.

After it had been found impossible to deny the correctness of the facts regarding electrisation of the cortex of certain regions of the brain, a vigorous onslaught was made from various quarters upon the method of experimentation. It was especially contended (by Dupuy and others) that the movements produced by this method are really due, not to excitation of the cortex cerebri itself, but to conduction of the current to the basal ganglia (corpora striata). But a single new fact entirely overthrows the last remnant of this objection, since it has been shown (by Franck and Pitres) that similar movements may be caused by mere mechanical stimulation of the cortex (p. 228). Indeed, the same observers entirely deny that the basal ganglia respond at all to direct electrical excitation, a statement which we shall afterwards see is not, however, accepted by Dr. Ferrier.

In the review above alluded to, Mr. Lewes alleges two principal facts against the doctrine that the gray matter of the cerebral cortex is directly excitable, *viz.*: (1) the fact that only the electrical current causes an excitation,—mechanical and chemical stimuli have no such effects, because they cannot pass through the cortex to reach the white substance; (2) what he terms the "decisive experiment" of Dr. Burdon Sanderson. "If that part of the surface of the hemisphere which comprises the active spots is severed from the deeper parts by a nearly horizontal incision made with a thin-bladed knife, . . the result is the same as when the surface of the uninjured organ is acted upon" (Proceedings of the Royal Society, No. 153). But we have just seen that, under suitable conditions, the cerebral surface may be excited mechanically; and, with respect to the second fact, I imagine that Dr. Sanderson would now be the first to admit that his results were due either to imperfect severance or to the spreading of a current of too great intensity.

Moreover, the study of the characters of the contractions which result from excitation of the cortex has tended to show that its excitation is indeed a stimulation of centrifugally discharging nerve-centres, and in conformity with this view it is found that destruction of the cortex in the excitable regions is followed not only by immediate paralysis of the parts in which movement is evoked on excitation, but also by speedy degeneration of the efferent nerve-fibres. The arguments upon this point are set forth briefly, but clearly, by the author (pp. 231–33).

With regard to the results of localised excitation of the cortex (in the monkey), some modifications which are not wholly unimportant have been introduced; but to obtain these the author appears rather to have again consulted his original memoir (Proc. Roy. Soc., No. 161, 1875) than the results of any new experimental investigations. The facts that the excitable region extends over the margin of the hemisphere to include the marginal gyrus upon the mesial surface, and that this part of the excitable region is associated with movements of the leg and trunk, had not been definitely determined at the time of publication of the first edition, but are duly recorded here (p. 245).

The general correctness of Dr. Ferrier's statements regarding the results of localised excitation of the brain in the monkey (and, from its resemblance to the human brain, these will be those of chief interest to most readers) seems at the present time to be universally admitted. I have myself so frequently had the opportunity of verifying them as to have no doubt of their general applicability. But the *inferences* which he has drawn from the results of excitation have not, as we shall presently see, been allowed to remain unquestioned.

The method of localised ablation is of yet more importance for the determination of the functions of the cortex than that which we have just considered. In carrying out this method, the necessity of strict adherence to Listerian precautions is demonstrated when we compare the results which were obtained in the first instance by Dr. Ferrier himself, and recorded in the first edition of this book, with those which have been yielded by the antiseptic method in the hands of Prof. Yeo and himself, in a series of experiments undertaken with the express object of testing the applicability of that method to brain-surgery, several of which experiments are recorded in this edition. The path which their experiments indicated has since been trodden by my colleague Mr. Horsley and myself, and it is to-day a beaten track leading to previously undreamed-of possibilities in surgical science. The fact that the brain can be as effectually searched with a view to the discovery and removal of a tumour as any other part of the human body is an advance of vast extent—a boon to suffering humanity of incalculable value. And that this boon has been acquired, could have been acquired, solely as the result of experiments upon animals, is a fact which may well make the most frenzied of anti-vivisectors pause ere he would deny to his fellow-men the opportunity of acquiring benefits of such inestimable worth!

At the present time it is admitted, even by those physiologists who, like Goltz, have been hitherto accounted the most strenuous opponents of the doctrine of cerebral localisation, that the results of localised extirpation of the cortex vary with the part removed. These results consist of a loss or diminution in the power of voluntary action of different groups of muscles, or of a loss or defect in the appreciation of sensory impressions (but, according to some observers, both volition and sensibility may be at the same time affected by the destruction of certain parts): lastly, from experiments upon some parts of the hemisphere, it may happen that no effect appreciable to the observer is obtained. With respect both to these results and those obtained by excitation, Dr. Ferrier, in the first edition of this work, took up certain positions which have in the meanwhile been vigorously assailed from various quarters. These positions are, in the present edition, for the most part defended by the author with no less vigour, although one or two have been somewhat shifted, and one, at least, altogether abandoned.

In order to make clear these positions to those readers of NATURE who may not have followed closely the controversies which have been carried on during the past fifteen years regarding this subject of cerebral localisation, it will be necessary briefly to describe, with the aid of a diagram, the main features of the external configuration of the monkey's brain (every fissure and convolution in which is represented in the human brain). It will then be easy to indicate the regions to which special functions were originally ascribed by Dr. Ferrier, the modifications which he has since seen reason to introduce in the original scheme, and the results which have been arrived at by certain other workers in this field of research.

Fig. 1 is a diagram of the outer surface of the left hemisphere of the monkey's brain: in it the fissures are represented by black lines. It is seen to be crossed obliquely by six prominent fissures (besides less important

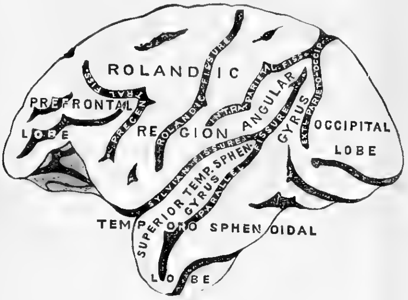


FIG. 1.

depressions). These, enumerated from before back, are the pre-central, Rolandic, intra-parietal, Sylvian, parallel, and parieto-occipital fissures. The anterior portion of the hemisphere in front of the pre-central fissure is termed the pre-frontal lobe. The part of the brain behind this, and bounded behind by the intra-parietal and Sylvian fissures, may be designated the Rolandic region, since it includes the Rolandic fissure. The next part, posteriorly, lies in the angle between the intra-parietal and parieto-occipital fissures, and has the end of the parallel fissure running up into it: it is known as the angular gyrus. Behind the parieto-occipital fissure is the occipital lobe. The rest of this surface of the hemisphere below and behind the Sylvian fissure is the temporo-sphenoidal lobe: the convolution in this which lies between the Sylvian and the parallel fissures, and which is thus very well marked off from the rest of the lobe, is the superior temporo-sphenoidal gyrus.

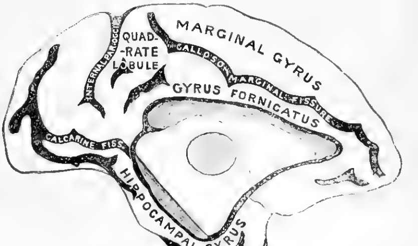

FIG. 2.

Fig. 2 represents the mesial and under surface of the left hemisphere. We here see, above the cut corpus callosum and the other parts which unite the two hemispheres, two convolutions running longitudinally, and separated by a well-marked fissure, the calloso-marginal. The upper one is termed the marginal gyrus, the lower the gyrus fornicatus. The latter expands posteriorly into the quadrate lobule, and is then continued around the posterior end of the corpus callosum on to the under surface of the temporo-sphenoidal lobe, where it becomes continuous with the hippocampal gyrus. The internal parieto-occipital fissure, continuous above with the external one of the same denomination, cuts off, like that, the occipital lobe from the rest of the brain.

Briefly stated, the positions taken up by Dr. Ferrier in the first edition of this work were as follows:—

(1) The Rolandic region is motor. This is the part of the hemisphere from which all volitional impulses (at least for the limbs, head, and face,—about the trunk-muscles nothing was ascertained) issue. It is not connected with sensory perceptions of any kind, not even with those of the muscular sense.

Evidence.—Electric excitation in this region in animals produces definite and co-ordinated movements of muscles of the limbs, neck, and face, similar to those which occur in voluntary efforts. Extirpation is followed by immediate and permanent paralysis of those muscles without the occurrence of any loss or impairment of sensation in the corresponding parts.

(2) The angular gyrus is the centre for vision with the opposite eye.

Evidence.—Electric excitation of this convolution produces movements of the eyes towards the opposite side, contraction of the pupils, and closure of the eyelids as if under the stimulus of a strong light. Movement of the head to the opposite side is also frequently produced. Extirpation of the angular gyrus on one side causes complete blindness in the opposite eye, but this is not permanent if the angular gyrus of the other hemisphere be intact. If this also be removed the loss of vision is complete and permanent.

(3) The superior temporo-sphenoidal convolution is the centre for hearing with the opposite ear.

Evidence.—Electrical excitation of this convolution produces sudden retraction or pricking up of the opposite ear, opening of the eyes, dilatation of the pupils, and turning of the head and eyes to the opposite side. "These phenomena resemble the sudden start and look of surprise which are caused when a loud sound is made in the opposite ear." Lesions of the temporo-sphenoidal lobe of one side which involve the superior convolution produce deafness of the opposite ear, as evidenced by the fact that the animal becomes deaf to ordinary sounds when the ear upon the same side as the lesion is stopped with cotton-wool. When the lesion is established bilaterally, so as to cause destruction of the superior temporo-sphenoidal convolution on both sides, the animal fails to respond to auditory stimuli.

(4) The hippocampal region is concerned with the appreciation of tactile sensation, if not of other forms of sensibility.

Evidence.—Unilateral destruction of this region is followed by complete absence of response to cutaneous stimulation on the opposite side of the body (without any true motor paralysis, although there may be disturbance of voluntary movements, "due to the loss of tactile sensation, by which movements are guided") "the effects being of a persistent character."

(5) The subiculum, or tip of the temporo-sphenoidal lobe, (under surface) is specially related to the sense of smell (in the nostril of the same side).

Evidence.—Electrical irritation of this part of the brain causes phenomena (torsion of the lip and partial closure of the nostril of the same side) such as are "produced by the direct application to the nostril of a powerful or disagreeable odour." Destruction of this region upon one side is accompanied, when the nostril of the opposite side is plugged, by impairment or loss of the olfactory sense: bilateral destruction by complete absence of reaction to olfactory sensations. "The comparative development of this region in animals in which the sense of smell is largely developed, as in the dog, cat, and rabbit, strongly bears out this view."

(6) The lower part of the temporo-sphenoidal lobe, close to the subiculum, is probably to be regarded as the centre of taste.

Evidence.—Electrical excitation of this region produces movements of the lips, tongue, and cheek-pouches, which "may be taken as reflex movements consequent on the excitation of gustatory sensation." And the abolition of taste coincides with (bilateral) destruction of this region.

(7) The pre-frontal region is probably related to the reflective and intellectual faculties.

(8) The occipital lobe is related to the visceral sensations, such as hunger and thirst. The evidence in favour of this opinion was regarded even by its author at the time as very inconclusive, and since the subject is entirely ignored in the later edition we need not further consider it.

E. A. SCHÄFER

(*To be continued.*)

THE UNIVERSITY COLLEGES

THE other day (March 3) the *Times* printed a letter from Prof. Jowett containing a powerful appeal to the State on behalf of the University Colleges which have recently been established in large towns by the exertions of private individuals. On Monday evening last, Mr. Mundella, having asked the Chancellor of the Exchequer whether his attention had been called to this letter, proceeded to inquire whether the Government "would introduce or facilitate the passing of a measure authorising local authorities to contribute towards the establishment and maintenance of schools and colleges adapted to the wants of their several localities, and would recommend to Parliament annual grants in aid of the same." That Mr. Goschen, so far as his personal sympathies are concerned, would have liked to give an affirmative answer to this question there can be no doubt; but, speaking as a member of the Government, he adopted a very discouraging tone. He was not in a position, he said, to recommend to Parliament annual grants in aid of local colleges. He admitted that it was an open question whether local authorities should not be empowered to aid such institutions, but the Government could not undertake to introduce or facilitate the passing of a measure dealing with the matter.

This decision is greatly to be regretted, and we must hope that the Government will soon be compelled by the pressure of public opinion to reconsider the subject. No one disputes that the University Colleges have done, and are doing, most valuable service to the communities in the midst of which they are placed. Until they were established, what is called a University education was accessible only to very well-off persons. The University Colleges have brought a high intellectual training within reach not only of the middle classes, but of working men, and large numbers of eager and intelligent students have taken advantage of the opportunities provided for them. Even, therefore, if no material benefit were derived by the nation directly from the University Colleges, it would be the clear duty of the State to afford them the help they need. But from the point of view of industry and commerce, as well as from the purely intellectual point of view, it is hardly possible to overrate the importance of these colleges. That our traders are being driven by German and other competitors from important markets is, unfortunately, only too certain; and it is not less certain that they will never recover the ground they have lost until English industry in all its branches is carried on in accordance with strictly scientific methods. This is beginning to be pretty generally understood, and it will be strange if the country does not insist that justice shall be done to institutions in which a serious attempt is being made to impart the kind of knowledge without which it is impossible for manufacturers to adapt their work to the rigid conditions of the present age.

No doubt it would be very satisfactory if the University Colleges could be made self-supporting, but this they cannot be. If those of them which do not possess any considerable endowment receive no aid from the Government, they will soon be placed in a position of grave difficulty; and the question will have to be faced, whether it is worth while to maintain them at all unless they can be maintained in a state of high efficiency. After all, it is no very great sacrifice that the State is asked to make for their benefit. What is claimed is simply that not less shall be done for the English colleges than is done for like institutions in Scotland, Ireland, and Wales.

An aspect of the question which does not always receive adequate attention was well brought out in Prof. Jowett's admirable letter. "Among other benefits," he wrote, "the influence which is exercised by these institutions on the society of a place is not to be forgotten. The residence in a large manufacturing town of a number of highly educated persons, having a variety of literary and scientific interests, is a social element of great value. They raise the tone of conversation; they create ideas and aspirations which would not ordinarily have arisen in a mercantile community. They break in on the dull monotony of wealth. The posts which they occupy, though poorly paid, afford leisure for study and opportunities for research. Among the holders of them are to be found some of the most promising young men of the country. Many of them are known by their writings, and a large proportion of the papers published in English scientific periodicals is a record of the work done in University Colleges."

The *Times*, we are glad to say, cordially supports the cause advocated by the Master of Balliol. "The good," it says (March 3), "which the local colleges do is not exaggerated by Prof. Jowett. They form centres of instruction for all the young men and young women of a town who desire to improve themselves. They foster the love of study, and teach the art of making use of time. 'They may have even kindled in the minds of one or two the spark of genius.' To put the matter on a lower but not less practical level, they have done much, by means of their technical schools, to provide that very instruction of which, as everyone admits, our artisans are so much in need to enable them to carry on the struggle for existence against foreign rivals. Nor does the Master overstate the advantages which the town indirectly derives from the presence of these colleges, whose teaching staff do much to raise the tone of social life throughout the district. It is a sound argument of the defenders of the Church Establishment that it is a great gain to English society to have at least one educated gentleman settled in every parish. The argument may be extended in favour of the University Colleges, and we may say that in a large town, where the pursuit of wealth through commerce is the characteristic of the whole society, it is a great advantage to have four or five men of high intellectual training, whose aims are different, whose standard is different, and who represent science and literature sometimes with great distinction. It would on many grounds be matter for extreme regret if the excellent institutions which foster such men should disappear. Yet there is too much reason to fear that such will be the fate of most of them, unless help more permanent and certain than any that can be derived from voluntary sources is at once forthcoming. Neither Leeds, Newcastle, Sheffield, Nottingham, nor Bristol is in a satisfactory financial condition. The fees cannot pay even the very modest stipends of the professors, and the annual subscriptions are showing a lamentable tendency to diminish. It seems as though there was nothing for it but an appeal to the Exchequer, sorely tried as it now is, and growing as is the need for economy. . . . The University Colleges during fifteen years have proved their value; and also, like every other educational institution, they have proved that they cannot live without external help. The only help that is likely to be permanent and that will enable them to feel secure is help from the State; and, in a moderate degree, it will be worth the State's while to give it."

The opinions of men of science on the subject were expressed in a letter from Sir Henry Roscoe, which appeared in the *Times* on Saturday last. "It is unnecessary now," he wrote, "to enlarge on the important national work in which these colleges are engaged. That the higher scientific and technical training which these colleges are now giving to the best of their power is a necessity, indorsed as this opinion has been by two Royal Commissions, is now, I am glad to think, generally admitted. It is, however, perfectly clear that if these colleges are to do the work which the country demands they must receive pecuniary assistance. They cannot from their very nature be made self-supporting. Their object is to afford a thorough but also a cheap education, and the localities have in almost all cases now practically exhausted the power of raising funds from private sources. How, then, are the necessary means to be found? They must come either from Imperial or from municipal sources. As the Master has pointed out, the remedy must be a speedy one. We cannot afford to wait until public opinion has reached the point at which ratepayers generally are convinced that it is to their advantage to support such colleges. The only alternative, therefore, is that the nation as a whole shall, through the Government, acknowledge its obligation to supply the necessary funds, the amount required being comparatively small and not one likely largely to increase. It is satisfactory to know that the whole subject of the furtherance of scientific and technical education in the country is at the present moment under the serious consideration of Members of Parliament of all political parties, and I have good reason to hope that our efforts to bring this question, vital as it is to the industrial and commercial supremacy of the country, to a satisfactory issue may, even this Session, be crowned by some measure of success. Among the several important matters engaging our attention, I need scarcely say that this particular one, affecting as it does the higher technical education of those who are hereafter to take positions as leaders in our commerce and industries, is by no means the least important."

We trust that the new impetus now given to this question may lead to beneficial results. It is to be hoped, however, that we shall hear less of the word "*technical*" in connection with these colleges, for if they are technical only, we may be better without them.

THE EARTHQUAKE IN SWITZERLAND

PROF. FOREL, the meteorologist, of Morges, on the Lake of Geneva, has just issued a report on the earthquake of February 23. He classifies the shocks under three heads—namely, preparatory shocks, strong shocks, and consecutive shocks. It is difficult, in the absence of trustworthy data, to indicate the precise locality of the first-named, but Switzerland was undoubtedly the region of the second; but it was to the third—that is, the consecutive shocks—that all the mischief was due. The professor traces the course of the phenomenon in Switzerland over a radius of at least four hundred square miles. Its force was greater in the southern parts of the country than in the north, though the shocks were felt throughout Geneva, Berne, Neuchâtel, Fribourg, Vaud, Valais, and Tessin; and observations go to prove that these shocks travelled almost due north and south, although the direction of the oscillations does not coincide with this course. The oscillations in Switzerland were characterised by their number and repetitions. In some localities they were longitudinal; that is, running parallel to the meridian; in others they were transverse, running or flowing from east to west. The vertical movements were marked by their feebleness where indicated, but in the greater part of the territory affected vertical oscillations were entirely absent. One of the peculiarities of the oscillations generally was the length of duration, which is set down as varying from 10 to 30 seconds. But the collected reports prove that the mean of these figures more nearly represents the prevailing duration. The intensity of the shocks was greater in the central and southern areas of the disturbance, and it would seem as if the shocks only just failed to attain the necessary strength which would have produced disastrous effects. As it was, church bells were rung, in some places violently; windows were rattled, doors thrown open, ceilings slightly cracked, and morsels of plaster were brought down, and here and there stacks of wood were thrown over. One of the most striking features of the phenomenon was the extraordinarily large number of clocks that were instantly stopped, and this fact has afforded the best possible means of determining with something like perfect accuracy the time of the shocks, which varies from three to four minutes past six in the morning, Berne time. The large astronomical clock of the Observatory at Basle stopped exactly at 6h. 4m. 7s. This, taken as representing Berne time, corresponds with 5h. 43m. 35s. of Paris, 5h. 55m. 43s. of Marseilles, 6h. 3m. 2s. of Nice, and 6h. 24m. 3s. of Rome.

The consecutive shocks, which were responsible for all the loss of life and damage to property, were centralised in the region of the Riviera. The greatest damage was done by the two first shocks, which occurred with an interval of fifteen minutes between them. The reports from the Swiss observatories also show that a series of feebler shocks were experienced in Switzerland later on in the same day, and also on several succeeding days.

NOTES

SEVERAL schools of science and art in the colonies and dependencies of the United Kingdom have expressed a wish to be allied with the Department of Science and Art and to have the advantage of its examinations. It has therefore been decided that upon the application of the Colonial Government or Educational Department, or other public authority of the colony, the Department of Science and Art will arrange for the examination of their schools, on the results of which examination certificates and returns of awards will be issued. The entire cost of the examination of the papers and works, and of their carriage, clearing in London, and conveyance to and from South Kensington, will, of course, have to be defrayed by the local authority concerned. The personal examinations, the subjects of which are stated in the Science and Art Directory, must be held in the colonies and dependencies upon the earliest date possible after the receipt of the examination papers, and these examinations must be conducted by qualified and responsible persons not immediately interested in the results of the examinations, who should on the conclusion of each examination furnish a certificate that the examination has been fairly conducted. The examination of works is held at South Kensington, and works to be examined must be forwarded to reach South Kensington not later than the end of April in each year. The Department will send upon application copies of lists of examples and prizes, and will, as far as possible, advise the local authorities in reference to the conduct of science and art schools or classes. The Department will also present specimen examination papers or works—when there are such in stock disposable—with the view of indicating the style of drawings and paintings done by students and candidates in the United Kingdom, and the standards of attainment for the various examinations.

CAPT. A. W. GREELY has been appointed to succeed the late General Hazen, as Chief Officer of the Signal Service in the United States, with rank of Brigadier-General. This announcement has been well received in America even by those who have hitherto wished to see the Signal Service separated from the army. Capt. Greely was next in rank to General Hazen in the bureau, and his eminent fitness for the duties of his new position is universally acknowledged.

THE Paris Geographical Society will shortly celebrate the centenary of the La Pérouse expedition round the world. The last news received from the unfortunate explorer and his companions was brought to France by an uncle of M. de Lesseps.

SEVERAL interesting speeches were delivered in the House of Commons, on Monday evening last, in connection with the supplementary vote of 10,560*l.* for the Science and Art Department. Mr. Mundella said the vote asked for was the result of an automatic increase in which every member who had spoken ought to rejoice. The increase had been large and rapid. In 1875 the total number of pupils in every branch of art instruction was 444,000, while in 1885 the number had increased to 883,000, or nearly double. There had been a large increase of art schools, where, he thought it would be admitted, the work was much better done than in art classes. He did not, however, profess to be satisfied with the position we have attained. It was true, he said, our Estimates were large as compared with twenty-five or thirty years ago; but, as compared with other countries similarly situated to ourselves, they were a disgrace to us. The expenditure on education in England was 5 per cent. of the whole expenditure of the country, but in some other countries the expenditure on education formed one-third of the whole expenditure of those countries—in Switzerland, for instance, it was rather more than one-third. While it was the duty of the Treasury to keep down expenditure, there would be no real good done in this country until the expenditure on education was largely increased. Prof. Stuart also insisted that England does not yet do nearly enough for scientific education. To illustrate this, he quoted the school statistics of New Zealand and Australia, showing the large proportion of children attending science teaching in those colonies. Prof. Stuart argued strongly in favour of technical instruction being carried on in evening classes, so that the minds of workmen might be concentrated on those branches of work which they might not so easily acquire in the workshop. An immense impulse had been given in the right direction when the examination in chemistry had been made one of a practical kind, instead of merely book-work and paper-work, and a similar step would have a good effect in the case of physics and mechanics. In conclusion, Prof. Stuart urged upon the Government the desirability of extending as far as possible the scholarships, local exhibitions, and prizes in connection with the science classes. Sir H. Roscoe gave it as his opinion that the money which the country voted for the purpose of science and art instruction was money well spent. The importance of the question could not be overrated, and the Science and Art Department was in a position to carry out in the main the requirements of the country in regard to such instruction. There was, however, one matter to which the Department had not yet given attention, and that was the question of manual instruction in the use of tools. In view of what was being done on the Continent in extending science and technical instruction, he trusted the Committee would pass the vote as only the beginning of what they might hope to get in time.

WE regret to announce the death of Dr. August Wilhelm Eichler, Professor of Botany at the Berlin University, and Director of the Royal Botanical Garden and Botanical Museum at Berlin. He died on Wednesday, the 2nd inst.

DURING the past month there have been several fine displays of the aurora borealis in Northern Sweden. The displays generally began about 8 o'clock p.m., and continued till towards midnight, the point of culmination being reached about 11 o'clock. The auroræ appeared in the form both of streamers and clouds, the colours being mostly white and yellow.

ON February 19, about midnight, a brilliant meteor was seen in Central Norway. It went in a direction north-east to south-west, and was observable for several seconds. The colour was at first brilliantly white, but changed during the passage into yellow and green. The greatest apparent size of the meteor was equal to that of the full moon. It left a trail a couple of yards in length, portions of which remained for some seconds after the meteor had been lost to view behind a mountain ridge. During its passage it lit up the country within a great area.

THIS year Prof. Du Bois-Reymond will celebrate the twentieth anniversary of his appointment as secretary of the Academy of Sciences of Berlin. He is the oldest member of the physico-mathematical class of the Academy.

IN a lecture delivered at the Society of Arts on Wednesday, the 2nd inst., Mr. E. J. Beale stated that last season's experiments in the cultivation of tobacco in England and Ireland resulted in a success satisfactory beyond the hopes of the most sanguine promoters of the experiments. While reasonable caution in the matter of area and extent of future operations was necessary, those results, he thought, more than justified further trials.

THE fifty-fifth annual meeting of the British Medical Association will be held at Dublin on Tuesday, August 2, and the three following days. Dr. Withers Moore, Senior Physician to the Sussex County Hospital, is President, the President-Elect being Dr. John T. Banks, Regius Professor of Physic in the University of Dublin. An address in Medicine will be delivered by Dr. W. T. Gairdner, Professor of Medicine in the University of Glasgow; one in Surgery by Dr. E. Hamilton, Fellow and Professor of Surgery in the Royal College of Surgeons in Ireland; and one in Public Medicine by the Rev. S. Haughton, M.D., Senior Fellow of Trinity College, Dublin. The scientific business will be conducted in eight sections and two subsections. Dr. G. F. Duffey, of 30 Fitzwilliam Place, Dublin, is local Honorary Secretary.

THE Exhibition of Marine Meteorological Instruments organised by the Royal Meteorological Society, which will be held at the Institution of Civil Engineers, 25 Great George Street, Westminster, from Tuesday to Friday next, the 15th to 18th inst., promises to be very interesting and instructive. Many of the instruments used in the *Challenger* and other expeditions will be exhibited. At the meeting of the Society on Wednesday evening, Dr. H. R. Mill will read a paper on "Marine Temperature Observations." Any persons, not Fellows, wishing to visit the Exhibition or to attend the meeting, can obtain tickets on application to the Assistant Secretary, Mr. W. Marriott, 30 Great George Street, S.W.

IN the State of New York there are at least fourteen distinct laws relating to the medical profession. The State Legislature is now considering a measure for the entire repeal of some of these laws, and for the abrogation of parts of others. *Science* is of opinion that the measure "should meet with the hearty support of the medical profession, and receive the vote of every member of the Legislature."

MESSRS. CASSELL AND CO. will have ready, shortly, "A Manual of Practical Solid Geometry, adapted to the Requirements of Military Students and Draughtsmen," compiled by Major William Gordon Ross, R.E., Professor of Geometrical Drawing and Fortification, Royal Military Academy, Woolwich.

MESSRS. GRIFFIN will publish, shortly, a work on pathology, by Prof. Julius Dreschfeld, of Owens College.

DR. THOMAS JONES, Lecturer on Surgery at Owens College, has a work on surgery in preparation. Messrs. Smith, Elder, and Co., will be the publishers.

MR. H. K. LEWIS will issue immediately "Photography of Bacteria," illustrated with eighty-six photographs reproduced in autotype, by Dr. Edgar M. Crookshank; also a second edition, revised and considerably enlarged, of "Manual of Bacteriology," by the same author.

WE have received the first number of the *Wesley Naturalist*, a monthly journal of the new Wesley Scientific Society, of which the Rev. Dr. Dallinger, F.R.S., is President. In an introductory paper, Dr. Dallinger says the Society does not hope to do important original work. Its aim will be "to direct, stimulate, and help, mostly the young and those engaged in daily work, in acquiring correct knowledge of the principles of a chosen branch of science."

MESSRS. GURNEY AND JACKSON, the successors to Mr. Van Voorst, are about to publish a List of British Birds, which has been revised by Mr. Howard Saunders. It will be printed so as to be available for the labelling of specimens. The use of varied type will enable the student to distinguish readily the rarer visitors and the species having a doubtful claim to be considered British.

AN extensive fish-culture establishment is being formed by Mr. William Burgess on his estate at Malvern Wells, Worcester, for the propagation of Salmonidæ and coarse fish. A series of breeding- and rearing-ponds has been made, and a hatchery capable of incubating four millions of ova is being constructed. The site selected for the purpose is said to be admirably adapted for fish-culture, as there is an abundance of pure water. Mr. Burgess has already turned into his waters a quantity of fish, including trout, salmon, and carp.

IN the spring the U.S. Fish Commission steamer *Albatross* will sail for her work on the Pacific. The fish-bearing properties of the Kiu Sawa, or Black Stream of Japan, will be investigated. The Kiu Sawa, crossing the Pacific in a high latitude, is said to modify the temperature and climate of Alaska and the Aleutian Archipelago in very much the same way as the Gulf Stream modifies the climate of the British Isles.

THE managers of the Royal Victoria Hall and Coffee Tavern show much discretion in the choice of subjects for their well-known "Penny Science Lectures." On Tuesday last a lecture on "Vesuvius and Ischia, a Volcano and an Earthquake," was delivered by the Rev. W. W. Edwards. On Tuesday next, Prof. George Forbes will describe "A Journey across Asia, through Siberia," and, on the 22nd inst., the Dean of Westminster will lecture on "Westminster Abbey."

A REPORT of the proceedings of the thirty-fifth meeting of the American Association for the Advancement of Science, held at Buffalo in August last, has lately been published. It contains, besides many short papers and abstracts, the address of Mr. H. A. Newton, the retiring President, and the addresses of the Vice-Presidents in the Sections of Mathematics and Astronomy, Physics, Chemistry, Mechanical Science and Engineering, Geology and Geography, Biology, Anthropology, and Economic Science and Statistics.

IN the second Bulletin of Miscellaneous Information, issued from the Royal Gardens, Kew, there is an interesting account of Cape boxwood. Some time ago a sample of the wood of this tree was sent to Kew, and it was found that the two woods were almost identical. It was clear, therefore, that Cape boxwood was none other than a species of *Buxus*, and perhaps *B. sempervirens* itself. Small samples were exhibited in the Cape Court at the recent Colonial and Indian Exhibition, and in the Catalogue it was stated that the wood had been "very favourably reported on for engraving purposes." The general appearance of the specimens at the Exhibition did not recommend Cape boxwood to the notice of engravers.

WE regret to announce the death of Dr. Birnbaum, Professor of Chemistry at the Technical High School at Carlsruhe, on February 20; and of Dr. Reinhold von Reichenbach, the well-known chemist, who died at Gratz on February 23.

THE South American Exhibition at Berlin has resulted in a great pecuniary loss.

M. E. BERILLON has just published a little book on Paul Bert's scientific career. Being a medical man himself, he has been able to give a very clear and accurate idea of M. Bert's work in physiology.

AT a recent meeting of the Paris Biological Society an apparatus was shown, made of iron and glass, in which a pressure of 1000 atmospheres can be developed for the purpose of studying the influence of pressure on animal life.

THE third meeting of the French Congrès de Chirurgie will take place in Paris in the month of April 1888. The second one was held in November 1886. Prof. Verneuil is President-Elect for 1888.

THE earthquake which took place on February 6 in Southern Indiana, Illinois, a small portion of Kentucky, and East Central Missouri is said by American newspapers to have had an area of about 75,000 square miles. The greatest intensity was in South-Western Indiana and South-Eastern Illinois. The U.S. Geological Survey is trying to obtain accurate information as to the boundary of the area covered.

CORRESPONDENTS in Athens report that on Friday last successive slight shocks of earthquake were felt from noon to midnight at Philiatra. The direction was south-west by south.

M. FLORAN DE VILLEPIGNE has devised, in Paris, an instrument, the autographometer, which records automatically the topography and difference of level of all places over which it passes. It is carried about on a light vehicle, and those who wish to use it have nothing to do but to drag it, or have it dragged, over the ground of which they desire to obtain a plan.

THE University of Berlin is being attended, during the present term, by no fewer than 5357 students. This is the largest number of students that have ever been enrolled by a German University. In the Faculty of Philosophy there are 1984 students; in that of Medicine, 1297; in that of Law, 1282; in that of Theology, 794. The number of instructors is 288, of whom 147 are in Philosophy, 103 in Medicine, 22 in Law, and 16 in Theology.

THE Chicago Manual Training School has lately issued its fourth annual Catalogue. The requisites for admission to this institution are that the candidates be at least fourteen years of age, and be able to pass a satisfactory examination in reading, spelling, writing, English composition, geography, and arithmetic. The course extends over three years, and includes instruction in mathematics, science, language, drawing, and shop-work, during the entire period. The school has a well-equipped wood-room, foundry, forge-room, and machine-shop, and ample apparatus for teaching the various subjects in which instruction is given. Although the regular school exercises were begun only in February 1884, the total number of pupils enrolled is now 190.

IN his Report for 1886, Mr. Andrew S. Draper, Superintendent of Public Instruction in the State of New York, points out that that State is now spending 14,000,000 dollars annually in support of its public school system; and he suggests that it might be well to spend a few thousands occasionally in efforts to determine the best way of using this vast sum. Mr. Draper puts some questions which show that he is far from being perfectly satisfied with the educational system he has to administer. "Is there not," he asks, "too much French, and German, and Latin, and Greek, and too little spelling, and writing, and mental arithmetic, and English grammar, being taught? Have we been as ambitious of progress in the lower grades as in the advanced? Are not our courses of study too complex? Are we not undertaking to do more than we are doing well? Is not the examination business being overdone? Are we not cramming with facts, which will soon be forgotten, rather than instilling principles which will endure?"

IN an article in the March number of the *Zoologist*, Mr. Robert Service tries to show that, until near the end of the first quarter of the present century, ptarmigan were natives of the south-west of Scotland. He thinks that when these birds were on the mountains of Dumfriesshire and Galloway they were probably also to be found on the Cumbrian Mountains. Mr. Service says that, in nearly all the outlying stations of the present race of ptarmigan in Scotland, such as Arran, Argyll, and the Outer Hebrides, they are decreasing.

MR. WILLIAM BURGESS, who owns an extensive pheasantry at Malvern Wells, has recently made some observations upon the red worm, which is one of the worst assailants of birds. He thinks it comes from the droppings of cattle, which when young are especially liable to the attacks of this insect. Mr. Burgess finds that agricultural salt acts as a remedy against it.

A DISCOVERY of great geological interest was lately made on Juckatoo Island, Sydney, in the shape of a Mastodonsaurus. There is a similar specimen from Stuttgart in the collection of the University, but this one is remarkable from the fact that it is the first Labyrinthodont found in Australia. It belongs to the Triassic age of the Hawkesbury Sandstone formation.

DR. WEILL, of Paris, having carefully studied the new therapeutical agent, antifebrine, or acetanilide, discovered by Cohn and Hepp, of Strasburg, says that it is an anæsthetic agent, and that it combats fever very effectually.

A FRENCH translation of the "Phantasms of the Living" is being prepared in Paris by M. Ch. Richet and some other persons.

M. HAYEZ, of Brussels, has issued a second edition of "A General List of Observatories and Astronomers, and of Astronomical Societies and Reviews," prepared by M. A. Lancaster, Librarian of the Royal Observatory of Brussels. The List has been drawn up with great care, and, from the fact that a second edition has been called for, we may assume that astronomers have found it of considerable service. The names and addresses of all well-known astronomers are given, and the compiler has noted every Observatory, whether public or private, in which work is actually being done.

IN the Proceedings of the U.S. National Museum, lately issued, there is a paper by Mr. G. H. Boehmer, on Norse naval architecture. Mr. Boehmer gives a clear and remarkably interesting account of the forms of boats represented in the ancient rock-sculptures of Sweden and Norway; of the boat-shaped stone burial-groups supposed to have been erected during the transition time from the Bronze period to the Iron Age; and of boat-remains dating from the third to about the ninth or tenth century of our era, and found at various times and places. The ship found at Tune, and the Gokstad ship, are carefully described. Mr. Boehmer thinks that the "Northland boats" now used in the fisheries along the coast of Norway are almost exactly like those which have always been used by Norsemen from the time of the rock-sculptures. These Northland boats are described as long, narrow, and low, light and elegant, and fit both for sailing and rowing.

THE additions to the Zoological Society's Gardens during the past week include a Black-winged Kite (*Elanus cæruleus*) from the Cape of Good Hope, presented by Mr. R. Southey; a Hawfinch (*Coccothraustes vulgaris*), British, presented by Mr. W. H. Quintin; two Pike (*Esox lucius*) from British fresh waters, presented respectively by Mr. H. E. Young and Mr. G. G. Sykes; two Gloved Wallabys (*Halmaturus manicatus* ♂ ♀), two Cereopsis Geese (*Cereopsis novæ-hollandiæ*) from Australia, a Blossom-headed Parrakeet (*Palæornis cyanocephalus*) from India, received in exchange; two Pike (*Esox lucius*) from British fresh waters, purchased.

OUR ASTRONOMICAL COLUMN

SOLAR ACTIVITY IN 1886.—The latter part of 1886 showed a most remarkable falling off in the number and size of the sun-spots, a falling off so great as to lead so experienced an observer as Prof. Tacchini to speak of it as possibly the minimum of the eleven-year period. The following numbers, taken from Prof. Tacchini's tables (*Comptes rendus*, vol. ciii. No. 2, and civ. No. 4), may be compared with those we gave (NATURE, vol. xxxiii. p. 398) for the year 1885:—

	Relative frequence	Relative size of spots	Daily number of spot groups	Relative size of faculæ
January	8·84	60·42	2·00	47·63
February	6·30	29·00	1·70	32·10
March	14·39	84·78	3·87	43·91
April	8·13	51·91	3·00	41·32
May	6·50	52·77	1·92	37·81
June	7·14	25·22	2·32	37·14
July	8·30	39·93	2·17	35·42
August	3·24	18·70	1·40	8·33
September	5·59	23·41	1·45	18·52
October	1·46	8·08	0·69	18·08
November	0·04	0·15	0·04	7·41
December	6·17	27·04	1·22	15·65

After the fine group of spots which were seen on May 7 and 8 had passed out of sight, the spots decreased in number and size pretty steadily until the end of October. From October 31 to December 12 there then ensued a long period of almost total quiescence. On six days only out of the forty-two could there be discovered on the sun any trace even of a spot, and on those days only one tiny spot could be seen. For an entire rotation and a half the sun was practically free from spots. M. Riccò has also drawn attention to this remarkable interval, and on searching the Palermo records for the earliest comparable period after the maximum of 1870, he finds a somewhat similar interval of quiescence in 1875, five years after the maximum of 1870, and nearly eight years after the minimum of 1867. The depression of last November follows the maximum of 1884 by less than three years, but the previous minimum by about eight years; reckoning from the minimum, the November depression follows the precedent of 1875, but reckoning from the maximum, it would appear to have occurred most exceptionally early. It would seem, therefore, that the irregularity has not been so much in the principal or secondary minima as in the maximum of 1884, which fell later than the mean by nearly two years. M. Riccò anticipates that the true minimum of the eleven-year period will fall in 1890.

A striking feature of the past year has been the great diminution, and for some months, the almost total cessation of spot activity in the northern hemisphere of the sun, nearly all the principal groups having been located in the southern hemisphere.

Faculæ and prominences have shown a falling off in 1886, but one far less marked than that shown by the spots. The following numbers derived from notes by the Rev. S. J. Perry in the *Observatory* for February 1886, and March 1887, shows that the mean extent of the prominence arc has greatly diminished, though the mean height of the prominences has suffered little change. This diminution in extent was especially marked during the last three months of the year.

	Mean height of chromosphere, excluding prominences	Mean height of prominences	Mean extent of prominence arc
	"	"	° ′
1885	8·00	28·67	28 25
1886	8·05	24·78	13 36
Mean 1880 to 1885 ...	8·07	25·71	32 45

The "mean extent" for October is 9° 54′, for November 7° 25′, and for December 9° 31′.

COMET 1887 *d* (BARNARD, FEBRUARY 15).—Prof. Boss has furnished other elements of this comet than those he gave in his first circular, the first set of elements being thus superseded. They are as follows:—

$$T = 1887 \text{ March } 28{\cdot}47$$

$$\left.\begin{array}{l}\omega = 36^\circ\ 37' \\ \Omega = 135\ \ 28 \\ \iota = 139\ \ 45\end{array}\right\} \text{Mean Eq. } 1887{\cdot}0$$

$$\log q = 1{\cdot}0059$$

Prof. Krueger (*Astr. Nach.*, No. 2774) has computed the following ephemeris for Greenwich midnight from these elements:—

1887	R.A.	Decl.	log r	log Δ
	° ′	° ′		
March 13 ...	54 13	57 49 N.	0·0162	9·9430
15 ...	52 53	57 11	0·0129	9·9730
17 ...	51 44	56 39	0·0100	0·0008
19 ...	50 41	56 11	0·0076	0·0265
21 ...	49 46	55 46	0·0056	0·0400

THE WARNER OBSERVATORY.—Mr. Lewis Swift, director of the private observatory of Mr. Warner, of Rochester, N.Y., has recently published a pamphlet giving a description of the dome and 16-inch refractor and other accessories of the observatory. The great telescope has been used by Mr. Swift, since July 1883, in a systematic search for new nebulæ, of which 540 have been discovered up to January 1, 1887. The places and descriptions of over 400 of them are given. Mr. Swift is also engaged in searching for comets. The pamphlet, in addition, contains a list of the recipients of the Warner Prizes for cometary and other astronomical discoveries, as well as a reprint of the essays on comets and on the "sky-glows" of 1883 and 1884, to which prizes have been adjudged.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *MARCH* 13–19

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 13

Sun rises, 6h. 21m.; souths, 12h. 9m. 39·3s.; sets, 17h. 58m.; decl. on meridian, 2° 56′ S.: Sidereal Time at Sunset, 5h. 22m.

Moon (at Last Quarter March 16) rises, 21h. 43m.*; souths, 3h. 8m.; sets, 8h. 23m.; decl. on meridian, 9° 34′ S.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury ...	6 22	12 54	19 26	5 33 N.
Venus	7 6	13 39	20 12	5 52 N.
Mars	6 41	12 46	18 51	0 15 N.
Jupiter... ...	21 49*	2 52	7 55	11 53 S.
Saturn... ...	11 34	19 43	3 52*	22 29 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

GEOGRAPHICAL NOTES

ON Tuesday last, the 8th inst., the Expedition under Mr. H. M. Stanley for the relief of Emin Pasha, arrived at Simonstown from Zanzibar. They were to resume their voyage on Wednesday, after taking supplies on board. Mr. Stanley is accompanied by Tippoo Tip, through whose agency, it is expected, Stanley Falls will be restored to the Congo State. Messengers have been sent across the continent to the Congo, and Mr. Stanley expects that a large addition to his caravan will be awaiting him when he arrives on the Upper Congo.

LIEUT. BAERT, of the Congo Free State, has recently made a journey up the Mongalla, a northern tributary of the Congo, considerably to the east of the Mobangi. The river had previously been navigated to some extent by Mr. Grenfell, but Lieut. Baert has succeeded in getting much beyond Grenfell's furthest. In fact, he attained the limit of navigation, at over 200 miles from the mouth of the river, where its course is broken by falls. The river flows in a general southward direction, through a well-wooded country, and its rapids are situated in about 3° 30′ N. lat., and 22° E. long. The Mongalla is very sinuous; its rapids are situated in a mountainous district inhabited by a people named Sebi, who do good work in iron.

A FRENCH traveller, M. Chaffanjon, is exploring the Orinoco. He has already surveyed the Bolivar and the San Fernando, and discovered numerous errors in existing maps. He has made large collections in ethnology, archæology, and philology. He hoped to solve the puzzling problem of the Casiquiare, and reach the sources of the Orinoco last December.

IN the first number for 1887 of the *Mitteilungen* of the Vienna Geographical Society, is a German translation of the interesting paper by D. Isabelo de los Reyes, on the Tinguians of the Philippine Island, Luzon. The author is himself an Ilocan, a tribe which marches with the Tinguians, and has had exceptional opportunities of investigating the origin, and customs, and beliefs of his fellow-countrymen, and, being educated, can tell what he knows. A good map accompanies the paper, and to this Dr. Blumentritt contributes explanatory text. To the same number Herr Edward Glaser contributes a sketch of his journeys in South Arabia, which, while mainly for archæological purposes, have yet been the means of adding much to our knowledge of the little-known South Arabian mountain-land.

THE *Bollettino* of the Italian Geographical Society for January publishes a detailed account of the recently acquired Italian possessions on the Red Sea coast, extracted from an official memoir presented to the Chamber of Deputies by S. E. di Robilant. These possessions are grouped under three separate divisions: (1) territory garrisoned and administered by Italy, including Massowa, Emberemi, the Abd-el-Kader peninsula, Gherar, Taulud Island, and the neighbouring Dahlak Archipelago; (2) protected territory, comprising the coast-lands from Adulis (Annesley) Bay southwards to Assab, with stations at Hawakil, Mader, and Ed; (3) territory placed under the absolute sovereignty of Italy—Assab and surrounding district stretching for thirty-six miles between Ras Dermah and Ras Sinthiar, and including the neighbouring islets, annexed in July 1882. Massowa, the centre of government, occupies a strong position on an island connected by an embankment with Taulud, and defended by forts at Gherar and on the Abd-el-Kader peninsula. Since the Italian occupation it has been largely rebuilt in European style, and according to a rough census taken in September 1885 has a population of about 5000. There are several mosques, a Catholic church attached to the French mission, and a meteorological observatory where observations have been regularly recorded since May 1885. During this period the temperature has varied from 19°·1 C. in January, to 42°·8 in August, with a mean of about 26°·4.

DR. OTTO KRÜMMEL publishes in the *Zeitschrift für wissenschaftliche Geographie*, under the title of "The Relief of the Australian Mediterranean," *i.e.* the sea lying between Australia and the islands on the north, some valuable data as to recent soundings therein. They are as follows:—

S. Lat.	E. Long.	Depth in fathoms
4° 45′	123° 40′	90
4° 29′	123° 48′	110
4° 14′	123° 58′	80
3° 58′	124° 10′	55
3° 45′	124° 18′	60
3° 32′	124° 34′	60
3° 22′	124° 51′	75
3° 12′	125° 10′	90
3° 3′	125° 22′	120
2° 53′	125° 36′	105
2° 45′	125° 48′	90

On the other hand, Dr. Krümmel recalls the fact that we have the neighbouring Banda Sea in a depth of 2000 to 3000 fathoms. These data seem to indicate that between Celebes and Buru there exists a sub-oceanic ridge. We cannot say whether it extends over Ceram to New Guinea, and so indicates an ancient land-bridge between Asia and Australia, for between Ceram and New Guinea we have no soundings, and those on the borders of the strait between Buru and Ceram are from 1500 to 3000 fathoms.

MR. W. GRIGGS has published a facsimile of the famous map of the world lent by the Pope to the Colonial and Indian Exhibition, and placed in the West Indian section. This map, which is a copy of the chart in which Pope Alexander drew the line dividing the possessions of Spain and Portugal in the New World, was bequeathed to the Pope by the last of the Borgias in 1830, and has since then been preserved with much jealousy. It is drawn on a sheet of vellum seven feet long by three broad. The colours of the original are reproduced.

ON RADIANT-MATTER SPECTROSCOPY:—EXAMINATION OF THE RESIDUAL GLOW[1]

II.

IN the search for bodies giving discontinuous phosphorescent spectra I have submitted a great number of earths and combinations to the electric discharge *in vacuo*, and have noted the results. As the superficial phosphorescence apart from the composition of the emitted light has formed the subject of several recent papers by my friend M. Lecoq de Boisbaudran, before the Académie des Sciences, it may be useful if I place on record some of the more striking facts which have thus come under my notice. The bodies are arranged alphabetically, and, unless otherwise explained, were tested in the radiant-matter tube in the form of ignited sulphates.

Alumina, in any of the forms which give the crimson line (λ6942—6937), has a very persistent residual glow. In the phosphoroscope rubies shine with great brilliancy. This phosphorescence of alumina has recently been the subject of a paper read before the Royal Society (Roy. Soc. Proc. vol. xlii., 1887, p. 25).

Antimony oxide with 95 per cent. of lime (in the form of ignited sulphate).—White phosphorescence, the spectrum showing a broad space in the yellow, cutting the red and orange off. In the phosphoroscopes the residual glow is very strong, and of a greenish colour. The spectrum of the residual light shows that the red and orange are entirely obliterated, leaving the green and blue very luminous. Antimony oxide with 99 per cent. of lime gives a pale yellowish phosphorescence, which on heating turns red. In other respects it is like the 5 per cent. mixture.

Arsenious acid with 99 per cent. of lime gives a greenish-white phosphorescence like pure calcium sulphate.

Barium 5 per cent., calcium 95 per cent.—The sulphates phosphoresce green, with specks of yellow and violet. The spectrum is continuous, with slight concentration in the red, great concentration in the green, and in the orange a broad black band hazy at the edges.

Bismuth 15 per cent., calcium 85 per cent., phosphoresces of a bright reddish orange. The spectrum shows a tolerably sharp and broad dark band in the red and orange, and a strong concentration of light in the green and blue; the spectrum being continuous and divided into two parts by a black band in the yellow, as in the case of the antimony-calcium spectrum. In the phosphoroscope the red and orange disappear and the green and blue remain. Bismuth 7 per cent., calcium 93 per cent.—The action is similar to the 15 per cent. mixture, except the colour of the phosphorescence, which is whiter. In the phosphoroscope the red and orange below the dark band is cut off. With 2 per cent. of bismuth the same phenomena occur. With 0·5 bismuth the phosphorescence is greenish blue and the spectrum is continuous, with strong concentrations in the orange and green. The phosphoroscope cuts off the red and orange.

Cadmium 1 per cent., calcium 99 per cent.—Similar to calcium sulphate, *q.v.*

Calcium sulphate was prepared from a colourless and transparent rhomb of Iceland spar which had been used for optical purposes. It was dissolved in nitric acid, the nitrate was decomposed with distilled sulphuric acid, and the ignited sulphate tested in the tube. The phosphorescence is bright greenish blue without bands or lines. In the phosphoroscope the colour is a rich green; the spectrum shows the red and orange entirely cut off, leaving the green and blue; the blue is especially strong.

Calcium sulphates prepared from Prof. Breithaupt's calcites (Phil. Trans., 1885, Part II., p. 697) were re-examined. All phosphoresce with the normal greenish-blue glow of calcium, except No. 11, which gives a reddish glow. A minute trace of samarium was found in this calcite, but not enough to affect the colour of the glow. In the phosphoroscope all the specimens give a continuous spectrum beyond the yellow, the red and orange being cut off as usual.

Chromium 5 per cent., calcium 95 per cent., as sulphates, gives a pale reddish phosphorescence. In the phosphoroscope the colour is green, and the red and orange are cut off. 1 per cent. of chromium with calcium phosphoresces green in the cold, and becomes a red when slightly heated. The behaviour of chromium with aluminium has already been described (Roy. Soc. Proc. vol. xlii. p. 28, *et seq.*)

Copper sulphate with 95 per cent. calcium sulphate behaves like calcium sulphate.

Diamonds phosphoresce of various colours. Those glowing pale blue have the longest residual glow, next come those phosphorescing yellow; I am unable to detect any residual glow in diamonds phosphorescing of a reddish colour. A large diamond of a greenish hue, very phosphorescent, shines almost as brightly in the phosphoroscope as out of it.

Glucina phosphoresces of a rich blue colour. There appears to be no residual glow with this earth in the phosphoroscope.

Lanthanum.—All the specimens of lanthanum sulphate I have examined in the radiant-matter tube phosphoresce of a reddish colour, and give a broad hazy band in the orange, with a sharp line—$1/\lambda^2 280$—superposed on it. This is identical with the line of Gε, one of the constituents of the samarium phosphorescent spectrum. Calcium added to lanthanum changes the colour of the phosphorescence from red to yellowish, and brings out yttrium and samarium lines, these metals being present as impurities; the Gδ and Gα lines are also seen, but the space which should be occupied by the Gβ green is now a dark space. I have shown that when Gδ, Gα, and Gβ are present in very small quantities with lime, the lines of Gδ and Gα are intensified, while that of Gβ is weakened. This new result seems to show that if only a small trace of Gβ is present with lime and lanthanum, the green line is not only suppressed, but the quenching

[1] Paper read before the Royal Society by Mr. William Crookes, F.R.S., on February 17. Continued from p. 428.

action has actually extended so far as to neutralise that part of the continuous lime spectrum having the same refrangibility as the Gβ line, the result being a black space in the spectrum. In the phosphoroscope the line of Gϵ is visible at the lowest speed; Gδ comes in at an interval of 0·0035 second, and the Gα line immediately afterwards.

Lead sulphate, by itself, in the radiant-matter tube glows with a nearly white colour, giving a continuous spectrum. In the phosphoroscope the red and orange are cut off, leaving a strong concentration of light in the green and blue. 5 per cent. of lead added to calcium sulphate phosphoresces like lime.

Magnesia phosphoresces pink. 5 per cent. with lime, as sulphates, give a greenish phosphorescence, with a tendency to turn red as the powder heats. The Oriental ruby containing about between 1 and 2 per cent. of magnesia, a mixture was prepared of acetate of alumina with 2 per cent. of magnesia, and tested after ignition. It gave no spectrum or lines. This was done to see if the crimson line of aluminium might be due to the presence of magnesia.

Nickel added to calcium sulphate in the proportion of 5 per cent. makes no alteration in the usual phosphorescent phenomena of calcium.

Potassium, 5 per cent., added to calcium sulphate gives a bright phosphorescence, and made the residual glow very persistent.

Samarium.—The phosphorescent behaviour of this body, alone and mixed with other substances, has been fully described in my paper on samarium (Phil. Trans., 1885, Part II., pp. 709–21.)

Scandium, either in the form of earth or sulphate, phosphoresces of a very faint blue colour, but the light is too feeble to enable a spectrum to be seen. Addition of lime does not bring out any lines.

Sodium sulphate mixed with an excess of calcium sulphate gives a greenish tinge to the usual colour of the phosphorescence. The sodium line is visible in the spectrum.

Strontia in the radiant-matter tube glows with a rich blue colour, showing in the spectroscope a continuous spectrum with a great concentration of light in the blue and violet. In the phosphoroscope the colour of the glow is bright green, showing in the spectroscope a continuous spectrum, with the red and blue ends cut off. A mixture of calcium sulphate with 5 per cent. of strontium sulphate behaves like calcium sulphate alone.

Thorium, as oxide or sulphate, refuses to phosphoresce, and the tube rapidly becomes non-conducting. A tube with thoria at one end and a phosphorescent earth such as lime or ytrria at the other end, and furnished with a pair of poles near each end, at a particular exhaustion is non-conducting at the thoria end, while it conducts at the yttria end. If the wires of the induction coil are attached to the poles at the thoria end, no current will pass; rather than pass through the tube, the spark prefers to strike across the spark gauge—a striking distance of 37 mm.—showing an electromotive force of 34,040 volts. Without doing anything to affect the degree of exhaustion, on transferring the wires of the induction coil from the thoria to the yttria end, the spark passes at once. To balance the spark in air the wires of the gauge must be made to approach till they are only 7 mm. apart, equivalent to an electromotive force of 6440 volts; the fact of whether thoria or yttria is under the poles making a difference of 27,600 volts in the conductivity of the tube. The explanation of this action of thoria is not yet quite clear. From the great difference in the phosphorescence of the two earths, it is evident that the passage of the electricity through these tubes is not so much dependent on the degree of exhaustion as upon the phosphorogenic property of the body opposite the poles. This view is supported by the fact that the thoria may be replaced by a metal wire, when the same obstructive action will result.

Lime does not give phosphorescent properties to thoria, if this earth be pure, but it brings out the lines of yttrium and samarium which are almost always present in small quantities in thoria unless it has been specially purified.

Tin with 95 per cent. of lime gives the lime phosphorescence only.

Thulium and *erbium* together phosphoresce with a green light, giving the erbium spectrum already described before this Society (Roy. Soc. Proc. vol. xl. p. 77, Fig. 1, January 7, 1886). There is, in addition, a faint blue line apparently double (see "Ytterbium"). The addition of lime causes the mixture to phosphoresce of a pale blue colour. The spectrum now shows a bright blue band, in the same position as the faint double blue band seen in the absence of lime. The blue line of Gα is also seen, and a faint line of Gδ. The red line of Gη, one of the constituents of the ordinary yttria spectrum, is prominent in this spectrum.

Tungsten and *uranium*, each mixed with 95 per cent. of lime, only give the lime spectrum.

Ytterbium.—I have not yet succeeded in preparing this body of trustworthy purity; but through the kindness of Prof. Clève, M. de Marignac, and Prof. Nilson, I have been enabled to experiment with specimens of ytterbia prepared by these chemists. Prof. Clève's ytterbia, in the form of sulphate, gives in the radiant-matter tube a blue phosphorescence, the spectrum of which shows a strong double blue band,[1] together with traces of the Gδ and the erbia green lines. The addition of lime broadens the blue band and makes it single. Prof. Clève writes that this ytterbia may contain some traces of thulia, perhaps also of erbia, but scarcely any other impurities. Measurements in the spectroscope give the following approximate results:—

Scale of spectroscope	λ	$\frac{1}{\lambda^2}$	Remarks
8·63	4626	4673	Commencement of first blue line. This edge is very hazy.
8·54	4574	4780	Centre of the first blue line.
8·45	4524	4885	End of first blue line.
8·44	4518	4898	Centre of dark interval between the two blue lines.
8·40	4475	4994	Centre of second blue line. This line is narrower than the first line.

The following are measurements taken with the mixture of this ytterbia and lime:—

Scale of spectroscope	λ	$\frac{1}{\lambda^2}$	Remarks
8·71	4674	4577	Up to this point there is the continuous spectrum of li-calcium. Here a black space commences.
8·515	4555	4819	Commencement of a hazy blue band.
8·475	4538	4855	End of hazy blue band. This band is of considerable brilliancy.

These blue bands are seen much fainter without lime, and are about as strong in the mixture of thulia and erbia with lime described above. I had ascribed them to ytterbia, when Prof. Nilson kindly forwarded me a small specimen of ytterbia, considered by him perfectly pure, and used for his atomic weight determinations. This ytterbia gives absolutely no blue bands. The origin of these bands therefore remains uncertain.

Ytterbia from Prof. Nilson, in the form of sulphate, refuses to phosphoresce without the addition of lime. When lime is added it only brings out traces of the phosphorescent bands of Gϵ, Gβ, and Gα. Evidently these are impurities.

Ytterbia from M. de Marignac is identical with that from M. Clève, as far as my examination can go. In sending me this ytterbia M. de Marignac warned me that he was very far from thinking it pure.

Yttrium.—During the fractionation of the higher fractions of yttria (+6, 118 and 119), a very sharp green line sometimes makes its appearance, situated between Gβ and Gγ (approximate position on the $1/\lambda^2$ scale, 325). It is very faint, and is not connected with the orange line of Sδ, although it is as sharp. The yttria showing these lines phosphoresces of a transparent golden-yellow colour, the fractions at the other end phosphorescing yellowish green.

I have previously described the action of a large number of

[1] This is the band spoken of in my Royal Society paper of June 9 last (Roy. Soc. Proc. vol. xl. 1886, p. 507), provisionally called Sγ, and ascribed to ytterbia. If it is not due to ytterbia it is a new body.

bodies on the phosphorescence of samarium ("On Radiant-Matter Spectroscopy; Part 2, Samarium," Phil. Trans., 1885, Part II. pp. 710-22.) The experiments resulting in the following observations were tried at about the same time. I will describe them in alphabetical order. Unless otherwise mentioned all the mixtures were in the form of anhydrous sulphates.

Yttrium 5 per cent., *aluminium* 95 per cent., gives a good yttria spectrum; the blue line of Gα is very distinct, and the double green of Gβ is well divided. In the phosphoroscope the Gβ and Gα lines first appear simultaneously, then the Gδ line.

Yttrium 99·5 per cent., *bismuth* 0·5 per cent.—The spectrum is bright, and on close examination a trace of samarium green, Gγ, is to be detected forming a wing to the Gδ line. In the phosphoroscope the citron line of Gδ entirely disappears and the samarium double green line, which out of the phosphoroscope is almost obscured by the great brightness of Gδ, now appears distinctly, together with the green Gβ line. Yttrium 95 per cent., bismuth 5 per cent., gives the usual yttria spectrum. No Gδ line appears in the phosphoroscope at any speed. At first only the Gβ line is seen, and next the Gα line appears, as in yttria. On gradually increasing the percentage of bismuth the spectrum of yttria grows fainter, until with 95 per cent. of bismuth the phosphorescence is bad and the spectrum faint.

Yttrium 5 per cent., *cadmium* 95 per cent., gives a brilliant phosphorescence, but the spectrum is almost continuous. In the phosphoroscope a faint concentration of light is seen in the green, which becomes sharper as the speed increases.

The action of calcium on the phosphorescence of yttrium has already been described.

Yttrium and *cerium*.—Cerium has the effect of deadening the brilliancy of the yttrium spectrum in proportion to the quantity added. All the bands remain of their normal sharpness.

Yttrium 5 per cent., *copper* 95 per cent., phosphoresces very feebly.

Yttrium 90 per cent., *didymium* 10 per cent.—This mixture gives a good yttria spectrum. Yttrium 70 per cent., didymium 30 per cent., phosphoresces very fairly, and gives all the usual lines.

Yttrium 50 per cent., *didymium* 50 per cent., refuses to phosphoresce. The tube is either too full of gas to allow the phosphorescence to be seen or it becomes non-conducting. When the mixture is illuminated by the glowing gas the absorption-lines of didymium in the green are seen. With higher proportions of didymium the same results are produced. On adding 25 per cent. of lime to the mixture containing 50 per cent. of didymium the yttria spectrum is brought out very well. Lime added to a mixture of 10 per cent. yttria and 90 per cent. didymium brings out the yttrium spectrum fairly, but the tube soon becomes non-conducting.

Yttrium 5 per cent. and *glucinum* 95 per cent. gives a bright phosphorescence, but the definition of the spectrum lines of yttria is bad.

Yttrium 5 per cent., *thallium* 95 per cent.—No spectrum is given by this mixture; it turns black and refuses to phosphoresce.

Yttrium 5 per cent., *tin* 95 per cent., phosphoresces faintly, the lines being very indistinct.

Yttrium 5 per cent., *titanium* 95 per cent., acts like thoria, and the tube becomes non-conducting.

Yttrium 5 per cent., *tungsten* 95 per cent.—This phosphoresces of a bright yellow colour, the spectrum is brilliant, but the lines are not sharply defined. In the phosphoroscope the colour becomes greenish, and the spectrum shows only the green lines of Gβ.

Yttrium 5 per cent., *zinc* 95 per cent.—The phosphorescence is of a pale yellowish-white, and the spectrum is very brilliant, being equal to that shown by 30 per cent. of yttrium with barium, calcium, magnesium, or strontium. In the phosphoroscope the colour becomes reddish, and the Gβ green line is the first to come. No citron line is seen. If the yttrium contains a trace of samarium, the samarium spectrum, which is scarcely seen under ordinary circumstances, now comes out distinctly.

Zinc sulphate mixed with 95 per cent. of calcium sulphate phosphoresces a bright bluish-green colour; the spectrum contains no bands or lines.

Zinc sulphide (Sidot's hexagonal blende, *Comptes rendus*, vol. lxii., 1886, pp. 999-1001; vol. lxiii., 1886, pp. 188-89).—This is the most brilliant phosphorescent body I have yet met with. In the vacuum tube it begins to phosphoresce at an exhaustion of several inches below a vacuum. At first only a green glow can be seen; as the exhaustion gets better a little blue phosphorescence comes round the edges. At a high exhaustion, on passing the current the green and blue glows are about equal in brightness, but the blue glow vanishes immediately the current stops, while the green glow lasts for an hour or more. In the phosphoroscope the blue glow is only seen at a very high speed, but the green glow is seen at the slowest speed, and the body is almost as bright in the instrument as out of it. Some parts of a crystalline mass of blende which, under the action of radiant matter, leave a glow with a bright blue colour, leave a green residual light when the current ceases; other parts which glow blue become instantly dark on stopping the current.

The different action of calcium, barium, and strontium on the constituents of yttrium is an additional proof, if confirmation be needed, that the bodies I have provisionally called Gα, Gβ, Gδ, &c. (Roy. Soc. Proc. vol. xl. 1886, p. 502), are separate entities. It may be as well here to collect together the evidence on which I rely to support this view. I will take the bodies *seriatim*:—

Gα.—An earth phosphorescing with a blue light, and showing in the spectroscope a deep blue line, of a mean wave-length 482. This earth occurs in different proportions in purified yttria from different minerals. Samarskite, gadolinite, hielmite, monazite, xenotime, euxenite, and arrhenite contain most Gα, whilst fluocerite and cerite contained notably less of this constituent. The addition of lime brings out the phosphorescence in Gα in advance of that of the other constituents. The behaviour in the phosphoroscope of Gα when mixed with the alkaline earths also points to a difference between it and its associates. With lime the blue phosphorescent band of Gα comes into view at a very low speed, the order of appearance with a small quantity of lime being Gβ, Gα, Gδ, and with a large quantity of lime, Gδ, Gα, Gβ. Employing strontia instead of lime, the order of appearance in the phosphoroscope when the quantity of strontia is small is Gβ, Gα, Gη, and when the quantity of strontia is in excess, Gα, Gη, Gβ. Baryta in small quantity brings out the lines in the phosphoroscope in the following order, Gβ, Gα, Gη; but when the baryta is in excess the order is Gβ, Gη, Gα. The chemical position taken up by Gα in the fractionation scheme precludes it from being due to the bodies I have called Gβ, Gγ, Gε, Gζ, Sγ, or Sδ. It closely accompanies Gδ (the earth giving the citron line), concentrating at the least basic end, and I have not yet succeeded in effecting a separation of the two. If, therefore, Gα is not a separate entity, its blue line must be due to the citron-band-forming body called Gδ. The difference between Gα and Gδ is brought out in a marked manner by the phosphoroscope when baryta or strontia is present; the citron line of Gδ being entirely suppressed, while the blue line of Gα is brought out with enhanced brilliancy. For these reasons I am inclined to regard Gα as a separate body, although the evidence in favour of this view is not so strong as in the case of some of its other associates.

Gβ.—An earth phosphorescing with green light, and showing in the spectroscope a close pair of greenish-blue lines of a mean wave-length of 545. This earth can be separated by chemical fractionation from the other constituents of yttrium. It concentrates at the most basic end, and is present in the samarium which invariably makes its appearance at this end of the fractionation of yttrium. It is one of the prominent lines in Yα, where also it accompanies some of the samarium lines. Gβ, however, is not a constituent of samarium, for it is easy to purify samarium by chemical means so that it does not show a trace of the Gβ green lines, although it is very difficult to get Gβ free from some of the samarium lines. The residual phosphorescence of Gβ is very considerable, and its green lines show first in the phosphoroscope when only yttrium is present. The addition of lime keeps back the glow of Gβ, and brings forward that of Gδ. Strontium and barium act on Gβ very differently to lime. A small quantity of strontium brings forward the residual glow of Gβ, whilst in large quantities strontium keeps the phosphorescence of Gβ back to the last.

Gγ.—An earth phosphorescing with a green colour, and showing in the spectroscope a green line having a wave-length of 564. This is one of the least definite of all the supposed new bodies. It appears to be a constituent of samarium, occurring in the fractionation of yttrium among the most basic constituents connecting yttrium and samarium. Its point of maximum intensity is, chemically, very well marked, and is at a different part of the fractionation scheme to those of the other lines of samarium, especially Gϵ. On dilution with lime, the phosphorescent line of Gγ vanishes before that of Gϵ.

Gδ.—An earth phosphorescing with a citron coloured light, and showing in the spectroscope a citron line having a wave-length of 574. Gδ is one of the least basic of all the bodies associated in yttrium, occurring almost at one extremity of the fractionation. It is not very difficult to separate chemically Gδ from all the other accompanying bodies except the one which I have called Gα (giving the deep blue line). Not only can Gδ be obtained free from the other four constituents of yttrium, but the body called by M. de Marignac Yα is a proof that the other four components of yttrium can be obtained quite free from Gδ. Lime intensifies the phosphorescence of Gδ, and deadens that of Gβ, while strontium has the opposite action. The behaviour of Gδ in the phosphoroscope, when mixed with lime, strontia, or baryta, also affords a striking evidence of individuality, lime enhancing the residual glow, while strontia or baryta altogether suppress it.

Gϵ.—An earth phosphorescing with a yellow colour, and, in the spectroscope, showing a sharp yellow line having a wave-length of 597. It is seen in the samarium spectrum as a sharp yellow line superposed on a hazy double band. As I have already pointed out, Gϵ fractionates out high up among the most basic earths, and generally accompanies lanthanum. In the phosphorescent spectrum of lanthanum the line Gϵ is seen quite free from the lines of other bodies.

Gζ.—An earth phosphorescing with a red light, showing in the spectroscope a red line of wave-length 619. This body is always more plentiful in yttrium obtained from samarskite and cerite than from gadolinite, hielmite, and euxenite, and is almost absent in yttrium from xenotime. Gζ is of about intermediate basicity. Working with samarskite yttria, Gζ becomes most brilliant after the line of Gη has completely disappeared. Further fractionation causes the line of Gζ to fade out, and the citron and blue lines are then left.

The phosphorescence of Gζ is developed to a different extent according to the metal with which the yttria is mixed. The order (beginning with the substance having the greatest action) is zirconium, tin, aluminium, bismuth, glucinum.

Gη.—An earth phosphorescing with a deep red light, and showing in the spectroscope a red line having a wave-length of 647. Like its fellow red constituent, Gη occurs most plentifully in samarskite yttrium, and scarcely at all in yttrium from hielmite, euxenite, and cerite. It is the first of the strictly yttrium constituents to separate out, on fractionation, at the most basic extremity, leaving Gα, Gβ, Gδ, and Gζ. In almost all samples of yttria, except when very highly purified, Gη is seen very brilliantly, and by its side can be detected the faint red band of samarium. In the phosphoroscope the line of Gη is the last to appear when yttria alone is being observed; strontia and baryta enhance the residual glow of Gη, strontia in moderate quantities bringing it out before that of Gβ, while baryta brings it out after Gβ.

Sδ.—An earth giving in the spectroscope when phosphorescing a very sharp orange line of wave-length 609. I have already (Roy. Soc. Proc. vol. xl. 1886, p. 504) discussed the claims of this earth to be considered a separate entity. It is not present in the rare earths from gadolinite, xenotime, monazite, hielmite, euxenite, and arrhenite; it is present in small quantity in cerite, and somewhat more plentifully in samarskite. In samarskite yttrium it concentrates at a definite part of the fractionation. Its sharp orange line is not strong enough to be seen in the phosphoroscope. A little calcium entirely suppresses the orange line, while samarium or yttrium seems to intensify it.

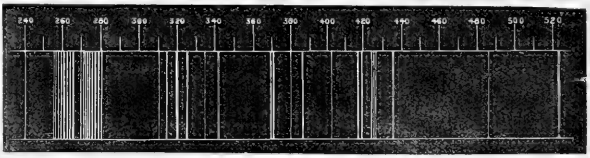

FIG. 5.

In addition to the above earths, it is not improbable that the sharp green line $\left(\frac{1}{\lambda^2}\ 325\right)$ mentioned under the heading "Yttrium" may be caused by still another earth.

The brilliant and characteristic spark spectra yielded when certain elements are volatilised and rendered incandescent by the spark from a powerful induction coil are relied on by chemists as an indisputable proof of the identity of such elements. Bearing this in mind I have endeavoured to ascertain how these yttrium constituents would behave in respect to the spark spectrum. Do the definite system of lines in the old yttrium spark spectrum belong to one constituent only, or are the yttrium lines broken up and distributed among the different bodies I have designated as Gα, Gβ, &c.? Also do the other constituents possess special spark spectra of their own? Very careful and long-continued experiments have shown me that neither of these hypothetical cases occur.

The spark spectrum given by old yttrium is shown in the drawing (Fig. 5). It is chiefly characterised by two very strong groups of lines in the red and orange. I now take the earth Gδ. This occurs near one end of the fractioning, and not only differs from the parent yttrium in its phosphorescent spectrum, but by virtue of the process adopted for its isolation it must likewise differ in its chemical properties. On examining its spark spectrum I see absolutely no difference between this spectrum and the one given by old yttrium.

I now pass to the other end of the fractionation of yttrium, where occurs a concentration of a body giving a totally different phosphorescent spectrum from the one at the first end. And it also differs chemically from old yttrium, and in a more marked manner from its brother, Gδ, at the other extremity of the fractionation. Here again its spark spectrum is perfectly identical both with old yttrium and with Gδ, and however closely I examine these three spectra in my laboratory, the whole system of lines is still identical.

Respecting the theoretical considerations involved in these results, I see two possible explanations of the facts brought forward. According to one hypothesis, research has somewhat enlarged the field lying between the indications given by ordinary coarse chemistry and the searching scrutiny of the prism. Our notions of a chemical element have expanded. Hitherto, the molecule has been regarded as an aggregate of two or more atoms, and no account has been taken of the architectural design on which these atoms have been joined. We may consider that the structure of a chemical element is more complicated than has hitherto been supposed. Between the molecules we are accustomed to deal with in chemical reactions and the ultimate atoms, come smaller molecules or aggregates of physical atoms; these sub-molecules differ one from the other, according to the position they occupied in the yttrium edifice.

An alternative theory commends itself to chemists, to the effect that the various bodies discussed above are new chemical elements differing from yttrium and samarium in basic powers and several other chemical and physical properties, but not sufficiently to enable us to effect any but a slight separation. One of these bodies, Gδ, gives the phosphorescent citron line, and also the brilliant electric spectrum. The other seven do not give electric spectra which can be recognised in the presence of a small quantity of Gδ, whilst the electric spectrum of Gδ is so sensitive that it shines out in undiminished brilliancy even when the quantity present is extremely minute. In the process of fractionation, Gα, Gβ, Gδ, &c., are spread out and more or less separated from one another, yet the separation is imperfect at the best, and at any part there is enough Gδ to reveal its presence by the sensitive electric spark test. The arguments in favour of each theory are strong and pretty evenly balanced.

The compound molecule explanation is a good working hypothesis, which I think may account for the facts, while it does not postulate the rather heroic alternative of calling into existence eight or nine new elements to explain the phenomena. However, I submit it only as an hypothesis. If further research shows the new element theory is more reasonable, I shall be the first person to accept it.

Neither of these theories agrees with that of M. Lecoq de Boisbaudran, who also has worked on these earths for some time. He considers that what I have called old yttrium is a true element, giving a characteristic spark spectrum, but not giving a phosphorescent spectrum *in vacuo*. The bodies giving the phosphorescent spectra he considers to be impurities in yttrium. These he says are two in number, and he has provisionally named them $Z\alpha$ and $Z\beta$. By a method of his own, differing from mine, M. de Boisbaudran obtains fluorescent spectra of these bodies; but their fluorescent bands are extremely hazy and faint, rendering identification difficult. Some of them fall near lines in the spectra of my $G\beta$ and $G\delta$. At first sight it might appear that his and my spectra were due to the same bodies, but according to M. de Boisbaudran the chemical properties of the earths producing them are widely distinct. Those giving phosphorescent lines by my method occur at the yttrium extremity of the fractionation, where his fluorescent bands are scarcely shown at all; whilst his fluorescent phenomena are at their maximum quite at the terbium end of the fractionation, where no yttrium can be detected even by the direct spark, and where my phosphorescent lines are almost absent.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Girton College has withdrawn from the arrangement by which it was hoped that a united scholarship for men and women might be established in geology and palæontology out of the Harkness fund. The council of Girton do not consider that the scheme proposed fulfils the essential condition of placing students of Girton and Newnham on the same terms as members of the University. A scheme has consequently been propounded for men alone, open to B.A.'s of not more than four years' standing. The electors are to be the Vice-Chancellor, the Woodwardian Professor, the Examiners in Geology in the Natural Sciences Tripos for the current and the preceding year, and an additional elected examiner. The electors are to take any steps they think desirable to ascertain the qualifications of candidates, and in making the award they are to have regard to proficiency in geology and palæontology, and to promise of future work. One scholar is to be elected annually; but in case no person shall be deemed worthy of election, the income for the year is to go to a reserve fund, to be given, when advisable, to scholars to aid them in prosecuting geological or palæontological researches.

The acceptance of the John Lucas Walker Studentship for the furtherance of original research in pathology, which has been offered to the University by the Attorney-General, is to be voted on in the Senate to-day. The amended regulations provide that the studentship shall be usually tenable for three years, with power of further prolongation for two years more when exceptionally valuable work has been done by the student. The fund, consisting of about 8300*l.* 4 per cent. debentures, is to be managed by the Professor of Pathology for the time being, the Professors of Physic and Physiology, and the President of the London College of Physicians. The studentship is not to be awarded by competitive examination, but any other mode of ascertaining qualifications may be taken. After full announcement of a vacancy, the Professor of Pathology is to nominate the best qualified candidate, but the other electors may overrule the nomination if they are unanimous in favour of some other candidate. The student shall not necessarily be a member of Cambridge University, and may be of either sex. No occupation interfering with pathological research may be followed by the student, who is also to vacate his studentship if elected to a professorship or fellowship. At least three terms of study are to be pursued at Cambridge. Exhibitions or prizes not exceeding 50*l.* may from time to time be awarded by the managers to any person, except the student for the time being, in respect of any essay, discovery, or meritorious service connected with or conducing to the science of pathology, and grants may be made for the furtherance of original research in the science.

The amended regulations for the Mechanical Sciences Tripos also come to a vote to-day.

The Senate has accepted the subscription of 500*l.* offered through Prof. Newton to enable the University to become a Governor of the Marine Biological Association.

The following new appointments of electors to various Professorships have been made: Botany, Mr. Thiselton Dyer; Political Economy, Right Hon. A. J. Balfour, M.P.; Experimental Physics, Dr. D. MacAlister; Downing Professorship of Medicine, Dr. A. Macalister; Mental Philosophy and Logic, Prof. A. Marshall; Surgery, Dr. A. Macalister. The remaining appointments are re-elections.

SCIENTIFIC SERIALS

American Journal of Science, February.—Kilauea after the eruption of March 1886. Under this general heading are grouped three separate papers, disposed in chronological order, describing the appearance of the volcano at different times since the great outburst of last March. The first is a communication to Prof. W. D. Alexander, Surveyor-General of the Hawaiian Islands, by J. S. Emerson, assistant in the Survey, dated August 27, and embodying a series of observations ranging from March 24 to April 14. This paper is illustrated by a plate showing the crater and new lake drawn to a scale of 1 : 20,000. The second, by L. L. Van Slyke, Professor of Chemistry, Honolulu, describes the general appearance of the volcanic district during the month of July, when considerable changes had already occurred, including a general upheaval in the centre of Halema'uma'u, and the reappearance of liquid lava in three different places. The third comprises a report to Prof. Alexander by Mr. Frank S. Dodge, on the survey of Kilauea in the last week of September and the first of October, with a plate of the crater on a scale of 1 : 6000. This observer expects that perhaps in a few months the great central pit will again fill up and overflow, as it did prior to the last eruption.—Volcanic action, by James D. Dana. The general question of igneous disturbances is discussed in connection with the recent eruptions of Kilauea, Vesuvius, and Tarawera. The author's conclusions on the causes of these phenomena, as summed up in his "Manual of Geology" (1863), are mainly confirmed, being attributed to the hydrostatic pressure of the column of lava; the pressure of vapours escaping in underground regions from the lavas, or produced by contact with them, acting either quietly or catastrophically; and the pressure of the subsiding crush of the crust forcing up the lavas in the conduit.—On the Coahuila meteorites, by Oliver Whipple Huntington. It is shown that the assumed new meteorite discovered near Fort Duncan, Maverick County, Texas, and recently described by Mr. W. E. Hidden, is really one of the "Coahuila irons," described by J. Lawrence Smith, and supposed to belong to one fall, although found on the opposite side of the Rio Grande from Maverick County.—A new rhizostomatous Medusa from New England, by J. Walter Fewkes. This is a large acraspedote jelly fish, not only new to New England, but also unlike any yet captured on the Atlantic coast of North America. It was captured in September 1886 in New Haven harbour, and is allied to a common species found on the west European seaboard, *Pilema* (*Rhizostoma*, auth.) *octopus*, Haeck., and to *P. pulmo* of the Mediterranean.—A short study of the atmosphere of β Lyræ, by Orray T. Sherman. The author's observations lead to the conclusion that in stars known to possess a spectrum comprising bright lines, these lines, while persistent in place, are not persistent in intensity. Comparing Lockyer's result in the study of the atmosphere with his own, he draws a general conclusion regarding the condition of the stellar atmosphere, describing it as consisting of an outer layer of hydrogen positively electrified, an inner layer of oxygen negatively electrified, and between them a layer of carbon mingling on its edge with the hydrogen. The electric spark passing through the mixture forms the hydrocarbon compound, whose molecular weight carries it into the oxygen region where combustion ensues with the formation of carbonic acid and aqueous vapour, both of which descending under the influences of their molecular weight are again dissociated by internal heat, and return again to their original positions.—Phenacite from Colorado, by Samuel L. Penfield, with notes on the locality of Topaz Butte, by Walter B. Smith. Some interesting facts are communicated with regard to the crystallisation of this remarkable mineral, the occurrence of which in the United States (Pike's Peak, El Paso County, Colorado), was determined by Messrs. Cross and Hillebrand.

Topaz Butte, five miles north of Florissant, marks the southern limit of the "crystal beds" whence have come most of the specimens labelled *Pike's Peak*. The largest phenacite ever found in this locality is a rough lenticular crystal about 15 mm. in diameter.—The norites of the Cortlandt series on the Hudson River, near Peekskill, New York, by George H. Williams. In continuation of his memoir on the peridotites of the Cortlandt series (*American Journal of Science*, 1886, p. 26) the author here begins a petrographic description of the massive rocks of this system. The present paper deals with the non-chrysolitic rocks, norite proper and hornblende norite. He designates all rocks in which one-half or more of the non-feldspathic constituents are hypersthene as norite, and names varieties of this after the prevailing accessory component.—A method for subjecting living protoplasm to the action of different liquids, by George L. Goodale. An apparatus is described by means of which the necessity is obviated of transferring specimens from the litre-flask to the stage of the microscope, all handling being thus avoided, while the object can be placed under the action of as large a quantity of liquid as may be desirable.—On the topaz from the Thomas Range, Utah, by A. N. Alling. The topaz crystals here under examination are from the cabinet of Prof. Brush, vary in length from 3 mm. to 10 mm., and are perfectly clear and colourless.—On a simple and convenient form of water battery, by Henry A. Rowland. A simple, convenient, and cheap form of water battery is described, which the author has had in use for many years.

Bulletin des Sciences Mathématiques, tome x. December 1886, tome xi. January 1887, Paris.—We single out these two recently issued parts, as they contain papers on subjects intimately connected with notices of Greek geometry, which we have from time to time communicated to NATURE when giving an account of Dr. Allman's contributions to *Hermathena*. In the *Mélanges* of the earlier number M. Paul Tannery has two notes: one of nine pages, entitled "Démocrite et Archytas" (see Gow's "History," p. 129, and NATURE, vol. xxxiv. p. 548); the other, of eleven pages, on "Les Géomètres de l'Académie." The later part has an article of, twelve pages, by the same writer, on "La Technologie des Éléments d'Euclide." All three are quite up to M. Tannery's well-known excellent form for thoroughness of research and soundness of inference. The rest of the matter consists as usual of reviews (*inter alia*, of the French translation of Clerk Maxwell's "Electricity and Magnetism" and Mr. Greenhill's "Differential and Integral Calculus"), and of useful abstracts of papers in the various Continental and British mathematical journals.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, February 24.—"Problems in Mechanism regarding Trains of Pulleys and Drums of Least Weight for a given Velocity Ratio." By Prof. H. Hennessy, F.R.S.

As trains of wheels, pulleys, and drums are frequently employed in machinery for the transformation of large and small velocities of rotation, it appeared to the author desirable to inquire into the conditions which would favour the greatest economy of weight of the parts forming such trains. Eighty years since Dr. Thomas Young had arrived at a theorem for the minimum number of teeth in a train of wheels and pinions with a given velocity ratio, and when the pairs of wheels and pinions are similar. By investigating the question of minimum volume or minimum weight of trains the author has been led to the following results, which are fully demonstrated in his paper: namely, that for a train of cylindrical pulleys composed of similar pairs the ratio of the diameter of a large to that of a small pulley should be as 19 to 10. For drums composed of hoops supported by disks of the same thickness, and with the breadth of each hoop equal to the radius of the small drum, the ratio of the diameters should be 11 to 5. If the hoop was supported by spokes whose volume taken together would be half the volume of a complete disk, the ratio would be 51 to 20. With regard to a train of pulleys, it was shown that a single pair possessing the same velocity ratio as a series with the ratio of diameters found for minimum volume, the latter would be considerably less than the former. Thus, with five pairs whose velocity ratio would be nearly 24¾, the volume would be less than the 1/26 of a single pair possessing the same velocity ratio. A model constructed in brass of such a train, with all the large pulleys 1·9 inches in diameter, and all the small 1 inch, weighed 18·34 ounces. A train of four pairs of drums illustrative of the last problem solved weighed 16·788 ounces, the large drums being 2·55 inches, and the small 1 inch diameter, while all the hoops were half an inch broad. The velocity ratio of this train is 42·2825, or a little more than 42¼.

March 3.—"The Etiology of Scarlet Fever." By E. Klein, M.D., F.R.S., Lecturer on General Anatomy and Physiology at the Medical School of St. Bartholomew's Hospital, London.

The investigation, the results of which I now record, was commenced at the end of December, 1885. It arose out of an inquiry into the prevalence of scarlatina in different quarters of London, undertaken by the Medical Department of the Local Government Board as a part of its business of investigating local epidemics. That inquiry had demonstrated milk from a farm at Hendon as the cause of the scarlatina, and had adduced strong circumstantial evidence that the scarlatina had been distributed, not in the whole, but in certain sections of the Hendon milk, and further that the ability of the sections of milk service to convey the disease had been related to a malady affecting particular cows. This evidence against particular cows at the Hendon farm could not and did not aim at furnishing direct and definite proof of the connection of this cow disease with scarlet fever of man, for the inductive methods usually employed by the Medical Department of the Local Government Board when applied to inquiries about epidemic spread of scarlatina can for obvious reasons yield but circumstantial evidence. As on various former occasions, so also on this, the Medical Department sought to put the above conclusions to the test of scientific experiment. This task was delegated to me by the Board. The first part of this work has been published in the recently issued volume of the Reports of the Medical Officer of the Local Government Board for 1885–86. I have therein shown that the suspected cows from the Hendon farm that had been made the object of special study, showed besides a skin disease—consisting in ulcers on the udder and teats, and in sores and scurfy patches and loss of hair on different parts of the skin—also a general disease of the viscera, notably the lungs, liver, spleen, and kidney, which resembled the disease of these organs in acute cases of human scarlatina. I have further shown that the diseased tissues of the ulcers on the teats and udder produced on inoculation into the skin of calves a similar local disease, which in its incubation and general anatomical characters proved identical with the ulceration of the cow; and further, that from the ulcers of the cow a species of micrococcus was isolated by cultivation in artificial nutritive media, which micro-organism in its mode of growth on nutritive gelatine, on Agar-Agar mixture, on blood serum, in broth, and in milk, proved very peculiar and different from other species of micrococci hitherto examined. With such cultivation of the micrococcus I have produced by subcutaneous inoculation in calves a disease which in its cutaneous and visceral lesions (lung, liver, spleen, and kidney) bears a very close resemblance both to the disease that was observed in the Hendon cows as well as to human scarlatina.

The second part of the work, carried out during 1886–87 for the Medical Department, had for its object to investigate whether or no the disease, human scarlatina, is associated with the identical micrococcus, and whether this, if obtainable from the human subject, is capable of producing in the bovine species the same disease as was observed in the Hendon cows and in the calves experimented upon from the latter source. The definite and clear proof that this is really the case has now been obtained, and the evidence I now bring to the notice of the Royal Society.

On examining acute cases of human scarlatina—for which opportunity I owe great thanks to Dr. Sweeting, the Medical Superintendent of the Fulham Fever Hospital—I soon ascertained the fact that there is present in the blood of the general circulation a species of micrococcus, which on cultivation in nutritive gelatine, Agar-Agar mixture, blood serum, and other media, proved to be in every respect identical with that obtained from the Hendon cows. Out of eleven acute cases of scarlet fever examined in this direction, four yielded positive results: three were acute cases between the third and sixth day of illness with high fever temperature, and the fourth was a case of death from scarlatina on the sixth day. In all these four cases several drops of blood were used, after the customary methods and under the required precautions for establishing cultivations in a series of tubes containing sterilised nutritive gelatine, and generally only a very small number of these tubes revealed after an incubation of several days one or two colonies of the micrococcus. This shows that the micrococci were present in the blood in but small numbers.

Having ascertained the identity in morphological and cultural respects of the micrococcus of the blood of human scarlatina with the organism obtained from the Hendon cows, the action of the cultivations of both these sets of micrococci was then tested on animals and the results compared. It was found that mice—wild mice better than tame ones—after inoculation or after feeding, became affected in exactly the same manner, no matter whether the one set of cultivations or the other was used. The great majority of these animals died after between seven and twenty days; the *post-mortem* examination revealed great congestion of the lungs, amounting in some cases to consolidation of portions of the organ, congestion of the liver, congestion and swelling of the spleen, great congestion and general disease of the cortical part of the kidney. From the blood of these animals, taken directly from the heart, cultivations were established in nutritive gelatine, and hereby the existence of the same species of micrococci was revealed; they possessed all those special characters distinguishing the cultivations of the micrococcus of the Hendon cows, and of the human scarlatina.

In the third and concluding section of the work, cultivations of the micrococcus of two cases of human scarlatina were used for infecting calves: two calves were inoculated, and two were fed from each set of cultivations. All eight animals developed disease, both cutaneous and visceral, identical with that produced in the calves that had been last year infected with the micrococcus from the Hendon cows.

From the heart's blood of calves thus infected from human scarlatina the same micrococcus was recovered by cultivation, possessing all the characters shown by the cultures of the micrococcus of the Hendon cows, and of the cases of human scarlatina.

It must be evident from these observations that the danger of scarlatinal infection from the disease in the cow is real, and that towards the study and careful supervision of this cow disease all efforts ought to be directed in order to check the spread of scarlet fever in man. It is also obvious that in the agricultural interest investigations of this cow disease are greatly called for.

Anthropological Institute, February 22.—Mr. Francis Galton, F.R.S., President, in the chair.—The election of Mr. Joseph Straker was announced.—Prof. Ferrier read a paper on the functional topography of the brain. He discussed the question how far recent investigations into the functional topography of the brain could be brought into relation with craniological and anthropological researches with a view to establish the foundations of a scientific phrenology. Then he sketched the functional topography of the brain so far as it had been settled, but pointed out that the psychological aspects of brain functions were still far from being made out, although that correlation must be established and proved before a practical psychology, in any degree serviceable to the physician or the anthropologist, could be regarded as possible. He offered some speculations on the subject, and illustrated them by reference to certain facts and phenomena of disease in man. On the question as to how far it was possible from an anatomical examination of the brain to form an estimate of the forces and capacities of the individual, he pointed out many great difficulties which had to be encountered. *Cæteris paribus*, greater anatomical development might be considered as an index of greater functional capacity. He thought the attempt to determine differences in functional capacity from the examination of the head involved all the difficulties connected with the examination of the brain, and a great many more. He indicated the cranial relations of the principal convolutions, but expressed his belief that in the present state of our knowledge the data of a scientific phrenology were still very deficient. There was reason to believe, however, that, if the subject were taken up from different points of view by anatomists, physiologists, psychologists, and anthropologists, great progress might be made.—Mr. H. D. Rolleston read a paper on the cerebral hemispheres of an adult Australian; and a paper by Mr. Sören Hansen on a fossil human skull from Lagoa Santa, Brazil, was taken as read.

Entomological Society, February 2.—Dr. D. Sharp, President, in the chair.—The President nominated Mr. R. McLachlan, F.R.S., Mr. O. Salvin, F.R.S., and Mr. H. T. Stainton, F.R.S., Vice-Presidents during the Session 1887-88.—The Rev. W. J. Holland, Dr. F. A. Dixey, Mr. C. J. Gahan, and Mr. S. Klein, were elected Fellows.—Mr. P. Crowley exhibited a new species of *Synchloë*—*S. johnstoni*—from Kilima-njaro; also, for comparison, specimens of *Synchloë mesentina* and *S. hellica*, which the new species closely resembled.—Mr. W. White exhibited a number of preserved larvæ of European Lepidoptera in various stages of growth, illustrating the gradual development of the markings and colours, as explained by Prof. Weismann, in his "Studies in the Theory of Descent."—Mr. Gervase F. Mathew exhibited a variety of a female of *Lycæna telicanus*, from the neighbourhood of Gallipoli; some specimens of a *Lycæna* from Vigo, believed to be varieties of *Lycæna baton*; and several examples of a *Leucophasia* from Vigo, which appeared to be identical with *L. æstiva*.—Mr. Porritt exhibited, on behalf of Mr. N. F. Dobrée, a series of a remarkable red form of *Teniocampa gracilis*, bred from larvæ collected in Hampshire.—Mr. Eland Shaw exhibited specimens of *Pachytylus cinerascens* (Fab.), *Mecostethus grossus* (Linné), and *Gryllus flavipes* (Gmel.), and read a note on the identity of *Gryllus* (*Locusta*) *flavipes* (Gmel.).—Mr. H. Goss read a communication from Prof. Riley, of Washington, on the subject of the Australian bug (*Icerya purchasi*). It was stated that the insect had of late years become very destructive to various trees and shrubs in California, into which country, as well as into New Zealand and Cape Colony, it had been introduced from Australia.—The Rev. T. A. Marshall communicated a monograph of the British *Braconidæ*, part 2.—Mr. F. P. Pascoe read a paper entitled "Descriptions of some new species of *Brachycerus*."—Mr. Francis Galton, F.R.S., read a paper "On pedigree moth-breeding as a means of verifying certain important constants in the general theory of heredity," in which he suggested the institution of a system of experimental breedings, to be continued for several years, with the object of procuring evidence as to the precise measure of the diminution of the rate at which a divergence from the average of the race proceeds in successive generations of continually selected animals.—Mr. F. Merrifield read a paper entitled "A proposed method of breeding *Selenia illustraria*, with the object of obtaining data for Mr. Galton." Mr. McLachlan said he considered the fact that *S. illustraria* was dimorphic an objection to its selection for the experiments proposed, and suggested that the common silkworm moth would be more suitable. Prof. Meldola remarked that, although for some reasons the species selected was well adapted for testing Mr. Galton's conclusions, he believed that the fact of the moth being seasonally dimorphic was likely to introduce disturbing elements into the experiments which might influence the results. The discussion was continued by Dr. Sharp, Messrs. Baly, Kirby, White, Klein, Porritt, Dunning, Waterhouse, Bates, Merrifield, Galton, and others.

Chemical Society, February 17.—Dr. Hugo Müller, F.R.S., President, in the chair.—It was announced that the following changes in the Council list were proposed by the Council:—As President: Mr. W. Crookes, F.R.S., *vice* Dr. Hugo Müller, F.R.S. As Vice-Presidents: Prof. McLeod, F.R.S., Prof. Schorlemmer, F.R.S., and Mr. Ludwig Mond, *vice* Mr. Crookes, F.R.S., Prof. Liveing, F.R.S., and Prof. T. E. Thorpe, F.R.S. As ordinary Members of the Council: Prof. A. H. Church, Dr. P. F. Frankland, Prof. Kinch, and Dr. H. F. Morley, *vice* Messrs. H. T. Brown, A. E. Fletcher, and Profs. Meldola and Pickering.—The following papers were read:—The influence of temperature on the heat of dissolution of salts, by Prof. S. U. Pickering. This is an extension of the author's previous work on the sulphates, entitled "The Influence of Temperature on the Heat of Chemical Combination" (Trans., 1886, 260), which tended to show that the heat of dissolution of a salt does not increase regularly with a rise of temperature, but that irregularities occur at various points, so that the heat of dissolution must be represented by a series of curves. The experiments with potassium sulphate, hydrated and anhydrous magnesium sulphate, and hydrated and anhydrous copper sulphate have been repeated, and the investigation extended to potassium, sodium, hydrated and anhydrous strontium chloride, potassium and the two strontium nitrates, the two sodium carbonates, sodium acetate and potassium sodium tartrate. The investigation comprises over 700 determinations, the mean results with each salt being deduced from two to five distinct series of experiments, each performed with different thermometers. The observations extended from 3° to 25°. In all cases it was found that the irregularities previously noticed were the result of error, and that the heat of dissolution of a salt is represented by a series of straight lines. In rising from low temperatures the heat of dissolution is expressed by a straight line up to a certain point, when the rate becomes suddenly lowered and remains constant till a further sudden reduction occurs at some still higher temperature. The average divergence of all the mean results from lines of perfect straightness amounted to less than one-thousandth of a degree. . . . The heat of combination of a salt with its water of crystallisation is deduced from the author's results. He concludes that it is not a constant quantity at all temperatures; the general effect of rise of temperature being to diminish it, although at very low temperatures this effect seems to be more than counterbalanced by some other cause, probably the tendency of the water molecules to unite with each other, the heat of combination diminishing then with fall of temperature. The more water a salt contains the more marked are both these results.—Periodates, by Dr. C. W. Kimmins.—Sulphonic acids derived from the β-monohaloid-derivatives of naphthalene, by Prof. Henry E. Armstrong and Mr. W. P. Wynne.—The decomposition of potassium chlorate and perchlorate by heat, by Dr. Frank L. Teed.—The formation of ethylic cyanacetoacetate, by Dr. J. William James.—The relation of diazobenzene anilide to amidoazobenzene, by Mr. R. J. Friswell and Mr. A. G. Green.—Note on Wallach's explanation of the isomeric transformation of diazoamidobenzene into amidoazobenzene, by Prof. R. Meldola, F.R.S.

Victoria Institute, February 21.—Prof. T. McKenny Hughes read a paper on caves, their formation, uses as places of refuge, and the influences which in many cases cause uncertainty as to the ages of the deposits therein. In regard to English sea caves he held that our coasts had not recovered their present elevation, after the submergence that followed on the Glacial age, before man came on the scene, marine shells being found buried in the same earth as Palæolithic man and the extinct animals.

Middlesex Natural History Society, February 15.—Mr. Mattieu Williams in the chair.—Mr. Logan Lobley read a paper on the geology of the parish of Hampstead. Commencing with a sketch of the work of those distinguished geologists who have made Hampstead classic ground, Mr. Lobley referred especially to the work of the late Mr. Caleb Evans, and mentioned that Mr. Evans's well-known model of the area had passed into safe keeping. The London Clay was described in detail; its minerals, the nature of its clays, and the material manufactured from them, were treated of, as well as the sections, and the fossils they have yielded. Passing on to the Bagshot Sands, Mr. Lobley traced their age, their connection with similar beds of other districts, and the important part they play in the question of water-supply. Some remarks upon the formation of the present features of the area by denudation, and some interesting and suggestive notes upon the sources and direction of flow of the former smaller streams, such as the Fleet, the West Bourne, and the Bays Water, with a reference to the great folds of the Chalk, and the relation of the geology of London to that of the southern area, concluded the paper.

Edinburgh

Royal Society, February 7.—Lord Maclaren, Vice-President, in the chair.—Dr. E. Saug read a paper on cases of instability in open structures.—Mr. W. Peddie communicated a paper on the time-rate of increase of electrolytic polarisation.—Sir W. Thomson discussed the equilibrium of a gas under its own gravitation alone, and pointed out the bearing of the problem on the question of the probable age of the sun.—Dr. Ralph Copeland, of Dun Echt Observatory, communicated some astronomical notes.

Royal Physical Society, January 19.—Dr. Alexander Bruce showed some microscopic specimens tending to confirm Gower's views with regard to the existence of the ascending lateral tract in the spinal cord. His sections were taken from a case of meningomyelitis confined to the lower dorsal cord. They showed ascending degeneration of Goll's columns, of both cerebellar tracts, and of a comma-shaped tract in the situation of the ascending lateral tract of Gower's.—Dr. R. H. Traquair communicated the first part of a revision of the nomenclature of the fishes of the Old Red Sandstone of Scotland.—Mr. W. E. Hoyle read a report on a collection of shells brought from the West Coast of Africa, the Canaries, and Cape Verde Islands, by Mr. John Rattray.

Mathematical Society, February 11.—Mr. George Thom, President, in the chair.—Mr. W. J. Macdonald gave a proof of a geometrical theorem; Mr. A. Y. Fraser submitted a paper on vortices, by Mr. Charles Chree; Mr. R. E. Allardice communicated a note on a theorem in algebra, by Mr. John L. Mackenzie; Mr. George A. Gibson called attention to a point in the history of definite integrals; and Mr. John S. Mackay gave a few trigonometrical notes.

Cambridge

Philosophical Society, January 31.—Prof. Babington in the chair.—On the motion of a ring in an infinite liquid, by Mr. A. B. Basset.—Form and position of the Horopter, by Mr. J. Larmor.—On the finer structure of the walls of the endosperm cells of *Tamus communis*, by Mr. Walter Gardiner. It would appear, from the author's more recent researches, that the perforation of the walls of the endosperm cells in the plant referred to is established after the formation of the wall, and in a similar manner to that which occurs in sieve-tubes during the formation of the sieve-plate. The author further hopes to show that this is a special instance of a general phenomenon.

February 14.—Mr. Trotter, President, in the chair.—On the influence of capillary action in some chemical decompositions, by Prof. Liveing.—On homotaxis, by Mr. J. E. Marr.—Note on the function of the secreting hairs found upon the nodes of young stems of *Thunbergia laurifolia*; on the petiolar glands of the Ipomœas; and on the occurrence of secreting grandular organs on the leaves of some Aroids, by Mr. Walter Gardiner. In the last paper the author remarked that it has been frequently stated that the entire absence of all extra-floral secretory structures in monocotyledonous plants furnishes one of the most striking points of difference between the above-named group and the Dicotyledons. One would be led to expect, however, that some form of secretive organ should be present, and that probably they would be found—if anywhere—among the Aroids. Guided by these considerations, the author made a careful examination of the Aroids at Kew, and was so fortunate as to find two individuals, viz. *Aglaonema Mannii* and *Alocasia cuprea*, which appear to him to possess definite organs of secretion. The structure of these organs was then shortly described, and a comparison was instituted between them and certain forms of extra-floral nectaries. As to the existence of intramural glands, *e.g.* in *Anthurium punctatum*, the author's observations confirmed those of Dalitzsch recently published in the *Botanisches Centralblatt*.

Liverpool

Biological Society, January 22.—Prof. W. Mitchell Banks, President, read his inaugural address, which dealt with the aims and objects of the Society.—Prof. W. A. Herdman read a paper on recent researches in connection with the vertebrate brain (the pineal eye in lizards, and the pituitary gland in the Vertebrata and Tunicata), and their bearing on the hypothetical protochordata.

February 12.—Prof. W. A. Herdman, Vice-President, in the chair.—Mr. A. O. Walker contributed some notes on the *Mysidæ* of Liverpool Bay, with a description of some abnormal specimens.—A paper was read by Mr. J. Lomas on some points in the structure of *Alcyonidium gelatinosum*.—The Secretary (Mr. R. J. Harvey Gibson) drew attention to the new English translation of Sachs's "Text-book of Botany," Book II., by Goebel, and made some remarks on the value of a uniform terminology for the reproductive organs, not merely in botany, but in biology generally.—Dr. Ellis contributed some notes on boring insect larvæ.—Dr. Larkin exhibited and described some physiological apparatus.

Paris

Academy of Sciences, February 28.—M. Gosselin, President, in the chair.—Remarks accompanying the presentation of MM. Charcot and P. Richer's work, "Les Démoniaques dans l'Art," by M. Charcot. Representations of persons "possessed by the devil," that is subject to epilepsy and other nervous affections, have been brought together from ivories, enamels, tapestries, engravings, paintings, and other sources, for the purpose of studying these works from the stand-point of scientific truth. Such masters as Andrea del Sarto, Domenichino, and Rubens are generally found to have depicted these subjects with a strict regard to nature, so that their figures accurately reproduce the traits of a now well-understood pathological state.—Determination of the constant of aberration: first and second method of observation, by M. Lœwy. The author here deals with the somewhat feeble part played by refraction in these already described processes. From this study it appears that, the action of refraction being at all altitudes the same, the measure of the distance (except for very low regions) may be everywhere effected under almost identical conditions of accuracy. Hence it is no longer necessary to observe the two stars only when found at considerable altitudes, a circumstance which greatly facilitates compliance with the other geometrical conditions of the problem.—On the great movements of the atmosphere, in connection with M. Mascart's last note of February 21, by M. Faye. The author reviews the whole subject of aërial movements as bearing more especially on his well-known theory regarding the direction of the wind in cyclones. The paper is followed by a brief reply from M. Mascart, who still maintains that this theory is unsupported by observation.—Note on the measurement of the photographic plates of the transit of Venus across the solar disk in 1882, by M. Bouquet de la Grye. These measurements, which have been executed in the Institute, deal altogether with 1019 plates, involving lengthy calculations which cover no less than 32,000 sheets of paper.—On the phosphorescence of the sulphuret of calcium, by M. Edmond Becquerel. In connection with M. Verneuil's recent paper on the determining causes of the phosphorescence of the sulphuret of calcium, the author makes some observations on the views already announced by him on the influence of foreign substances in modifying the molecular condition of the sulphuret of phosphorescent calcium.—On the red fluorescence of alumina, by M. Lecoq de Boisbaudran. It has recently been shown that highly calcined alumina yielding a bluish fluorescence *in vacuo* assumes a red tint in the phosphoroscope. Notwithstanding this observation the author still contends that the presence of chromium is necessary to obtain the red fluorescence of alumina. A mere trace of Cr_2O_3 superadded suffices to produce the fine fluorescence described by M. Becquerel in his work on "Light."—Note on the earthquake of February 23 at Marseilles Observatory, by M. E. Stephan. The movement which was attended by such disastrous effects along the Riviera, and even in the Maritime Alps, was very little felt at Marseilles, where two series of shocks were recorded at the Observatory, the first at 5.55 in the morning, and lasting about 90 seconds, the second ten minutes later, and lasting only some 15 seconds. The astronomic pendulums were somewhat disturbed, but the meridian-circle was not appreciably affected.—Observations of Barnard's new comet (1887 *d*), and of Palisa's new planet 265, made at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan.—On a new method of determining the parallax of the sun by the photographic observation of the transit of Venus, by M. Obrecht. The method here described yields formulæ by means of which the parallax may be determined from the observations of *a single station*.—Additional note on the measurement of aberration, by M. J. C. Houzeau. It is shown that the objections recently raised by M. Lœwy to the author's method rest on a serious error.—On applicable surfaces, by M. E. Amigues. A definition is given of rectilineal applicable surfaces, from which several theorems are deduced.—On the product of two sums of eight squares, by M. X. Antomari. A fresh demonstration is given of the theorem that the product of two sums of eight squares is a sum of eight squares. It is further remarked that by means of this theorem a rule of multiplication of complex quantities in a space of eight dimensions may be conceived analogous to the rule of multiplication of quaternions.—Note on entropy, by M. Félix Lucas. It is shown on theoretical grounds that when a gas is heated under a constant volume or under a constant pressure, the increase of its entropy is in proportion to the increase of its true temperature.—On the coefficients of chemical affinity, by MM. P. Chroustchoff and A. Martinoff. Certain analytic and thermic experiments are described, from which it is inferred that neither the initial nor the final composition of precipitates can serve to give coefficients of chemical affinity. Characteristic constants of affinity cannot be evolved by the method of simultaneous precipitation.—The action of heat on heptene, by M. Adolphe Renard. From the experiments here described, it follows that under the influence of heat heptene is decomposed chiefly into toluene and hydrogen, at the same time yielding a certain quantity of its lower homologues, hexene and pentene.—On the special characters of the loss of activity experienced by diastase under the action of heat, by M. Em. Bourquelot. A series of experiments are described, from which it would appear that the quality of the fermentation is modified rather than its quantity diminished, unless it be admitted that in natural diastase there are two or more soluble ferments intermingled, which by the increase of temperature become successively destroyed.—On the earths of cerite, M. Eug. Demarçay.—On the ferrite of zinc, by M. Alex. Gorgeu. Several methods are described for easily preparing this substance, and comparing it with the natural ferrite known as franklinite.—On the nitrates and superphosphates, by M. A. Andouard. The author's experiments show that it is a mistake to mix these substances together as artificial manures.—On the destruction of the Nematodes of beetroot, by M. Aimé Girard. The sulphuret of carbon is proposed as a more practical remedy than the expensive system of "decoy plants" (*plantes pièges*) introduced by Kühn.—On the cause of the changes which take place in the blood on contact with air, oxygen, and carbonic acid, by M. A. Béchamp. These changes are referred to the activity and influence of the microzymes of the blood.—On the transfusion of blood into the head of decapitated animals, by MM. Hayem and Barrier. It is argued that the assertions contained in M. Laborde's recent communication on this subject are not justified by his own publications.—On the gastric glands secreting mucus and ferment in birds, by M. Maurice Cazin.—On the structure of the muscular fibres in the edriophthalmous crustaceans, by M. R. Kœhler.—On the anatomy of Bilhazia (*B. hæmatobia, Distomum hæmatobium*), by M. Joannes Chatin.—On the geology of the Lake Kelbia district and of the Central Tunisian seaboard, by M. G. Rolland. From his extensive studies of this region the author concludes that during the historic period the relief of the land has not perceptibly changed, and that in the Roman epoch as well as now Lake Kelbia communicated only intermittently with the sea.—On the deposits of tin, from the geological stand-point, by Mr. Reilly. Excluding those of Mexico and Bolivia, the author argues that all these deposits, from Cornwall to Australia, are connected by a vast curve, which he calls the "axis of Sumatra."—On some new methods of artificially producing crystallised silica and orthose, by M. K. de Kroustchoff.—On the earthquake of February 23, recorded at the Perpignan Observatory, by M. Fines. As at Marseilles, the vibrations were but slightly felt in this district.—On the effects of the same earthquake in East Switzerland, by M. F. A. Forel. The main shock appears to have been very generally felt throughout this region.—Papers followed describing its effects at Nice, Voreppe (Isère), and Saint-Tropez, and discussing the relations that may exist between seismic and magnetic disturbances.

Berlin

Physiological Society, January 28.—Prof. Du Bois-Reymond in the chair.—Dr. Benda mentioned that his researches, according to which the "spermatoblasts" resulted from the coalescing of the cells forming the spermatozoa with the supporting cells, had some years earlier been anticipated by the French anatomists, and that Prof. Grünhagen, who formerly opposed this view, was now likewise presenting it as his own.—Dr. Rawitz had examined the green gland of fresh-water crayfish. It was situated on the first member of the antennæ, was uniformly green on the ventral side, but on the dorsal side only at the periphery, elsewhere white, with a round yellow-brown speck in the centre. The gland consisted of two tubules closely interwoven. The cells of the green part had a round grass-green drop of protoplasm, the yellow-brown cells a uniformly yellow-brown coloured nucleus. The tubules anastomosed, the yellow-brown cells being the terminal portions of the tubules, and secretory. No conclusions respecting the function of the glands could be drawn from their anatomical structure.—Dr. Gad made a communication respecting the peculiar strange albumen-precipitate with salt recently described by Dr. Wurster. If to the white of eggs lactic acid, peroxide of hydrogen, and common salt were added, almost the whole of the albumen was precipitated as a white flaky mass, perfectly similar in appearance and taste to newly-precipitated caseine (curd), but distinguished from caseine by its chemical reactions. The easy digestibility of this form of albumen, which had hitherto been precipitated by no other reagent was especially remarkable. It was interesting that, in accordance with the reactions shown by Dr. Wurster's test paper for active oxygen, hydrochloric acid was formed on the mixture of lactic acid, peroxide of hydrogen, and common salt, and this acid *in statu nascendi* might be the specific precipitate for this new form of albumen, which could be obtained just as well from blood serum as from white of eggs.

Meteorological Society, February 1.—Prof. von Bezold in the chair.—Dr. Frölich gave a report on measurements of solar heat, which, following up those instituted in 1883 and already published, he had made in the years 1884 to 1886 after some alterations in his apparatus. The most important modifications made in the apparatus consisted in the removal of the rock-salt plate in front of the thermo-electric pile which he had made use of in his first measurements. He had been induced to remove the rock-salt plate by the conviction that after a time rock-salt developed a quality of transmissibility which was not identical both for luminous and for non-luminous heat. The bare thermo-electric pile showed itself by oft-repeated proofs to be constant towards the rays of a Leslie cube. The relation of the rays from the blackened side of the cube to the rays from the white side continued invariably the same. The same constancy was manifested in the registrations of the thermal element towards the luminous heat of a white-glowing platinum chimney, which was uniformly heated by two gas-flames. The observations of solar heat were made on perfectly bright days and under a perfectly clear atmosphere, the thermo-electric pile being directed to the sun under very different heights, as far as 10°, and exposed to the sun till the diversion of the galvanometer had become constant. The values obtained on the various days and under different solar positions were graphically delineated, on the supposition that the absorption of the atmosphere was an exponential function of its density. The result came out that the "curve" was practically a straight line, or a line concave or convex to so small a degree as to deviate but very little from a straight line. When the curve was lengthened till it met the perpendicular co-ordinate, then the intersecting point representing the magnitude of the solar heat was the same for all days of observation. The deviating results of Mr. Langley and Messrs. Angot and Crova were explained, in part from the fact that in their calculation the reflection of the thermal rays in the different atmospheric strata had not been taken account of, and in part from the fact that the different atmospheric strata were assumed to be parallel, and so their incurvation was left out of account. Notwithstanding the circumstance that the absorption by the atmosphere was different for the different kinds of rays, and also different from day to day, yet was the "curve," the co-ordinates of which were represented by the observed heat and the abscissæ by the logarithms, without exception, a straight line. This empirically ascertained fact was the main result of the whole series of investigations extending over three years.

Physical Society, February 4.—Prof. Helmholtz in the chair.—Dr. Sprung described the barograph designed by him, which avoided the errors of the older balance-barometer (first constructed in 1760 by Samuel Moreland) by making the barometer work on a resting horizontal beam, which through horizontal automatic displacement of a sliding weight was kept always in exact equilibrium. The travelling vertical tread-wheel constantly marked its position on the writing-table of the instrument. Seeing, moreover, that this displacement of the tread-wheel was effected by a clockwork, any disturbance that might arise from its rubbing against the barometer was completely precluded. The automatic equilibration of the beam of the balance was produced by an electric current. The speaker had quite recently instituted a series of the most various experiments, by which he demonstrated how the registering balance designed by him was with great advantage available for a large number of physical investigations: how, for example, he was able by his balance to permanently register the state of the quicksilver in the barometer; the progress of the evaporation of alcohol; the discharge of a fluid from a capillary tube; the change of intensity in an electric current; the evaporation of water through a clay-ball; the changes of density in the atmospheric air recorded by the variations of rise on the part of a large glass ball; and phenomena connected with permanent change of weight. The registering balance, which was being executed by the mechanician Fues in Berlin, allowed, in short, a large series of physical processes to be automatically recorded, and would prove highly useful in many physical investigations.—Prof. Helmholtz, by an experiment, demonstrated the great cohesion of an air-free column of water. A siphon-shaped glass tube, the longer leg of which was closed and the shorter one open, was filled with quicksilver, and above the quicksilver there was superposed a small quantity of distilled water. If the filling was effected without admission of air, then, on the tube being placed in an upright position, the water adhered to the closed end, and its adhesion supported the quicksilver column, which was longer than the barometer height. The speaker now brought the open end of the siphon tube into communication with an air-pump, and caused to be pumped out as much as down to 2 mm. pressure, but even then the cohesion of the water supported the quicksilver column. Only by shaking was the water column shattered, and the quicksilver immediately sank. If there was no shaking, the apparatus continued for an unlimited length of time unchanged. This contrivance should serve the purpose of electrolysing air-free water and ascertaining the strength of the current under which gas bubbles developed themselves by electrolysis. The experiment showed that on the transmission of a current of 2 volts the water continued adherent. The depression of the quicksilver column in consequence of gas development occurred, however, in an experiment with a current of 2·15, and in another with a current of 2·18 volts.

February 18.—Prof. Schwalbe in the chair.—Dr. Frölich spoke of his measurements of the solar heat in the years 1883, 1884, and 1886, and refuted at length the objections which had been raised against these measurements by MM. Vogel, Langley, Angot, and Crova. In the discussion following thereon, Dr. König stated that experiments carried out in the Physical Institute with a Langley bolometer indicated that very considerable influence is exercised by the air-currents on this delicate measuring-instrument.

THE STATE AND HIGHER EDUCATION

IT is seldom that a Cabinet Minister receives so influential a deputation as that which on Friday last requested Mr. Goschen to supplement the revenues of the Victoria University from the National Exchequer. The gentlemen present represented the intelligence and industry of the North of England: they told a story of earnest and patriotic effort, and we sincerely trust that Mr. Goschen will feel able to afford them the moderate assistance they desire.

The ground on which the request was made, and on which Mr. Goschen promised to consider it with favourable attention, was designedly circumscribed by narrow limits. Neither the deputation nor the Chancellor wished to raise the wide question of the future relations between the State and the higher education. Both were anxious to regard the matter in hand from one point of view only. For good reasons the State has seen fit to confer the power of granting degrees upon the Victoria University, but it insists that external examiners shall take part with the Professors of the University in the conduct of the degree examinations. The cost thereby entailed on the Colleges, though not very great, is still an appreciable burden to institutions which can barely pay their way. It is therefore suggested that without committing itself to any far-reaching scheme of a general endowment of University Colleges, the State might properly defray the cost of the restrictions which it has itself imposed. Unlike the Universities of Oxford and Cambridge, the Victoria University has hitherto depended on funds which have been accumulated in a single generation. Unlike the University of London, it is a federation of Colleges engaged in educational work. These institutions want their class fees and their examination fees as well as all their slender resources from endowments, and could turn them to good account. Their case is, that to do so would be to the public advantage. They ask that 2000*l.* a year may be given towards the salaries of the examiners and other University officials, in order that the Colleges of the Victoria University may be able to devote the whole of their available funds to the work of teaching.

With this position we have no fault to find. The circumstances of the Victoria University are exceptional, and we think that the Chancellor of the Exchequer, if he grants the request of the deputation, may fairly contend that he has not committed himself on the wider issue that must before long be raised.

We cannot, however, refrain from pointing out that the question of State aid to higher education cannot remain in its present position. Whether such aid shall or shall not be given is no longer open to discussion. It is given already, but not, apparently, on any definite principle.

If it is right that 12,000*l.* a year should be supplied from the national funds for three new Colleges in Wales, which have still their reputations to make, it is surely wrong that England should have received no help till a school of science of European celebrity like the Owens College is forced to ask for a share in a grant of 2000*l.* a year. Scotland, Wales, and Ireland receive upwards of 40,000*l.* a year in aid of higher education. Why is England, who pays no small share of this, to have no equivalent aid herself? It has not been found that a liberal educational policy discourages the "pious founder." University College, Dundee, and Lord Gifford's recent bequest are proofs that he still flourishes in Scotland. Why should a contrary result be feared if England shared Scotland's advantages?

It may be said that the fact that the northern Colleges have reached their present degree of efficiency without State support is sufficient proof that it has not been needed. We doubt the validity of this argument. Time is an important element in the industrial warfare of the present day. If we are to wait till prosperity and high prices enable our provincial Colleges to struggle through the slough of financial difficulty in which many of them are involved, we may find too late that efficient educational institutions have helped to bring to others prosperity which has not come to us. The higher education of our industrial population is no mere luxury to be attended to at a more "convenient season," but a vital necessity, a fundamental condition of commercial success. The State should indeed do nothing to choke the fount of private generosity by which in the past that education has for the most part been provided. It should do all in its power to direct local effort towards those channels in which most good can be done. The promoters of the Yorkshire College were four years in collecting one-third of the sum which they originally regarded as necessary for their enterprise; and the undertaking might have languished for several years more had not the Clothworkers' Company come forward with an offer of timely and judicious help. Much good might be done if in like manner the State would assist and encourage the founders of a College in the earlier and more difficult stages of their work.

We are, however, clearly of opinion that if after fair trial it is evident that a "University College" cannot hope to attain efficient support, or to fill its class-rooms from the surrounding neighbourhood, the State would do well to transfer its patronage of higher education elsewhere. If an institution, whether called a "University College" or not, is really doing elementary work, it can, under our present system, obtain State aid. If its pupils are entered for the South Kensington and City and Guilds of London Examinations, it may, by the grants thus received, largely diminish the sum which would otherwise be required for the payment of its teachers. If, then, it is sufficiently proved that any institution belongs to this class, it is already provided for, and has no special claim for further and exceptional help.

On the other hand, it must be remembered that the higher education has never been self-supporting, and that the most successful College can only hope to make both ends meet by endowments or by a sufficient income obtained from some other source than fees. More good will be done by allotting any sum devoted to higher education to Colleges which may be in financial difficulties, but which have proved that they are situated where the want of such education is felt, than in affording exceptional support to institutions in thinly-populated districts, where the "raw material" for a successful experiment in teaching of the highest class cannot be found. An able lad gains much valuable knowledge, and, most important of all, self-knowledge, by contact with those who are his equals not only in talent but in years. It would be better, by a system of scholarships, to give the youth of country districts an opportunity of learning what competition means in a flourishing College, than to foster a large number of half-equipped and struggling institutions, which cannot reasonably hope to attract students of more than average capacity in numbers sufficient to justify their claim to being centres of the higher learning.

To encourage in their initial stages promising educational enterprises; to determine, if need be after fair trial, whether any given institution can do most good as a centre of elementary, secondary, or higher instruction; to afford to institutions of each grade help, the amount and continuance of which depend upon the educational results they attain and upon the increase or withdrawal of local support,—these are the general lines on which the State may aid secondary and higher education. It would thus encourage the performance of good work in each educational stage at those points where in the nature of things good work of that kind could best be done. It would be led no doubt into expenditure, but in this, as in so many other cases, the old induction holds good. "There is that scattereth and yet increaseth," is true of nations as of individuals, and most true of national expenditure on education.

PRACTICAL ZOOLOGY

An Elementary Course in Practical Zoology. By B. P. Colton, Instructor in Natural Sciences, Ottawa High School, Illinois. (Boston: D. C. Heath and Co., 1886.)

THIS volume is one of the latest additions to the stock of laboratory hand-books based upon the well-known type-system. It is more comprehensive, but, in detail, much simpler and more elementary, than any of its predecessors, while it differs from them in its method of treatment. The objects and scope of the work are set forth in a short introduction, and the detailed matter is embodied in thirty-two fasciculi, each devoted mainly to a consideration of some one type of organisation. Of these, ten are devoted to Insects and three to Crustacea—this, however, for a special purpose to which we shall allude. Practical hints dealing with methods and the like are incorporated with the text.

Certain emendations will be necessary in a subsequent edition, and to these we shall refer duly. In not a few cases the descriptions of the structural features of a given animal have been prefaced by a brief account of its habits and movements. An arrangement, this, of which we heartily approve. It must not be imagined, however, that the book stops short here. The author sets himself "to aid the student in getting a clear idea of the animal kingdom, as a whole, by the careful study of a few typical animals," and he reminds us that "a definition thought out by the student himself, imperfect though it be, is of more value to him than a perfect definition learned from a book, which often appeals to mere memory. Definitions made in the way these pages require are good as far as they go: they should be corrected and supplemented by the instructor. It develops a boy more to earn a dime than to receive a dollar as a gift."

The contents of the work are well arranged, the style is clear and concise, and the facts are presented in logical sequence, nothing being anticipated; but despite the assertion quoted above, there are far too few facts recorded. Some of the descriptions are meagre in the extreme, while others are so brief as to be useless. For example: on p. 8 the nervous system is introduced to the beginner for the first time (and that in the grasshopper) as consisting "mainly of a white cord extending along the floor of the whole body-cavity. In most of the abdominal rings the nerve-cord has enlargements called ganglia, from which nerves branch to the surrounding parts." The like is to be said of the descriptions of the spider's organs of respiration (p. 22), of the clam's kidney (p. 52), and other organs which could be named; while those of the dorsal vessel and "liver" of the earthworm demand early rectification. On p. 30 the author says of the "line of division between the head and thorax" in the crayfish:—"Huxley places it between the second pair of maxillæ and the first pair of maxillipeds. Hyatt places the division between the first and second pairs of maxillæ, as the space between these is membranous entirely across the sternal region, while back of this line the parts are hard and firmly soldered together." One primary object of a book of this kind should be that of imparting a sound training in methods by way of systematising the work of the student, and every conscientious teacher of zoology knows that by no means the least formidable difficulty to be encountered is that of teaching his pupils how much, and what, they shall leave aside. Bearing this in mind, we would fain see all matters which involve differences of opinion such as that alluded to above, eliminated from an elementary work.

The author has evidently been struck with the fact that there has manifested itself, under the growth of the type-system, a tendency to produce a lop-sidedness in the mind of the student. He is by no means alone here, but he sets himself to rectify the matter. This he does by extending and considerably modifying the said system; with what amount of success, has yet to be seen. He, and others who have since come into touch with him, must bear in mind that the type-book is, for the most part, but a tool in the hands of the student working (as does he for whom the author prescribes) under the guidance of a teacher, whose bounden duty it is personally to direct the work in all its details. He, and he alone, is to blame for this apparent defect.

One charge frequently brought against the type-system is that of apparent neglect of classification. The author meets this difficulty in a praiseworthy manner, by first describing a given animal as fully as his case demands, and then dealing with certain allied forms sufficiently to bring out the nature of those comparisons upon which our existing classifications are based. He introduces the subject of classification (p. 12) in an absolutely dogmatic and empirical manner, which, while it does not do justice to his intentions, exposes at the same time the dangers of the method adopted. He supplements the afore-mentioned chapter for chapter. Writing on p. 44, he says:—"Animals are ranked according to the number of things they can do, and do well. The earthworm has many parts, but they are nearly all alike, and do not enable it to do many different things. A part of an animal having a specia work to do is called an organ, and its work is its function. The earthworm has many organs, but few functions. Apply this principle to man and an ape. Each has four limbs. The ape is called four-handed, but has no good hands; he cannot handle things well. He has not good feet; he cannot walk well. What is the one thing he can do well with his four foot-hands? How many distinct functions has man with his hands and feet? Multiplication of parts without corresponding variety of structure and function mark an animal as low in rank." In striving for originality, the author has here gone astray; and with regard to the study of classification in all its branches, we are of opinion that it ought not to form a primary object in a work of purely educational value. For the advanced student, consideration of it must come as a matter of course sooner or later: for the beginner it is better that it be dealt with at the hands of the teacher, and that with the utmost caution.

On p. vi. of the introduction we read: "If the main object of this study is the mere acquisition of facts, full descriptions of most animals can be elsewhere obtained; but if the more important part in education is to lead the pupil to see and think for himself, then some such method as this" (above cited) "should be used." It is under the influence of this desire to "educate" the mind of the student that the author's plan is most novel and his labour most successful. One example will illustrate. On p. 124 the student is directed, when examining the lungs of the mammal, as follows: "Keeping the eyes fixed on the lung, prick a hole through one side of the diaphragm, and note the collapse of the lung." Then follows the question, "Is the lung on the other side affected by this operation?" A forcible means, this, of bringing home a fundamental fact of lung-structure, which, though so simple, is, as any teacher of experience knows to his sorrow, so generally overlooked by the beginner. It is here introduced in a manner which cannot fail to bring home conviction or to create a lasting impression; and the student who shall have thus learned it will some day wake up to the fact that he has made an important discovery. Many other charmingly simple examples of the kind might be cited. In one or two cases the idea is overdone. In others the student is misled for want of a technical term; and speculating upon the probable nature of the retort which might be in such a case elicited, the writer is reminded of a reply obtained from a beginner who had worked out most satisfactorily the mammalian portal vein, in ignorance of the conventional nomenclature. The question, "What do you call this vein?" was met by the rejoinder, "Stomacho-liver." More technical terms might, with advantage, be introduced into this book. The acquisition of a technical nomenclature must go hand in hand with that of the fundamentals of a science, and we are of opinion that, until such are rightly and fully mastered, the student must be, as a tool in the hands of his teacher, guided with an unfailing precision.

In consideration of the pernicious rubbish which, even yet, occasionally finds its way into our own elementary schools under the guise of the elementary text-book of science, it is pleasant to reflect upon the merits of this work. The author is fortunate in being unhampered with the everlasting syllabus; he performs his experiment in his own manner, and it is worthy of a fair trial. We question, however, the advisability of making the study of insects the focal point. The author asserts that his work "has usually begun with the fall term. At this time insects are abundant, and many kinds may be easily collected; they therefore serve well to show how animals are classified." We presume, therefore, that he adopts the inevitable. He further claims that "insects are attractive: from insects the student passes on to forms which, if taken up at first, would perhaps be distasteful to him." This may be, but we doubt it. For the analogous use of flowers as a means of introduction to the study of botany much more is to be said. This book is written for special use upon special ground and under special circumstances; it forms part of a system, and its success can only be rightly judged by someone cognisant of the whole. The task which the author has in hand is one, of its kind, the most difficult, and at the same time the most pleasing, of which we can conceive. In it he is honoured, and his plan of work must, like all which have preceded it, have its shortcomings. That these will be made good with a ripening experience we doubt not.

It remains to call attention to one or two matters standing in need of immediate reconsideration. On p. 169 we find the heresy of the evaginated hydra revived, with much emphasis. P. 71 bears the extraordinary statement that "a fish whose body is flattened from side to side is said to be 'compressed'; the word 'flat,' when used in describing a fish, means flattened from above downwards, and is applied to such a fish as the flounder." Directions are given (p. 120) for injecting the blood-vessels of the mammal, but they are wholly superfluous, as more than that which is required for the purpose in hand can be made out without it, while the process is involved in difficulties which are beyond the pale of such elementary students.

The author's directions for killing most of the animals are surprisingly novel; those for despatching the turtle and pigeon being worthy of the modern executioner. P. 102 reads: "with a strong pair of pinchers seize the head" (of the turtle), "pull it well out, and chop it off; examine the mouth; are there teeth present?" No experienced zoologist needs to be reminded of the effects which this repulsive piece of butchering would produce; but even that pales beside the injunction (p. 105) to "open the pigeon's mouth, and insert a pipette containing about a teaspoonful of chloroform into the opening of the glottis, at the base of the tongue" (this has to be found by the student), "blow the chloroform into the lungs, being careful that the point of the pipette does not slip out of the glottis." Never was insult worse than this added to injury. These things must be speedily altered if intended for the juvenile who is "to see and think for himself."

G. B. H.

THE DUTCH COLONIES IN SOUTH AMERICA AND THE WEST INDIES

Westindische Skizzen: Reise-Erinnerungen. Von K. Martin, Professor für Geologie an der Universität zu Leiden. vii.-186 pp. 8vo, with 22 Plates and 1 Map. (Leiden: E. J. Brill, 1887.)

TOWARDS the close of 1884 several learned Societies in Holland granted collectively the means for a scientific mission to the Dutch colonies in South America and the West Indies. Prof. Suringar, with an assistant, took charge of the botanical work, whilst Prof. Martin was to carry on mineralogical and geological investigations, and Mr. Neervoort van de Poll volunteered as zoological collector. The party visited Dutch Guiana, Curaçao, Oruba, and Buen Ayre, and made also a short trip to Venezuela.[1]

Prof. Martin's preliminary report on Curaçao and adjacent islands appeared in the Journal of the Dutch Geographical Society (1885) soon after his return to Holland; and the part referring to Guiana was printed in the "Contributions towards the Linguistics, Geography, and Ethnography of Dutch India" (1886). Of two short notices on the geology of the countries visited, one was inserted in the *Revue Coloniale Internationale* (1885), and the other in the Proceedings of the Royal Academy of Sciences, Amsterdam (March 1886).

The present work is the first part of the author's final report. The narrative of the expedition is cast in the general shape of a diary, but the author usually brings together all the information bearing on the same topic. Strictly scientific matters are excluded, and will be given in a second volume. There is, however, no deficiency of interesting facts referring to the geography and natural history of those out-of-the-way places. The ethnographical chapters on the ancient Indian population of Oruba (with a plate giving samples of old rock-paintings found in certain caves of the island) and on the Bush-Negroes of Surinam are especially valuable. Perhaps Prof. Martin might with advantage have given a little more general geological information, which certainly would have been not less acceptable to the readers of this volume than his notes on the botanical and zoological character of the ground covered by his explorations.

In Guiana the author went up the River Surinam as far as the Negro settlement of Toledo (4° 33′ N. lat., and 55° 18′ W. of Greenwich), a place not formerly visited by any scientific explorer, and indeed not even by any white man. The further ascent of the river would have given no geological results, as the waters began to rise with the beginning of the rainy season, making it impossible to collect specimens from the rocks in the middle of the stream.

The general situation of Dutch Guiana unfortunately is far from being prosperous. The development of the colony has not kept pace with that of its English neighbour. Agriculture, which ought to be its main strength, is going down-hill, and we believe Prof. Martin is quite right when he expects very little aid from the increasing produce of the gold-washings in the interior. The cause of the evil appears to be rather complicated, as may be seen from a very clever article published by B. E. Colaço Belmonte in *Timehri* (December 1885 and June 1886).

The Dutch islands off the northern coast of Venezuela are so very little known outside the narrow circle of people connected with the interests of those colonies that any information about them must be as welcome as if it came from Corea or Madagascar. The islands are very small, measuring only about 1000 square kilometres, and are inhabited by 36,000 people, most of them being descendants of Negroes, who speak the *Papiamento*, a jargon which is a curious mixture of Spanish, English, Dutch, Portuguese, and Carib words. The climate is excessively dry, and the vegetation is therefore very poor. For the same reason Curaçao is an important sanitary station; and as the port of Willemstad is one of the safest in existence, it is to be expected that the island will gain in importance by the opening of the canal through the Isthmus of Panama. The principal article of export is phosphate of lime, which is found there in large quantities and of considerable richness. Here as well as on the Venezuelan islands of Los Roques, Orchila, Las Aves, Los Testigos, &c., the phosphates owe their origin to an epigenetic change of the coralline limestone, which became infiltrated with phosphate of lime from overlying deposits of guano, exposed to the action of the periodical rains. All these islands have a nucleus of eruptive rocks (diorite, diabase, gabbro, eclogite): the same geological constitution exists in the central hill of the peninsula of Paraguaná and in the mountain-ridges of La Guajara. We have thus a line of volcanic out-flows corresponding to a long fissure running from east to west.

The chapter referring to Prof. Martin's visit to Venezuela is short, as was his stay in that country. It does not pretend to give anything new, but it is a very proper conclusion to the author's "Recollections of Travel."

When speaking of the so-called flight of flying-fishes, Prof. Martin says it appeared to him that the animals now and then, by a jerk of their tails, gave a new impulse to their ascending movement, in addition to the work done by their fins ("als ob die Thiere sich mit Hülfe des Schwanzes manchmal von neuem emporschnellten und so die Arbeit der Flossen unterstützten"). Our own observations of several species of flying-fishes lead us to adopt entirely Prof. K. Möbius's conclusions, viz. that the pectoral fins do no propelling work at all, but only keep the body of the animal resting on the air, and that the occasional rise in the line of movement, when the latter goes against the wind and the direction of the waves, is due to the lifting pressure of the wind, which ascends the opposite slope of the wave (K. Möbius, "Die Bewegungen der fliegenden Fische durch die Luft," Leipzig, 1878).

Prof. Martin's style is very clear and fresh. The plates which accompany the book, mostly engraved from his own drawings, are excellent illustrations of scenery and ethnographical objects, and the whole volume is got up in a manner which is highly creditable to the publisher. We expect with great interest the concluding part of this valuable report, which, no doubt, will be an important contribution to South American natural history.

A. ERNST

[1] Prof. Suringar, on his way home, spent some days on the Dutch Leeward Islands St. Eustatius and Saba. He has published as yet only a small part of his very interesting report in the Journal of the Dutch Geographical Society (unfortunately in the Dutch language, so that few botanists abroad will be able to read it), besides a paper on a new Melocacti from Curaçao, in the Proceedings of the Royal Academy of Sciences, Amsterdam.

HYDRAULIC POWER AND HYDRAULIC MACHINERY

Hydraulic Power and Hydraulic Machinery. By H. Robinson, M.I.C.E., &c. Pp. xiv. + 190, and 42 plates. (London: Charles Griffin, 1887.)

THIS work purports to "record existing experience in this branch of engineering." It is divided into thirty-five short chapters (not numbered, and therefore not quite easy of reference). Five of these treat of general subjects, and the rest of particular machines or details.

The work opens with a well-written summary (16 pp.) of what is known of the flow of water under pressure, including a statement of the formulæ from Torricelli down to our own day, with a short account of some o the more recent experiments. Then follow some "General Observations," in which it is explained that the fears entertained on the first introduction of high-pressure water-power that accidents would be frequent from the bursting of pipes, especially in frosty weather, have proved groundless. The "relief-valves" necessary to avoid the shock from suddenly stopping or changing the motion of a non-elastic fluid like water are described and drawn. In another chapter the author describes the mode of "packing" so as to produce joints tight under high water-pressure, explains the use of "cupped leathers" to form a self-tightening joint, and shows the necessity of clear water, since dirty or gritty water causes rapid wear of the leathers.

The advantages of "power co-operation" all over large towns are considered in a short chapter (6 pp.), and illustrated by its successful application at Kingston-upon-Hull. Much more space might have been given to this now very important branch of the subject. A short chapter (6 pp.) details the cost of water-power in various places: it seems to vary from $\frac{1}{10}$ of a penny, to nearly 2*d.* per 100 foot-tons.

There are three chapters (covering only 7 pp. in all) on water-wheels, turbines, and centrifugal pumps. These chapters are too short to be of any practical use. The remaining 27 chapters are almost entirely devoted to the description of the appliances necessary for the use of high-pressure water-power, and to the very varied machines which may be thereby worked: many of these—especially the larger and more recent machines—are very fully illustrated. All this part of the work is of great interest. The pressure required for various purposes is stated to be 700 lbs. per square inch for ordinary hydraulic machines, 1500 to 2000 lbs. for shop-tools, and up to 20,000 lbs. for compressing iron and steel; and the advantages in the use of high-pressure are explained. The conditions to which this hydraulic power is suitable are shown to be those in which great power is to be exerted at scattered points for a short time only, and at irregular intervals. The machines and appliances described and illustrated are very numerous and diversified—far too many to enumerate here. Among the more interesting may be mentioned cranes, riveters, dock-gear, swing-bridge-gear, steering- and ship-gear, gun-lifts, and hoists of all sorts.

The practical part of this work is excellent: it is, in fact, a short monograph on the use of high-pressure water-power. But the theoretical part sadly needs revision. The term "power" is loosely used, sometimes meaning "force" (say in pounds), sometimes "work" (say in foot-pounds), sometimes "horse-power" (of 33,000 foot-pounds per minute). It is not surprising, therefore, to find the following mistakes: (1) a factor, 60 (*i.e.* 60 seconds in a minute), omitted in computing "horse-power" on p. 24; (2) a factor, 33,000, omitted in computing "horse-power" on p. 27, also the units (feet and pounds) not mentioned in same place; (3) a result on p. 35, which seems to be inch-pounds ÷ 33,000 (*i.e.* ÷ by foot-pounds per minute) marked as H.P.; (4) the following on p. 98, "the power (or foot-pounds) transmitted through a high-pressure water-main is determined by multiplying the fnumber of pounds of water flowing per second by the pressure." From a numerical example lower down it may be seen that the "power" referred to in this sentence is to be estimated (not in foot-pounds, but) in foot-pounds per second, and that by "pressure" is meant head of pressure, in feet.

ALLAN CUNNINGHAM, Major, R.E.

OUR BOOK SHELF

The Statesman's Year-Book for 1887. Edited by J. Scott Keltie. (London: Macmillan and Co., 1887.)

THIS work is so well known and so generally appreciated that it is necessary merely to note the appearance of the volume for 1887. The editor has made every effort to bring the statistics up to the latest date, and those who have been in the habit of referring to the book will find that its value has been considerably increased by important additions and modifications. An adequate account of the smaller British colonies has been introduced, and much new information is given with regard to the various systems of land-tenure in India. The leading facts brought out by the new censuses in Germany and France are embodied, and Mr. Keltie has been careful to show the precise results of the recent colonial enterprises of these two countries.

Joint Scientific Papers of James Prescott Joule, F.R.S. Published by the Physical Society of London. (London: Taylor and Francis, 1887.)

AMONG the contents of this volume are some elaborate papers on "Atomic Volume and Specific Gravity," prepared by Mr. Joule in association with Sir Lyon Playfair. Mr. Joule took the principal part in the experiments on the expansion of salts, the maximum density of water, &c.; but the important theoretical results arrived at with regard to atomic volume he attributes almost entirely to his colleague. Another valuable series of papers were the joint work of Mr. Joule and Sir William Thomson. The subjects are: "The Thermal Effects experienced by Air in rushing through Small Apertures," and "The Thermal Effects of Fluids in Motion." In the year 1843, Mr. Joule read a paper on "The Caloric Effects of Magneto-Electricity and the Mechanical Value of Heat," to the Chemical Section of the British Association assembled at Cork. The subject did not excite much general attention, so that, when he brought it forward again at the meeting in 1847, the Chairman suggested that he should not read his paper, but confine himself to a short verbal description of his experiments. "This," says Mr. Joule, "I endeavoured to do, and, discussion not being invited, the communication would have passed without comment if a young man had not risen in the Section, and, by his intelligent observations, created a lively interest in the new theory. The young man was William Thomson, who had, two years previously, passed the University of Cambridge with the highest honours, and is now probably the foremost scientific authority of the age." The work they afterwards did together, the results of which are here recorded, was chiefly experimental, performed in Manchester and the neighbourhood.

LETTERS TO THE EDITOR

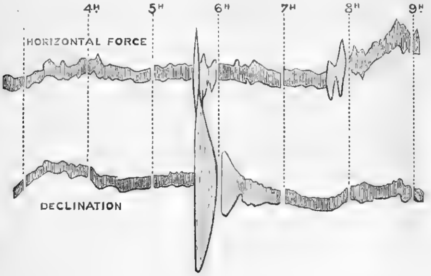
The Earthquake

WITH reference to the earthquake which occurred on the morning of February 23 last, it may be of interest to inform you that two of the magnetic registers of the Royal Observatory, Greenwich, entirely confirm the fact shown by the Kew horizontal-force register (NATURE, March 3, p. 421), of the shock having been sensible in England. The particulars are as follows:—

At 5h. 38m., Greenwich civil time, the declination and horizontal-force magnets were suddenly thrown into vibration by some cause not magnetic, the extent of vibration being in the case of declination 20′ of arc, and in the case of horizontal force ·004 of the whole horizontal force. Other smaller vibrations will be observed, on the annexed copy of the Royal Observatory photograph, as occurring in declination at about 6h. 0m., and in horizontal force at about 5h. 45m., 7h. 40m., and 7h. 50m. respectively. No motions of this character were shown in the vertical-force magnetic register, the two earth-current registers, or in any of the meteorological registers.



Copy of the photographic registers of the declination and horizontal-force magnets, as recorded at the Royal Observatory, Greenwich, 1887, February 23.

It may be mentioned that the declination magnet is a bar 2 feet long, suspended by a single thread about 6 feet long, and stands in the magnetic meridian, and that the horizontal-force magnet, also 2 feet long, has a bifilar suspension, the threads, about 7½ feet long, being twisted horizontally to cause the magnet to stand at right angles to the magnetic meridian. The time of vibration of the declination magnet is 24 seconds, and that of the horizontal-force magnet 21 seconds. The magnetic declination at Greenwich at the present time is about 17° 53′ west.

The *Engineer* on the Dimensions of Physical Quantities

IN a brief book-notice (*ante*, p. 387) I commented on the grave error of measuring potential energy in terms of horse-power, comparing it with the allied absurdity of measuring distance in terms of speed. I also cited the following passage:—

"dividing 3,942,400 foot-pounds per minute by 33,000 foot-pounds, we get 119·4 horse-power";

and I put beside it the allied absurdity:—

"dividing 500*l.* a year by 50*l.*, we get 10*l.* a year."

I thought it superfluous to point out the nature of the mistake, but I judged rashly. For the *Engineer* (in a leader, of March 4, 1887) has made a somewhat excited attack on this and other of my statements:—remarking

"we are in doubt whether 'P. G. T.' really has any idea what (*sic*) the expression means."

To this charge I plead guilty. For if I were myself to divide 3,942,400 foot-pounds per minute by 33,000 foot-pounds, the result would contain the unit of *time* alone; and could certainly not express horse-power. It might be angular velocity perhaps. It is true that if I were to divide 3,942,400 foot-pounds per minute by the mere *number* 33,000, I should probably obtain the result 119·4 horse power. But the *Engineer* will ascribe all this to the pedantry of the "professor," for its article goes even farther in absurdity than does the passage quoted above. It leaves out the "per minute" and says the author "is strictly correct (*sic*) when he says that 3,942,400 foot-pounds are to be divided by 33,000 foot-pounds to get the horse-power"! Alas for Fourier, and *Dimensions* of physical quantities!!

I wonder what the *Engineer* would assign as the result of dividing 10 eggs per minute by 2 eggs. Would it, or would it not, be 5 eggs per minute?

P. G. T.

Tabasheer

MR. W. T. THISELTON DYER'S ingenious contribution on Tabasheer in NATURE (p. 396) will doubtless be interesting in connection with the subject of the nature and mode of distribution of silica in vegetable bodies, in which it is so often contained.

Brewster, in 1819, says (*Edinburgh Philosophical Journal*, n. 1, p. 147):—"It is found in the joints of the female (?) bamboo, sometimes in a fluid state like milk, sometimes with the consistency of honey, but generally in the form of a hard concretion. Some specimens of it are transparent, and resemble very much small fragments of the artificial pastes made in imitation of opal; others are exactly like chalk, while a third kind is of an intermediate character, and has a slight degree of translucency.

"In the year 1804, Messrs. Humboldt and Blonpland brought with them from America some specimens of tabasheer, called *guaduas butter* by the Creoles, taken from the bamboos which grow to the west of Pinchincha in the Cordilleras of the Andes (Humboldt's 'Personal Narrative,' vol. i. Introd. p. xii. note). These specimens were analysed in 1805, by Messrs. Fourcroy and Vauquelin (*Mémoires de l'Institut*, tom. vi. p. 382), who found them to be different from the tabasheers of Asia. Instead of being wholly composed of silex, they contained only 70 per cent. of this earth, and 30 per cent. of potash, lime, and water."

Cohn speaks of two kinds of tabasheer, viz. crude and calicified. The former consists of roundly-angular pieces of unequal sizes, possessing all degrees between transparency and opaqueness, and passing from brownish, reddish, yellowish, or dark gray to black in colour; the latter is opal-like, milky, or pale in colour, not unlike a lump of sugar. Tabasheer can be cut into pieces very easily, and shows, in polarised light, only extremely feeble double reflection.

Brewster, moreover, by studying the optical properties of tabasheer, formed one of the semi-transparent specimens, which he obtained from Nagpore and Hyderabad, into a prism, and found to his "great surprise that the refractive power of tabasheer was not only lower than water, but so much lower, as to be almost intermediate between water and gases." The results he obtained are as follows:—

		Index of refraction
Air		1·0000 +
Tabasheer from Hyderabad, yellowish by reflected light ...		1·1115
Tabasheer from Nagpore ...	bluish by reflected light	1·1454
,, ,, ,, harder	bluish by reflected light	1·1503
,, ,, ,, ...	bluish by reflected light	1·1535
,, ,, ,, very hard	bluish by reflected light	1·1825
Water		1·3358

As to the chemical constituents of this substance, Poleck's recent analysis (*Bot. Centralbl.* Band xxix., 1887, p. 95) shows that it contains 99·6 per cent. of pure silicic acid and only 0·4 per cent. of other mineral matters, as natrium, sulphuric acid, &c., but neither potash nor phosphoric acid has been detected. The crude specimens contain 58 per cent. of water; the calicified specimens, on the other hand, are free from water.

We may perhaps dwell shortly upon the *habitat* of tabasheer. Mr. Dyer has fully shown its occurrence in India; now let us consider whether it occurs further in the eastern parts of Asia, as in China and Japan, where the growth of bamboos is still in full vigour. In China, tabasheer is known as Tien-chü-hwang or Chü-hwang, that is, the "yellow (substance) of bamboo"; or sometimes called Chü-kaou, or the "cerate of bamboo." "Pun-tsaou-kang-mûh" says: "They are produced inside the stem of bamboos, and look somewhat like yellow earth; they may be often found attached in masses to the inside of the bamboo cane."

From the well-known old Japanese encyclopædia, "Wakan Sansai Dsuyé," the following descriptions may be quoted: "After bamboos have been cut down in March or April, and left for some time, tabasbeer is sometimes found inside the stem when broken." In Japan it is called *Take Miso*, and I have only heard that some portion of fluid, or some solid particles, occur inside the stem of bamboo, but not to such a remarkable extent as we meet with in India. In the Island of Kiusiu, the stem of bamboos is found sometimes filled with fluid, and especially in the province of Satsuma, particles like grains of sand are often detected. In a new Japanese work about bamboos, entitled "Nihon Chikufu," or "A Collection of Japanese Bamboos," by Nawoto Katayama, published in three volumes in Tokio in 1885, it is stated that in Tokio, if bamboos from the neighbouring provinces of Shimotsuké and Hitachi are kept till July or August and then broken, some watery juice or particles like sand may frequently be found. These particles are pale yellow in colour, but the quantity is only sufficient to fill a very small shell. "Sōmoku Seifu," and other Japanese botanical books, also mention tabasheer. TOKUTARO ITO

Cambridge

"The Origin of Mountain Ranges"

THE reviewer of "The Origin of Mountain Ranges in NATURE (Feb. 17, p. 361) says, in reference to my views on the contraction hypothesis:—"He seems to hold that, according to the contractionists, crumpling is produced by unequal contraction in the solid shell itself, which certainly is not their view. And he entirely omits all reference to the one fact which is the life and soul of the hypothesis, that the earth's crust is not strong enough to stand by itself without support, a fact which admits of rigid mathematical demonstration."

Will you kindly permit me to state that this is an entire misapprehension; that I hold neither view; and I have a difficulty in understanding how such inferences can be drawn from anything contained in the work. T. MELLARD READE

Liverpool, February 18

I AM very sorry if I have represented Mr. Reade as saying what he did not intend to say, but the construction I put upon his words seemed, and still seems, to me to be that which they naturally bear. Mr. Reade's notion of what it is that the contraction hypothesis maintains, and his reasons for differing from its conclusions, are apparently summarised in Chapter XI. on pp. 121–25. He there tries to form an estimate of the ratio between the radial and circumferential contractions *within a shell of* 30 *miles* in thickness which he assumes to be solid. It seemed to me accordingly that he was contemplating only contraction within a thin shell which he himself starts with assuming to be solid, and that he deals only with "unequal contraction in the solid shell itself."

If Mr. Reade meant something quite different from this, I failed to grasp his meaning; that this was so may or may not be my fault, but in either case I am much obliged to Mr. Reade for putting me right, and very sorry that I should have laid upon him the troublesome necessity of pointing out my mistake.

What the other view is which Mr. Reade disavows, and what other inferences are contained in the passage he has quoted, I confess that I am unable to discover. A. H. GREEN

Leeds, March 13

The Vitality of Seeds

IN a letter in your last issue (p. 414) upon the vitality of seeds, "N. E. P." states that Prof. Judd in his address to the Geological Association (I presume he means the Geological Society) was reported to have said: "The botanist cites the germination of seeds, taken from ancient Egyptian tombs, as a striking illustration of how long life may remain dormant in the vegetable world." This appears to be a remarkable assertion to emanate from such an eminent scientific man as Prof. Judd, for if he really did make this statement one would think he must have some good proof quite incontrovertible. I must admit I am sceptical, and do not place credence in the statements that have been made by certain people, that wheat or barley, which is frequently found in the ancient tombs of Egypt, could possibly germinate after the lapse, say, of 3000 years.

We have often heard of people having had tricks played upon them by crafty Arabs, who, when discovering grain, knowing, perhaps, that the purchaser wished to test it, substituted for it some of modern date, which was said to be of the same species. When this was sown, it germinated, and probably yielded a fine crop; but the real grain found in the tomb was to all purposes dead. Mummy-wheat is, I presume, simply a commercial name for a certain species, which has no sort of connection with the tombs of ancient Egypt. Sir Gardner Wilkinson, in his book "The Ancient Egyptians," vol. i. p. 471, refers to experiments having been successfully made with some grains of corn discovered in the tombs. Dr. Birch added the following footnote:—"The experiments are said to have been made in France. (The possibility of corn germinating after so many years is strongly denied by some botanists on account of the impossibility of the delicate and minute embryo, placed immediately below the surface, being preserved so long in life, close to the surface.)"

As the late Dr. Birch in the above made reference to experiments having been made in France, I beg to quote the opinion of M. Paul Pierret, a very eminent Egyptologist, Conservateur du Musée Égyptien du Louvre, in his "Dictionnaire d'Archéologie Égyptienne," under the head of "Blé":—

"Tout ce qui a été dit sur la germination des grains recueillis dans les hypogées est absolument faux; tous les essais tentés dans les conditions voulues de sincérité scientifique ont avorté. Ce blé, semé dans la terre humide, s'amollit, s'enfle, se décompose, et, au bout de neuf jours, est entièrement détruit." F. G. HILTON PRICE

29 Weymouth Street, W., March 7

I BEG to refer your correspondent "N. E. P.," on this subject, to my "Memoir of the Late Professor Henslow," p. 207, where I have given the results of copious experiments made by him in reference to the vitality of seeds, as well as the results of a close investigation of the whole subject by himself, Dr. Daubeny, and others—being a Committee appointed for the purpose in 1840 by the British Association; all tending to show that no seeds retain their vitality for much more than forty years, and very few for anything like so long, and throwing utter discredit upon often-received statements as to the long-retained vitality of the so-called mummy-wheat found in the catacombs of Egypt.

Bath, March 7 L. BLOMEFIELD

THE question put by your correspondent with reference to the germination of seeds taken from ancient Egyptian tombs appears to be directly answered by M. A. de Candolle in his work on "The Origin of Cultivated Plants." His words are:—"I think it pertinent to say that no grain taken from an ancient Egyptian sarcophagus and sown by agriculturists has ever been known to germinate. It is not that the thing is impossible, for grains are all the better preserved that they are protected from the air and from variations of temperature or humidity, and certainly these conditions are fulfilled by Egyptian monuments; but as a matter of fact, the attempts at raising wheat from these ancient seeds have not been successful."

However, if the germination of mummy-wheat is not sufficiently authenticated, Prof. Judd might perhaps point to other cases which, although of less value on account of their antiquity, would nevertheless go far enough to prove his point. There is, I believe, the case recorded by Dr. Lindley of some raspberries "raised in the garden of the Horticultural Society from seeds taken from the stomach of a man whose skeleton was found thirty feet below the surface of the earth, at the bottom of a barrow which was opened near Dorchester. He had been buried with some coins of the Emperor Hadrian, and it is therefore probable that the seeds were sixteen or seventeen hundred years old."

The following well-ascertained fact, recorded by Prof. Duchartre and others, may prove of interest. Some years ago in Paris, when a number of very old houses were being pulled down in the "Cité" to make room for Haussmannian improvements, Dr. Boisduval examined some dark-looking earth taken from the very foundations of one of those houses. The earth was found to contain seeds, which, being planted carefully under a glass bell, germinated in due time, and proved to be seeds of *Juncus bufonius*, L. This plant, as is well known, affects damp, marshy places such as the island was on which Lutetia Parisiorum grew up. It was therefore admitted as very probable that those seeds of *Juncus bufonius* must have been dormant in the ground ever since the time when the "Cité" marshes became dried up, and the ground began to be occupied by houses. University College, Dublin

CEREBRAL LOCALISATION[1]

II.

WE have considered the main positions first taken up by Dr. Ferrier with regard to functional localisations, and it will be convenient to examine in the same order the criticisms and statements of other observers regarding those positions.

(1) *The Rolandic region.*—The effects of excitation and ablation in this region, so far as relates to the production, or the paralysis, of the movements of voluntary muscles, are almost universally admitted, and to this extent the researches of Dr. Ferrier have received brilliant corroboration. But the inference that this region is therefore of necessity motor has not been so generally acceded to. The attacks to which it has been subjected are based, almost without exception, upon a denial of the statement that lesions of this region do not involve the loss or impairment of sensation in the paralysed parts. It is alleged that, on the contrary, the motor paralyses are invariably accompanied by loss or impairment of sensation, either of the so-called muscular sense (Hitzig, Nothnagel; "sense of movement," Bastian), or of tactile sensibility (Schiff, Tripier), or of sensibility in general, muscular and cutaneous (H. Munk); and it has been supposed that the paralyses of motion which result from these cortical lesions are not true motor paralyses, such as would be caused by destruction of a motor centre, but are rather due to the loss of the sensations which guide the volitional movements, or the ideas of such sensations, of which the part of the cerebral cortex removed is assumed to be the seat.

The question seems, on the face of it, one which is easily determinable. Do animals, and especially monkeys, in which a lesion in the Rolandic region has been established, exhibit loss of tactile (or any other form of) sensibility? Are cases of motor hemiplegia in man which are produced by injury or disease of this region accompanied by loss of cutaneous or muscular sensibility, or are they not? As regards animals, many, indeed most, observers answer this question emphatically in the positive sense. As regards man, the evidence is more conflicting. We have, it is true, the advantage of being able to obtain a direct answer regarding the existence, or absence, of sensibility in any particular case; but on the other hand there is not necessarily the same restriction of the lesion to the cortical gray matter, and the exact localisation is much more difficult of determination. Accordingly we find that cases of motor paralysis from cortical lesions in man have been put in as evidence upon both sides, according as they have been accompanied or not by impairment of sensibility. Dr. Ferrier is, however, very positive upon this point, relying upon the accuracy of his own observations in animals, as well as upon evidence derived from pathological observations in man, and the allegations to the contrary are disposed of by him in the following manner:—

"The conclusion that tactile sensibility is lost or diminished after destruction of the cortical motor area is based on defective methods of investigation and erroneous interpretation of the reactions of the lower animals to sensory stimulation. Though an animal does not react so readily to sensory stimulation of the paralysed side, it does not follow that this is due to diminished or absent perception of the stimulus. An animal may not react, or react less energetically, to a sensory stimulus, not because it does not feel it the less, but because it is unable, or less able, to do so from motor defect. . . . All that the experiments of Schiff and Tripier demonstrate is that motor reactions are less readily evoked on the side opposite the cortical lesion. But the same thing occurs in cases of purely motor hemiplegia in man" (pp. 374-75).

[1] "The Functions of the Brain." By David Ferrier, M.D., LL.D., F.R.S. Second Edition, re-written and enlarged. (London: Smith, Elder, and Co., 1886.) Continued from p. 441.

"Strictly cortical lesions of the motor area do not cause anæsthesia in any form, and it may be laid down as a rule to which there are no exceptions that if anæsthesia is found along with motor paralysis the lesion is not limited to the motor zone" (p. 378).

"The total abolition of the muscular sense (as in locomotor ataxy) does not paralyse the power of effecting movements. Even though the impressions ordinarily generated by muscular contraction are not perceived, yet the person can walk or move his limbs with perfect freedom under the guiding sense of vision. Even with the eyes shut the patient can intend his movements with correctness" (p. 380).

"Loss of the muscular sense never occurs without general anæsthesia of the limb. . . . The statements to the contrary, sometimes met with, rest only on the foundation of a demonstrably false hypothesis as to the nature of the ataxy which it is invoked to explain" (p. 380).

"The idea of a movement may be perfect when the motor centres are entirely destroyed. A dog with his motor centres destroyed has a clear idea of the movement required when asked to give a paw, and exhibits its grief at being unable to do so in an unmistakable manner; and the patient suffering from cortical motor lesion, after making futile efforts to carry out his ideally realised movement, not uncommonly bursts into tears at his failure. There is no defect in the ideation, but only in the realisation, of the movement" (p. 383).

"The cortical centres are motor in precisely the same sense as other motor centres, and are differentiated anatomically from the centres of sensation, general as well as special" (p. 393).

Certainly, if it can be shown that a distinct part of the cortex is concerned with the perception of impressions of general sensibility, this would afford strong *primâ facie* evidence against the Rolandic region being endowed with sensory functions. And we shall presently see that such evidence is forthcoming.

(2) The evidence for the second proposition (that the visual centre is situated *exclusively* in the angular gyrus) has not found confirmation, and is virtually surrendered by the author. That the angular gyrus is at all concerned in the visual process is entirely denied by H. Munk, who has shown that complete blindness is produced by removal of the *occipital lobes* alone, without the implication of the angular gyri, and that removal of one occipital lobe produces blindness of the corresponding half of both retinæ (hemianopsia). According to Munk, this blindness is permanent; but Luciani and Tamburini, who have obtained the same immediate result, affirm that it may after a time disappear. Dr. Ferrier, however, denies that the mere removal of the occipital lobes is followed by any perceptible deficiency of vision; and in support of this statement, which was already made in the former edition, he quotes the results of his own more recent experiments, which were performed in conjunction with Prof. Yeo, and also certain unpublished results which have been obtained by Mr. Horsley and myself. Dr. Ferrier has, however, been mistaken in supposing that our observations bear out his statement, for we invariably found, when an extensive removal was effected in the occipital region, that hemianopsia resulted therefrom, as described by Munk. But in the few experiments which we performed the blindness was not permanent, only persisting, so far as we could judge, for some days, or, at the utmost, weeks; and in one of these cases, in which we *afterwards* destroyed the angular gyrus, hemianopsia which appeared to be permanent was produced. This is confirmatory of the statements of Drs. Ferrier and Yeo. I am myself, however, not at all sure that the permanence of the result was due to the destruction of the angular gyrus, and may not rather have been produced by the more complete removal of the occipital lobe which that destruction

involved. As for the angular gyrus, the author seems now to admit that the blindness of the opposite eye which he has obtained on destroying that convolution is quite temporary, not, indeed, persisting for more than an hour or two after the operation. Nevertheless, he infers that this loss of vision which he describes is due to the fact that the angular gyrus is concerned with the appreciation of *direct* or *central* visual impressions. I have myself failed to obtain evidence either of permanent or temporary visual disturbances as the result of destruction of the gray matter only of one or both angular gyri; and I confess it is to me somewhat surprising that an experimentalist so experienced, and a reasoner so clear-sighted, as Dr. Ferrier, should have attempted to erect a theory of such importance upon a foundation so insecure!

(3) A similar idea arises in one's mind when one considers the evidence which the author has to bring forward of the localisation of the auditory centre in the superior temporo-sphenoidal convolution. Of course, if this be the case, it must follow that bilateral removal of this gyrus will produce complete and permanent deafness. According to Dr. Ferrier, this is actually what happens; but there is only one case followed by complete recovery from the immediate effects of the operation which he is able to quote in support of that statement. This case is that of a monkey which was exhibited to the International Medical Congress in London in 1881, and the animal certainly appeared to be deaf, for it in no way reacted to a loud noise, such as the report of a pistol fired near its head. But, convincing as this test seemed at the time to most of those present, I may here remark that a test of this character is of little or no value when applied to monkeys. For a perfectly normal monkey, if its attention or curiosity is excited in any way, and especially if it is brought into a strange room and surrounded by strange faces, will often give not the slightest sign of perceiving even a loud sound, such as the report of a pistol, when such sound is suggestive of no ideas. On the other hand, a sound which is habitually associated with an emotional idea, *e.g.* the noise made by the approach of a hostile companion, or a footstep which is associated with the expectancy of food, will generally be instantly reacted to. It is true that Dr. Ferrier, in the case mentioned, has not relied entirely upon the negative result obtained from the pistol-report, but expressly mentions other tests as having been applied by him. One remark which he makes is, however, very significant: "Occasionally a doubt was raised as to whether the absence of reaction to sounds was absolute."

I have always been inclined to think that Dr. Ferrier, in localising the auditory centre exclusively in this convolution, has relied too much upon this single case—especially since his deductions therefrom have not been supported by the results of other experimentalists. Luciani, in particular, insists upon the fact that extensive destruction of the temporo-sphenoidal lobe is necessary in order to produce deafness, and that even then the loss of hearing is not permanent. This statement I can myself fully corroborate. I have recently, in conjunction with Dr. Sanger Brown, entirely destroyed the superior temporo-sphenoidal gyrus on both sides in several monkeys, and in not one of them has there been any appreciable loss or impairment of hearing. On the other hand, when the lesion has involved not only the superior gyrus but also the greater part of the lobe there has in one or two instances seemed to be at first, not an entire loss, but a diminution of the power of appreciating auditory sensations—this condition, however, being recovered from after a few days.

I am aware that in locating the auditory centre in the superior temporo-sphenoidal gyrus Dr. Ferrier does not rely alone upon the result of extirpation, but adduces also the movements of the ear and eyes which follow electrical excitation as evidence that a subjective auditory sensation is thereby evoked. Taken by itself this is no evidence at all, for similar movements may be obtained from excitation of totally different portions of the cerebrum, to say nothing of the cerebellum and of the lower nerve-centres. It only becomes evidence as corroborating the effect of extirpation. But a single "negative instance" is sufficient to overthrow the hypothesis that the auditory centre is situated in the superior temporo-sphenoidal convolution alone, and would outweigh many "positive instances." We have, however, only the one well-recorded "positive instance" of Dr. Ferrier (and this was not altogether free from doubt) as against several "negative instances" (those of Munk, Luciani, and ourselves; which last have not yet been published, and could not, therefore, be taken into account by Dr. Ferrier). It is probable, therefore, that Dr. Ferrier's inference is too exclusive, and that other parts of the temporo-sphenoidal lobe must be included in the auditory centre.[1]

(4) The view that tactile sensibility is localised in the hippocampal region has naturally been attacked by those who hold that it is to the Rolandic region that the perception of this and other forms of sensibility are to be referred. It would not appear, however, that they have taken the trouble to repeat Prof. Ferrier's experiments upon this region, so that his position can hardly be said to have been seriously assailed. On the other hand, it has received both corroboration and extension from the experiments of Mr. Horsley and myself, the results of which were shown to Dr. Ferrier, and the conclusions arrived at fully concurred in by him (pp. 340-45). These experiments showed in the first place that extensive destruction in the hippocampal region, especially of the posterior part of the hippocampal gyrus, is followed by hemianæsthesia, which is not, however, of a permanent character, but disappears after a few days; and further, that destruction or injury of the gyrus fornicatus (which, as Broca showed, is to be regarded as a direct extension around the corpus callosum of the hippocampal gyrus (see Fig. 2), produces still more marked and far more permanent symptoms of a like kind.

(5) and (6) With regard to the cerebral localisation of the functions of taste and smell, the author in this edition brings forward no new proofs of an experimental nature. But he adduces and quotes evidence from comparative anatomy to show, not only that in animals in which the sense of smell is largely developed (the "osmotics" of Broca) the hippocampal lobule is greatly developed, but also that the development of the anterior commissure, especially of its posterior division, goes hand in hand with that of the hippocampal lobule, and its internal extension, the nucleus amygdalæ, and is therefore to be regarded as a commissure of the olfactory centres. The evidence in the first edition regarding the localisation of taste-perceptions was of the scantiest description, and has been in no way subsequently strengthened, and it is necessary that further experiments should be made upon the subject with the view of testing the opinion which the author has with all caution put forward on the subject.

(7) Upon the special functions of the pre-frontal lobes, or whether any function is in fact specially concentrated in this part of the brain, very little light has been thrown by the researches of the past fifteen years. There is a very prevalent idea that intellectual capacity goes hand in hand with the development of this region, an idea which has existed from the time of the old Greeks, although it was not apparently shared by peoples of yet more ancient civilisation. The idea does not, however, appear to receive any confirmation from the experimental method.

[1] Dr. Ferrier is mistaken in supposing (*vide* p. 310) that the results of the experiments of Mr. Horsley and myself confirm his conclusions regarding the localisation of the auditory centre in the superior temporo-sphenoidal gyrus. The error seems to have arisen from the misunderstanding of a verbal communication. What we did find in one or two cases was that the whole of the temporo-sphenoidal lobe exclusive of the superior gyrus might be removed on both sides without loss of hearing—not the converse, that hearing was abolished on destroying only the superior gyri on both sides. Indeed, we did not in any single instance perform this last experiment.

Animals from whom these lobes have been removed exhibit "a total absence of symptoms" (p. 396). "In my first series of experiments (carried out without antiseptics), I noted, after removal of the prefrontal regions, a decided alteration in the animals' character and behaviour. . . . They had lost, to all appearance, the faculty of attentive and intelligent observation" (p. 401). But that this was due to an extension of the effects of the lesion consequent on the want of antiseptic precautions appears from what immediately follows:—"In some of my latest experiments, in which the lesions were strictly limited (under antiseptic precautions) to the pre-frontal regions, I could not satisfy myself of the existence of any appreciable mental deterioration. . . . A similar total absence of discernible symptoms has been observed also by Horsley and Schäfer" (p. 396).[1]

On the other hand, Dr. Ferrier believes that he has in one or two instances obtained unequivocal evidence that the whole of the pre-frontal lobe is concerned with the movements of the head and eyes, being an extension forwards of the centre for those movements which he had previously described. Nevertheless, he quotes approvingly certain observations of Hitzig and of Goltz upon dogs in which this region had been destroyed upon both sides, and which appeared in consequence to exhibit weakness of memory and lack of attention, without any paralysis of movement or sensation, as tending to confirm, what the comparative study of the relative development of the frontal lobes in different animals and individuals appears to show, "that the frontal lobes, the cortical centres for the head and ocular movements, *with their associated sensory centres*, form the substrata of those psychical processes which lie at the foundation of the higher intellectual operations" (p. 467). The qualification which I have italicised takes away the whole point of the statement so far as relates to the region under discussion. And a single well-recorded instance in man (such as the celebrated American crowbar case), in which there has been extensive destruction of this region without the occurrence of any appreciable symptoms during life, renders it manifest that there can be no restricted localisation of any special function in this part.

"Munk professes to have found that after destruction of the pre-frontal region in dogs and monkeys, paralysis occurs in the muscles of the trunk on the opposite side. . . . My own experiments, as well as those of Horsley and Schäfer, disprove Munk's assertions in the case of monkeys," and "in regard to dogs they are flatly contradicted by Hitzig, Kriworotow, and Goltz." Moreover, "Horsley and Schäfer have shown that the centres for the trunk-muscles" in the monkey "are in the marginal convolutions" (pp. 400-401). It is not a little curious to observe how in the desire to conform to the prevalent view regarding the frontal region being the special seat of intelligence, both Ferrier and Munk endeavour to prove that the different movements which they respectively asssociate with this region are particularly related to the development of the intellectual faculties. Munk even goes so far as to assert that the development of the *trunk-muscles* in mammals marches *pari passu* with the evolution of the intellectual capacity. One is surprised that he has not carried the comparison yet further, and drawn attention to the relation between the "wisdom of the serpent" and the complexity of the movements of the reptilian trunk!

The amount of space which it has been necessary to occupy in discussing the question of cerebral localisation may be justified, not only by its general interest and importance, but also by the fact that the author of this work is one of the most prominent exponents of a doctrine which, whether wholly or partially right, has revolutionised cerebral physiology and profoundly modified the department of medicine with which this branch of physiology is linked. We can consequently only refer very briefly to some of the principal alterations and additions which we find recorded regarding other subjects.

The structure of the nerve-centres is treated at much greater length than in the former edition, and is copiously illustrated with many original microscopic drawings by Mr. Bevan Lewis and others. The conducting functions of the spinal cord, which were somewhat cursorily dismissed in the former edition, are here considered at length. The view of Brown-Séquard that there is a differentiation within the cord of the paths for different forms of sensibility is subjected to a searching criticism, with the result that the existence of such tracts is entirely rejected by Dr. Ferrier. He, however, nowhere refers to the question of specific paths for temperature-sensations, a question which has become one of much importance in connection with the recent researches of Blix, Goldscheider, and others on the differentiation of specific cutaneous points for these and other forms of cutaneous sensibility. To the question of the existence of a "muscular sense," by which is meant that faculty by which we are aware of the position and movements of our limbs without calling in the aid of our visual perceptions, Dr. Ferrier brings forward a considerable weight of argument to prove that it is not to be regarded as in any way a specific form of sensation, and still less a sense of effort or innervation produced by the appreciation by the sensorium of centrifugal discharges which are emitted from motor centres (Bain, Wundt), but that it is merely the result of impressions of tactile sensibility conveyed by the ordinary sensory or afferent nerves both of the muscles and of the parts acted upon by them, and, as such, can have neither a specific path of conduction nor a central terminus apart from the paths and termini for tactile sensibility.

The functions of the spinal cord as a centre for co-ordinate movements are also treated more fully than before, and it is shown that even in the higher animals each segment of the cord may act as a co-ordinating centre for complex and apparently purposeful movements of the limbs. For it has been demonstrated in monkeys by the author, working conjointly with Prof. Yeo, and in dogs by Bert and by Marcacci, that such movements may be evoked by the excitation of single anterior roots in the cervical and sacral regions. And Dr. Ferrier describes one or two experiments, in which he succeeded in stimulating the anterior cornu of the gray matter alone, and which yielded similar results (*vide* note to p. 77). In relation to the functions of the cord, the tonus of the muscles and the so-called "tendon-reflexes" are carefully considered, and their importance as an expression of the condition of the reflex are pointed out. Many new facts are accumulated regarding the remaining parts of the central nervous system, and their bearing upon the functions of the several organs is gone into in several instances with great care and at considerable length. To most of these it is impossible to refer particularly. It may, however, be noted that the direct excitability of the corpus striatum, at least of its caudate nucleus, which has been denied by Franck and Pitres, is positively re-affirmed, and the motor functions of that organ maintained, by Dr. Ferrier, as the result of new experiments performed by him. But, whether or not it be the case that they are directly excitable, it would appear that the precise functions of the basal ganglia, and the relation which they bear to motion and sensation, are as much a matter of conjecture as ever.

To the chapter which deals with the cerebral hemispheres from the psychological aspect one or two important additions have been made, especially in the part

[1] Further on (p. 402) the author states that we have noted signs of stupidity in the monkeys in which we had removed the pre-frontal regions. I do not think, however, that such dullness as was exhibited in one or two of these cases was more marked or lasted longer than with equally extensive lesions of other parts of the brain.

devoted to the consideration of speech, in which the conditions of "word-deafness" and "word-blindness" are now discussed. The view which has been put forward, amongst others, by Dr. Hughlings Jackson, that there are other and higher centres, over and above those which have been demonstrated by physiological and clinical research, which form the substrata of the higher mental operations, does not receive support from Dr. Ferrier. "It seems more reasonable to believe that there may be higher and lower degrees of complexity in the same centres than to assume the separate existence of more highly evolved centres, for which no evidence is obtained by the results of experimental research" (p. 460).

It might have been expected that the remarkable conditions of the cerebral functions which are met with in both man and animals in an hypnotic state would at least have been alluded to in this edition, but they appear to have entirely failed to attract the author's interest, and the subject is passed over in silence.

In conclusion it may confidently be affirmed that, whatever exception may be taken to this or that statement or opinion, or to the mode in which this or that question is discussed, this new edition of Dr. Ferrier's work, from the care with which it has been revised, the extent of the information which it contains, and the clearness of style and lack of ambiguity which characterise its every page, must prove of the greatest value to the student of neurology, and cannot fail to enhance the high reputation of its author. E. A. SCHÄFER

THE VALUE OF THE NEW APOCHROMATIC LENSES

AT the annual meeting of the Royal Microscopical Society, the Rev. Dr. Dallinger, who was elected President for a fourth year, delivered his annual address, in the course of which he gave a judgment concerning the new object-glasses made with the new German glass, in the following terms:—

In proceeding to fulfil the honourable duty that, by your courtesy, devolves upon me, I purpose in the main to follow the line I have taken in preceding years. I congratulate the Society on its work, and on its steady influence in promoting progressive improvements in the optical and mechanical construction of the microscope, devoid of all prejudice as to how, or from whence, such improvements may come. And whilst, happily, it is not of necessity a President's duty to pass in cursory review the microscopical work of the year, there are times when it may be well for him to review the points of improvement that have been made in the instrument itself.

For the past twenty years I have had an increasing interest in the continuous improvement of the optical appliances of our instrument—an interest which, from the first, applied not only to objectives, but also to eyepieces and condensers, which consecutive calculation, thought, and experience have shown to have a correlated importance.

Eighteen years ago I had, by practice, made myself fairly master of a 1/25-inch objective of that period made by Powell and Lealand. I still possess that lens, and it is as good a lens of its class as they ever constructed. Soon after, I became equally familiar with a 1/50-inch of the same class by the same makers.

By saying that I became master of these lenses, I mean that I discovered exhaustively what they would and what they would not do. By this, I learned definitely what I wanted in lenses, if I could get it; and to get that has been my unceasing endeavour until now. And certainly the quest has not been vain. And my method has been to examine impartially, and possess myself of, English, Continental, or American lenses, whenever they have shown any capacity for doing best what my work proved to me required to be done.

I know that, in estimating the quality of a lens by the class of image it affords of certain test-objects well known to us, a certain amount of empiricism must take place. We do not absolutely know the image it ought to present. But this only applies within very narrow limits. Take the Podura scale: I can give you an image of it with my 1/25-inch and 1/50-inch of twenty years ago. What I, in common with most microscopists, considered then the *best* result, the most sharp, clear, and delicately defined image, with those lenses I can get now; but, with those lenses, nothing better.

But the elements—the essential features that constituted the quality of beauty in that image—are the very elements, the actual features, that every admitted improvement in our object-glasses has brought out more perfectly. So that if I now put, say, the Podura scale under my old dry 1/25-inch objective, and, beside it, another precisely similar scale under a new homogeneous 1/20-inch objective of N.A. (numerical aperture) 1·5, the very qualities of the image which I, and experienced microscopists generally, thought the best twenty years ago are incomparably transcended in beauty and perfectness now.

But that is not, and has not been, my only or my chief test. It has been one more eminently practical, so far as my own work went; at least for some years.

Up to ten years ago, although I had spent weeks in patient effort, no lens that I possessed, or that was within my reach, could be made to reveal the flagella of *Bacterium termo*. The flagella of many minute monads and of such Bacterial forms as *Spirillum volutans*, and even *Bacterium lineola*, I could demonstrate, though some of them with difficulty; but not a trace of that of *B. termo*. But, near that time, Powell and Lealand produced a battery of immersion-lenses on a new formula and of much relative excellence; and with these lenses the flagella of *B. termo* were brought within the range of sight.

Since that time that has been a good lens, to me, in proportion to the greater or less ease and perfection with which it has revealed this delicate fibre. And let me say that such lenses as do this are those that always, without fail, give us the best ideal image of Podura scales and other tests. You will pardon me, I trust, for this amount of personal reference, since it will give a greater relevancy to what will follow.

Improvements of great optical importance have been made during the last few years. The manufacture of homogeneous lenses by Messrs. Powell and Lealand gave us the opportunity, which we could not have with foreign makers, of urging certain modifications. The addition of the correction collar was a minor, but still important, point. But the great point was the increase of the N.A. These makers have shown themselves most anxious, and have spared no efforts, to reach the highest aperture yet attained.

Advancing, say, from N.A. 1·25, they attained to 1·35 in such powers as the 1/25-inch and the 1/50-inch; subsequently to 1·47 in 1/8- and 1/12-inch objectives; and finding these, from my working point of view, of such supreme gain, I urged them still on, and was ultimately rewarded by the possession of a 1/6-inch N.A. 1·5., followed by a 1/12- and a 1/20-inch foci of the same great aperture. From each of these I obtained special advantages over all like powers, but with lower apertures, within my reach.

A question frequently asked may be asked again, In what way do these last increments of aperture aid us? The practical answer is not difficult. Speaking from observation, I may say that all the objectives I have employed for the most critical work fail to produce images by the extreme marginal zone of the aperture. It is the judgment of competent judges that it will be fair to roughly estimate this defective outermost zone at 10 per cent.; so that, from the total measurement of the aperture by Prof.

Abbe's method, I find that in practice this amount may be deducted as of very little service, in all apertures beyond about 1·3; hence, to be able to utilise fully any given aperture beyond 1·3, it is practically necessary that the measurement by means of Abbe's apertometer should be about 10 per cent. higher.

But a further advantage of great numerical aperture is that, other things being equal, we can utilise with excellent results deeper eye-pieces.

I have long realised the advantage, with finely corrected objectives, of a far larger series of eye-pieces than the catalogues provide. Messrs. Powell and Lealand several years ago made me one or more eye-pieces between each of their deeper eye-pieces of standard catalogued focus, and they certainly, within the limit of excellence beyond which greater eye-piece power cannot be employed, bring out to far greater perfection the qualities of any high-class object-glass.

But we have had announced to us an improvement in the optical arrangement of the microscope, based upon an important and fundamental change in the media employed in the construction of object-glasses and eye-pieces. It will be known that I refer to the system of apochromatic object-glasses and compensating eye-pieces devised by Prof. Abbe, and under his auspices carried out by Messrs. Zeiss, of Jena.

The aim of the construction of these new objectives and eye-pieces has been to provide a higher degree of achromatism than could be reached by the old media; the new kinds of glass produced at the Jena Optical Glass Works, under the superintendence of Dr. Schott and Prof. Abbe, can be so combined in the construction of an object-glass as to achromatise not only the essential portion of the primary spectrum, but also to a great extent the secondary spectrum, leaving only small residuals of the tertiary order still visible under certain test conditions. The final elements of correction are supplied by "compensating" eye-pieces of special construction designed to correct what Dr. Abbe refers to as "the differences in the amplification of the image for the various colours . . . formed by the objective outside the axis, which cannot be corrected by the objective itself."

The first trials of these new optical combinations made in Germany evoked unstinted praise, and those who, like myself, desired nothing so much as real improvement, awaited their arrival in England with eager and even anxious curiosity.

The first that came to this country came to Mr. Frank Crisp, and by his courtesy this lens, an apochromatic of 1/8-inch focus was placed in my hands. I subjected it to comparison, in succession, with my complete set of high powers, including those of N.A. 1·5, and upon tests, and by methods, which I have indicated.

It will be well understood that the high excellence and great aperture of my three latest object-glasses would have given a very elevated standard of comparison, a standard of comparison, so far as I know, never before reached, and the result was that with the potentiality of the system represented by the apochromatic lens I was most powerfully and hopefully impressed. I felt, in fact, that the lens itself was of great merit. But withal, by my standard of test I felt that its merits had been over-estimated.

It is quite true that on some of my delicate test-objects the images shown by the apochromatic lens in combination with the "compensating" eye-pieces appeared to advantage when compared with my lenses combined with the ordinary eye-pieces; but when I tried my own various powers with the same compensating eye-pieces I am constrained to say that no real advantage over my latest lenses could be discovered. My judgment, therefore, was most favourable as to the immense advantage of the eye-pieces and of the possibilities that lay in the entire system rather than in the special apochromatic object-glass taken by itself; and although pressed again and again by the editors of journals to give a public expression of my judgment, I steadily declined, feeling that it was not, and could not at that time, be exhaustive.

Later, an opportunity was courteously afforded me by the makers to examine a complete series of these object-glasses, from 1-inch to 1/8-inch focus, and with eye-pieces fitted for English stands. In the examination of these objectives and their system of eye-pieces I spared no pains to be exhaustive and impartial. I desired to find the evidence of progression in optical excellence, for which I am always in search, and the excellence of the 1-inch greatly impressed me; but I failed to realise my high hopes in the behaviour of the higher powers. The result, however, of a most critical examination was to very greatly strengthen my conviction of the value of the optical system which these lenses represented, and above all of the excellence of the actually new resource provided for us by the compensating eye-pieces.

In what I have here said I must again remind you that the comparison of Zeiss's apochromatic object-glasses was with a group of object-glasses the most carefully made, most excellently corrected, and with the widest numerical apertures, of any object-glasses that had ever passed through my hands, based on the old system of correction. But with this understanding it appears to me a responsibility that I must not evade to state the facts at this crisis in the development of object-glasses. And I do this with the more confidence that, as I have already informed you, Mr. Mayall, wholly independent of me, examined this set of objectives and eye-pieces, and we each recorded separately, in writing, our judgments at the time of examination; and I subsequently found that our resulting judgments were almost identical.

During this time samples of the new optical glass had reached the English opticians, and Messrs. Powell and Lealand in relatively brief time, and on a formula of their own, made an apochromatic 1/12-inch object-glass, and eye pieces, constructed on the plan devised by Abbe By the wise advice of Mr. Mayall this was exhibited at our November meeting. My high opinion of that lens and its compensating system of eye-pieces I at that meeting expressed, and need only add that since I have become the possessor of a second object-glass of precisely similar construction and power made by the firm, I am much strengthened in the opinion I gave.

We all appreciate the splendid services rendered to microscopy by Prof. Abbe, and it was a happy expression of that appreciation that led Mr. Mayall to propose a visit to Jena, with his microscope and such object-glasses as he thought would worthily represent the standpoint we had now reached in England.

I understand that Prof. Abbe greatly desired this, wishing to possess the fullest information as to our methods of testing object-glasses, and to be permitted to examine our best optical work.

I need hardly say that it was a source of great pleasure to me to place at Mr. Mayall's disposal all the lenses and apparatus I possessed that would serve him; for it was in the highest interests of the microscopy of the world that so great a leader in recent progress should see the effects of his teaching and practice as evidenced by our latest object-glasses, and especially by the new apochromatic 1/12th by Powell and Lealand, with its system of compensating eye-pieces.

Mr. Mayall has told us the story of his visit: of his kindly reception; of the earnest and repeated trials of the object-glasses he was able to submit to Prof. Abbe; and of the frank appreciation expressed by Prof. Abbe of the English object-glasses. This comparison will, in my judgment, "make history" for the future of our instrument. It will react here and in Germany. Prof. Abbe's splendid powers are more than ever concentred on the work of touching a higher perfection in object-glasses;

he knows that every improvement initiated in Jena will be watched by keen eyes in England; and he has evidence, which will be as welcome to him as his work is to us, that we are not likely to neglect any point of excellence, provided only we can be made to see it as such. I understand that Dr. Zeiss admits that the formulæ on which his apochromatic objectives are constructed involve far greater technical difficulties than were met with in the older formulæ; and this is evidenced by the great number of separate lenses combined in the construction.

Now it has long been my judgment, and a judgment that has been confirmed by men of large practical experience, that errors of technical execution, when present, are shown at once by deep eye-pieces: with an object of regular structure, whose image fills the field of the eye-piece, the experienced eye readily detects a want of sharpness. I am bound to say that the apochromatics from Jena did not impress me by this test as having accuracy of technical execution equal to the object-glasses with which they were compared.

On the other hand, I find that with the new apochromatic made by Powell and Lealand I can employ advantageously deeper eye-pieces than I had ever used before.

Now there is a less number of separate lenses in the London objective, and whether this superiority is due to the lesser number of lenses or to other causes I may not determine. I refrain from details concerning the comparisons I, amongst others, made of the lower power apochromatic of Zeiss, further than to remark that in my judgment too much has been sacrificed to the object of enabling the observer to employ very thick cover-glasses. This is, no doubt, a convenience; but if, as in Zeiss's 1/4-inch and 1/6-inch, the choice lies between object-glasses that cannot be used for covered and uncovered objects and object-glasses that, with a moderate range of thickness for cover-glass, provide that facility, the latter appear to me from a practical point of view to be the better.

I note with interest that Powell and Lealand have made an achromatic oil-immersion condenser of N. A. 1·4, and will probably be able to increase the aperture to 1·5 in proportion as thinner glass is used to mount objects upon. The mechanical part of this instrument had, when it first reached me, a very neat form, but was difficult of manipulation; and this, involving as it did alteration, has prevented me from really testing its merits. But I have just received it, with a mechanical modification I suggested well carried out, and I have little doubt but I shall realise now its optical excellence. On the whole, then, we may rejoice in the fact that a distinct advance has been made in the optics of the microscope, and the more so from a conviction that there lies considerable potentiality still in the sources from which the amount of progress made has resulted.

ATLANTIC WEATHER CHARTS

THE Meteorological Council has just issued a folio of synchronous weather charts for the North Atlantic Ocean and the adjacent continents, those now published forming the first part of a series which embraces the thirteen months from August 1, 1882, to August 31, 1883. The whole series is to be issued in four parts, Part 1 containing the charts from August 1, 1882, to November 7, 1882. Two charts are given for each day—one shows the barometer, wind, and weather, whilst the other gives the air- and sea-temperature, and weather, the weather being given on both charts for the purpose of easy comparison with other elements. The isobars, or lines of equal barometric pressure, are drawn for each tenth of an inch, and figures are given in the central areas of the several depressions to show the lowest reading of the barometer recorded by vessels passing through these disturbances. The direction and force of wind are shown by a system of arrows which fly with the wind, and the different forms of arrow exhibit very readily where the wind reaches the force of a gale, whilst the winds at high-level stations, where the elevation is 4000 feet or upwards, are indicated by red arrows. The air- and sea-temperatures are shown by different coloured isotherms, or lines of equal temperature, which are drawn for each 5° F. The weather, such as rain, fog, or mist, is shown by different methods of shading, and, as mentioned above, is given with each style of chart. The synchronous hour for which the observations are charted is noon Greenwich time, except in the case of air- and sea-temperature, where local noon has been taken in preference. No letterpress has been published with the charts except a few explanatory notes, in which it is stated that the study of the weather of Western Europe for many years has established in a manner that is beyond question that the atmospheric disturbances, on which the changes of weather are in a great measure, if not mainly, dependent, reach our western coasts after having passed for a longer or shorter distance over the Atlantic. The Meteorological Council undertook the investigation with a view to ascertaining as far as possible the conditions under which such disturbances either originate in or traverse the Atlantic, and the extent to which the direction of their course, their magnitude, and persistence, may be influenced by the general meteorological conditions of the area within which they are generated, or of the regions which surround that area.

The period embraced by the charts is that during which the international system of circumpolar observations was being carried out, and data have thus been obtained from very high northern latitudes, which could not otherwise have been procurable, and by these means the results embodied in the charts have not only been rendered far more complete, but are of an exceptional value, not likely to be soon equalled. Among the circumpolar observations regularly used for the charts are those made at Spitzbergen and Jan Mayen, two stations which add materially to the value of the information on the eastern side of the Atlantic, as they enable many very important barometric changes to be traced which would otherwise be lost, and they help much in fixing the position of disturbances which have skirted the British coasts, and at the time when our weather is improving as these bad-weather systems are passing away.

There are, on an average, observations from rather more than 400 ships for each day, in addition to which there are daily observations from about 300 land stations. In all 11,236 returns, each containing the records of many days, have been received from about 3000 vessels. So large a number of observations have never before been used in the drawing of synchronous charts, and this of itself renders the work quite unique in its character. The area embraced, which extends from the Pacific Coast of America to the east of Moscow, in the heart of Russia, and from the Arctic to the Equator, enables the numerous weather changes to be watched day by day for days together, and allows of a very extensive and comprehensive view of the influence of the several varying conditions of the weather.

The charts show many very interesting features of weather changes, and they exhibit very clearly the general way in which the weather systems move from west to east in the middle latitudes. They show very frequent tracks of low-pressure areas to the north of the parallel of 40°, such areas being frequently observed over the United States; and after traversing North America, they intensify and develop energy on reaching the Atlantic, apparently gaining much of their strength from the supply of vapour over the ocean. Many such storms can be traced across the Atlantic, while some die out after traversing only a part of that ocean. On the other hand, others are formed over the Atlantic, and especially in the vicinity of Newfoundland, where there is the mingling of hot and cold water, and where, as shown by both air- and sea-isotherms, there is a very great difference of temperature in a very small area. There are numerous instances both of the formation of storms and also of their sudden breaking up. It is also seen how at one time a storm will divide into two parts, and each will follow its independent course, while at another time two well-developed storms will merge and become one. The charts show how, as one of these travelling disturbances is approaching the British Islands, the weather becomes unsettled, and how, as the outer edge of the front segment strikes our coasts, the wind backs to the southward, and in a short time rain begins to fall and the wind freshens. If the disturbance passes over the British Islands, the changes are generally both important and rapid, whilst, if the storm area merely skirts our western coasts, as is the more common experience, the changes are less marked, and influence in the main only our western and northern coasts. The first issue of these charts deals only with the autumn, but they show very different conditions of weather at the early part of this season from those at its close, the whole system of weather being more disturbed as the season advances. There is, however, throughout the period a permanent area of high barometric pressure situated in mid-Atlantic, on the northern side of which the travelling disturbances move. This area of high barometer oscillates from day to day within fairly well-defined limits, and is very seldom altogether broken up; and doubtless a close study of the behaviour of this high-pressure area will tend to materially advance our knowledge of the now almost hopelessly puzzling weather changes with which in weather-forecasting we have to combat.

Among other points of interest exhibited by the charts may be mentioned the graphic manner in which the earlier charts show the meeting of the north-east and south-east trade-winds and the seasonal march of the limits of these winds with the sun. They also show that at the end of the summer the temperature of the air is warmer than the sea to the extent of 2° or 3°, while, as winter is approached, the sea is slightly the warmer. In September there is a good instance of the formation of a West Indian hurricane which eventually crosses the Atlantic and passes to the north of Scotland, and the chart of November 1 shows the vast extent of some of these Atlantic storms, one gale blowing over the whole ocean from the coast of America to that of Europe.

It is scarcely possible to over-estimate the high value of this series of charts. The most practical outcome of their publication, it is hoped, will be an improvement of our weather forecasts and storm warnings and a general extension of our knowledge of the laws which regulate the weather changes in our own islands; whilst from a nautical point of view they are of the utmost value to the seaman in enabling him to follow in detail the many changes he experiences, and they may assist him at times in making a better passage.

GILDED CHRYSALIDES[1]

PREVIOUS WORK.—Mr. T. W. Wood in 1867 published the observation that certain pupæ (*Pieris brassicæ*, *P. rapæ*, &c.) resemble in colour the surface on which they are found. Although this was disputed by some naturalists, it was confirmed by Mr. A. G. Butler and Prof. Meldola. In 1874 Mrs. M. E. Barber published some very striking observations on the colours of the pupa of *Papilio nireus* (South Africa), confirmation being afterwards afforded by Mr. Trimen, from the case of *Papilio demoleus*. Dr. Fritz Müller, however, shows that *Papilio polydamus* is not sensitive to surrounding colours. The observations were explained by supposing the moist skin of the freshly-formed pupa to be "photographically sensitive" to the colour of surrounding surfaces; but Prof. Meldola pointed out that there can be no real analogy with photography. Furthermore, many pupæ are formed at night, when the surrounding surfaces are dark. The present investigation was undertaken with the belief that the influence would be found to work upon the larva as it rests upon some coloured surface before pupation.

I. *Experiments upon Vanessa Io.*—This pupa appears in two varieties, being commonly dark gray and much more rarely yellowish-green. Six larvæ placed in a glass cylinder covered with green tissue-paper, produced six green pupæ; one of these, transferred to a black surface while still moist and fresh, became a green pupa precisely like the others.

II. *Experiments upon Vanessa urticæ.*—The pupæ have no green form, but appear in many shades of dark gray, the lighter ones having golden spots on them, while the extreme forms are almost covered with the golden appearance. These latter are very rarely seen in nature, except when the pupa is diseased. Over 700 pupæ were obtained in the following experiments:—

1. *Effects of Colours.*—*Green* and *orange* surroundings caused no effect on the pupal colours; *black* produced, as a rule, dark pupæ; *white* produced light pupæ, many of them being brilliantly golden. This last result suggested the use of *gilt* surroundings, which were found to be more efficient than white, and produced pupæ with a colour which even more resembled gold.

2. *Mutual Proximity.*—The larvæ being dark, it was found that when many of them became pupæ on a limited (white or gilt) area, the pupæ were darker than when they had been more isolated. The colours of each were in fact affected by that part of the surroundings made up by the black skins of its neighbours.

3. *Illumination.*—Black surroundings produced rather stronger effects in darkness than in light, but the pupæ were dark in both cases.

4. *Time of Susceptibility.*—The mature larvæ, after ceasing to feed, wander (stage i.) until they find a surface on which to pupate; they then rest upon it (stage ii.), and finally hang, head downwards, suspended by their last pair of claspers (stage iii.), in which position pupation takes place. Stage i. is variable in length, stage ii. may be estimated at 15 hours (but it is also variable), while stage iii. is fairly constant, and lasts about 18 hours; while the whole period is commonly about 36 hours in length. The larvæ are probably affected by surrounding colours for about 20 hours before the last 12 hours of the whole period, and in this time the pupal colours are determined. These facts were discovered by a very large number of experiments, in which larvæ were placed in surroundings of one colour, and then after a variable time were transferred to another colour producing an opposite effect. It was thus found that stage ii. is more sensitive than stage iii., although there is some susceptibility during the latter stage.

5. *The Part of the Larvæ which is Sensitive to Colour.*

(α) *The Ocelli.*—The most obvious suggestion was that the larval eyes (or ocelli, six on each side of the head) saw the colours, and, being influenced, transmitted an impulse to the nervous centres which regulate the formation of the pupal colours. When, however, these organs were covered with black varnish, the pupæ resembled surrounding surfaces to the same extent as when they were produced from normal larvæ.

(β) *The Complex Branching Spines.*—It seemed possible that these structures might contain some organ which was influenced by the colour, but after cutting them off the larvæ remained normally sensitive.

[1] Abstract of Lecture delivered by Mr. Edward B. Poulton at the Royal Institution, on Friday, February 11.

(γ) *The General Surface of the Skin.*—This was tested by *conflicting colour experiments.* It had been previously shown that the larvæ were sensitive during stage iii., and therefore they were covered in this stage with compartmented tubes, so constructed that the head and anterior part of the body hung in the lower chamber of one colour, while the posterior part of the body was in the upper chamber in another colour. In another method the larvæ were hung upon a vertical surface, while the head and front part of the body passed through a hole in a shelf, the vertical surface above the shelf, and the upper side of the shelf itself being one colour, while the vertical surface below the shelf and the lower side of the shelf were of the colour tending to produce the most opposite effects. The result of all these experiments was to show that the colour influence does act on some element of the larval skin, and that the larger the area of skin exposed to any one colour the more does the pupa follow its influence. Parti-coloured pupæ were not obtained, thus perhaps pointing towards the action of the nervous system rather than towards the direct action of light on or through the skin itself.

6. *The Nature of the Effects Produced.*—The colouring-matter of the dark pupæ is contained in a thin superficial layer of the cuticle; below this is a thicker layer divided into exceedingly delicate lamellæ, between which fluids are present, and the latter form the thin plates which, by causing interference of light, produce the brilliant metallic appearance. The thinner upper layer, being dark, acts as a screen in the dark pupæ. Precisely the same metallic appearances are caused by the films of air between the thin plates of glass which are formed on the surface of bottles long exposed to earth and moisture. Both have the same spectroscopic characters and the same transmitted colours (complementary to those seen by reflection). The brilliancy of the cuticle can be preserved in spirit for any length of time; it disappears on drying, but can be renewed on wetting (this had been previously known), and the colours are seen to change during the process of drying, and when the cuticle is pressed, for the films are thus made thinner. The same lamellated layer exists in non-metallic pupæ of other species, and is used as a reflector for transparent colouring-matter contained in its outer lamellæ. Thus the structure which rendered possible the brilliant effects due to interference probably existed long before these special effects were obtained, and was used for a different purpose.

7. *The Biological Value of the Gilded Appearance.*—It is probable that the gilded pupæ of Vanessidæ resemble glittering minerals such as mica (which is very common in many places); their shape is very angular, and like that of minerals: conversely the gray pupæ resemble gray and weathered rock-surfaces, and the two conditions of rock would themselves act as a stimulus for the production of pupæ of corresponding colour. The power was probably gained in some dry hot country, where mineral surfaces do not weather quickly. Once formed, it may be used for other purposes, and in certain species is probably a warning to the enemies that the insect is inedible. It is interesting to note how the Vanessidæ, primarily coloured so as to resemble mineral surroundings, are modified for pupation on plants. Thus *Vanessa Io* has a green form which is produced among leaves; *V. atalanta* has no green form, and spins together the leaves for concealment, but both these species commonly pupate freely exposed on mineral surfaces; *V. urticæ* has neither the green form nor the habit of concealment, and it has a strong disinclination to pupate on its food-plant, as many observations concurred in proving.

III. *Experiments upon Vanessa atalanta.*—This species was also made brilliantly golden or dark-coloured by the use of appropriate surroundings in the larval condition.

IV. *Experiments upon Papilio machaon.*—This species, like *P. polydamus* (Fritz Müller), has no power of being influenced by surrounding colours. A brown pupa was obtained on the food-plant, and many green ones upon brown twigs, &c. It is possible that the amount of shade may determine the formation of the dark pupa irrespective of colour, or that less healthy and smaller larvæ may produce the brown form, just as diseased Vanessa larvæ produce gilded pupæ.

V. *Experiments upon Pieris brassicæ and P. rapæ.*

1. *Effects of Colours.*—*Black* produced dark pupæ, and the greater the illumination the darker the pupæ (*P. rapæ*), this result being the reverse of that obtained with *V. urticæ*; *white* produced light pupæ, and the greater the illumination the lighter the pupæ (*P. rapæ*); *dark red* (*P. brassicæ*) produced dark pupæ; *deep orange*, in both species, produced very light pupæ of a green colour; *pale yellow* and *yellowish-green* produced rather darker pupæ than the orange; *bluish-green* produced much darker pupæ; while *dark blue* produced still darker pupæ (*P. rapæ* only). Hence there is a remarkable and sudden fall, followed by a slow and gradual rise in the amount of pigment formed as the light from various parts of the spectrum from red to blue predominates in the reflected rays which fall on the larval surface. But their effects on the formation of superficially placed dark pigment are accompanied by changes affecting the formation of greens and yellows, &c., in the deeper sub-cuticular tissues. Hence the results of any given stimulus are exceedingly complicated.

2. *Other Experiments.*—It was shown by the method described above that the ocelli are not sensitive in this species, and by similar transference experiments it was proved that the influence acts on the larva and not on the pupa itself.

VI. *Experiments upon Ephyra pendularia.*—In this genus of moths the exposed pupæ are often green and brown in different individuals, but these colours follow the corresponding tints of the larvæ, and therefore cannot be influenced unless the latter themselves were changed, and such susceptibility in the larval state has not been proved for this genus. This is the only known instance of a constant relation between the larval and pupal colours.

VII. *Experiments upon the Cocoon of Saturnia carpini.*—It was found that the larvæ spin dark cocoons in black surroundings, but white ones in lighter surroundings.

NOTES

The principal officers for the Manchester meeting of the British Association, to begin on August 31, under the presidency of Sir Henry Roscoe, have now been selected. The following will be the Presidents of the various Sections:—Section A, Mathematics and Physics, Sir Robert S. Ball, Astronomer Royal for Ireland; B, Chemistry, Dr. Edward Schunck, F.R.S.; C, Geology, Dr. Henry Woodward, F.R.S.; D, Biology, Prof. A. Newton, F.R.S.; E, Geography, General Sir Charles Warren, R.E., G.C.M.G.; F, Economic Science, Dr. Robert Giffen; G, Mechanical Science, Prof. Osborne Reynolds, F.R.S. For Section H, Anthropology, a President has not yet been chosen. One of the public lectures will be given by Prof. H. B. Dixon, who has taken as his subject "The Rate of Explosions in Gases." The lecture to the working classes will be given by Prof. George Forbes. It is expected that, socially, the Manchester meeting will be one of the most brilliant ever held. A very large sum has already been subscribed, and liberal arrangements are being made for excursions and other entertainments.

The trustees of the fund established by Mrs. Elizabeth Thompson, of Stamford, Connecticut, "for the advancement and prosecution of scientific research in its broadest sense," having accumulated income available for grants, desire to receive applications for appropriations in aid of scientific work. This endowment is not for the benefit of any one department of science, but it is the intention of the trustees to give the preference to those investigations which cannot otherwise be provided for, which have for their object the advancement of human knowledge, or the benefit of mankind in general, rather than to researches directed to the solution of questions of merely local importance. Applications for assistance from this fund should be addressed to the Secretary of the Board of Trustees, Dr. C. S. Minot, Harvard Medical School, Boston, Mass., U.S.A., and should be accompanied by a full statement of the nature of the investigation, of the conditions under which it is to be prosecuted, and of the manner in which the appropriation asked for is to be expended. The new grants will probably be made in May next.

IN consequence of the date fixed for the celebration of the Queen's Jubilee, the Senate of the University of London have deemed it necessary to change the time of holding the ensuing Matriculation Examination from the week beginning Monday, June 20, to the preceding week beginning Monday, June 13.

IN his annual Report for the year 1886, Mr. H. B. Medlicott, Director of the Geological Survey of India, explains how it happens that Bengalis have not hitherto been employed in connection with his department. The Survey, he points out, has no duties of a mechanical nature to which, and through which, it would be possible to break in the uninitiated. Its work is strictly scientific, and requires the constant exercise, upon scanty data, of an independent, conscientious, and sober judgment. Now, Mr. Medlicott holds that Bengalis have not yet shown that they are fit for such work as this. "In Bengal," he says, "the word of knowledge has been preached for the last two generations, but in no single case has it found the needful germ in which it might come to maturity and bear fruit in original scientific work; it seems only to develop a more obnoxious kind of weed—words of science without substance. In the medical and engineering services they have for long had like teaching and opportunities to those from which Darwin, Huxley, Tyndall, and a host of others have arisen, but of like result in Bengal there is no symptom even. For a still longer period the practical results of the new knowledge in the shape of material progress have been displayed with ever-increasing energy from the West, but neither has this awakened in the Oriental mind a a power to do likewise. Of imitation there is no lack, but of creative power there is no sign. If this is not a demonstration on the part of the Bengali of his ineptitude for science, evidence counts for nothing. He would do well to take it to heart, if by any means he may correct his failing. Meanwhile, even if there were not particular evidence to confirm it, I hold this as sufficient warrant for objecting to the appointment of natives to the slender staff of the Geological Survey."

MR. A. LAWRENCE ROTCH, the proprietor of the Blue Hill Meteorological Observatory in the United States, has recently issued a pamphlet giving an account of the foundation and work of the observatory. According to the *American Meteorological Journal*, the station on Pike's Peak, 14,000 feet above the sea, is of problematic value to meteorology, whereas "the Blue Hill Observatory, only 635 feet above the sea, and much younger, has already been of considerable meteorological service."

SOME time ago we referred to the fact that experiments were being made at Fort Scott in connection with the manufacture of sugar from Sorghum. A report on these experiments was lately presented to the U.S. Department of Agriculture by Mr. H. W. Wiley, to whom the conduct of the work was intrusted. The results were very discouraging, and the failure is attributed by Mr. Wiley to the following causes:—(1) Defective machinery for cutting the canes and for elevating and cleaning the chips and for removing the exhausted chips. (2) The deterioration of the cane due to much of it becoming over-ripe, but chiefly to the fact that much time would generally elapse after the canes were cut before they reached the diffusion battery. The heavy frost which came on October 1, 1886, injured the cane somewhat, but not until ten days or two weeks after it occurred. (3) The deteriorated cane caused a considerable inversion of the sucrose in the battery, an inversion which was increased by the delay in furnishing chips, thus causing the chips in the battery to remain exposed under pressure for a much longer time than was necessary. The mean time required for diffusing one cell was twenty-one minutes, three times as long as it should have been. (4) The process of carbonatation, as employed, secured a maximum yield of sugar, but failed to make a molasses which was marketable. This trouble arose from the small quantity of lime remaining in the filtered juices, causing a blackening of the syrup on concentration, and the failure of the cleaning apparatus to properly prepare the chips for diffusion. With regard to the future, Mr. Wiley is of opinion that the chief thing to be accomplished is the production of a Sorghum plant containing a reasonably constant percentage of crystallisable sugar.

MR. HENNESSY, of the Indian Survey, to whom, as we have already announced, the Government of the Straits Settlements applied to aid in a survey of the latter territory, has declined the appointment offered him. *Indian Engineering* observes that as the size and population of the Straits do not come up to those of an Indian district, and as the colony has already a Surveyor-General, a Deputy Surveyor-General, several Assistant Surveyors-General, with a full complement of subordinates, as well as a Special Commissioner of Lands, there must be something wrong when another surveyor from India is required in order to carry out a satisfactory survey. The circumstance appears to require some explanation.

ON December 10, a volcanic eruption of great violence took place in Mount Tarumai in Yezo. Ashes continued to fall for several hours in the vicinity of the foot of the mountain, and on the neighbouring coasts, and even after this had ceased the underground disturbances continued. On December 13 the eruption recommenced, and lasted for four days. A large slip occurred on the side of the volcano, an area of about 10,000 feet square being affected, and stones and other debris fell so thickly as to change the configuration of the sea-shore to some extent. Previous eruptions, according to Prof. Milne's work on the volcanoes of Japan, occurred on February 8, 1874; October 7, 1883; January 4, 1885; and April 21, 1886.

ON March 15 a strong shock of earthquake passed through Mandalay, perceptibly moving buildings and trees. No damage occurred.

ON the 9th inst. Mr. W. A. Carter lectured to the Croydon Natural History Society on "Marine and Fresh-water Fishes." Mr. Carter stated that fish have the power of influencing each other by sounds and action, and in support of this assertion he described the movements of a shoal of carp in a pond. He had observed them following the lead of a single congener, which conducted them to a quantity of food a considerable distance off. Referring to fish monarchs, the lecturer said he had noticed that certain freshwater fish, such as the trout, were subservient to a ruler, which might be seen swimming at the head of his tribe, as might also certain marine forms, such as herring and bass.

THE new gun-powder melinite has already begun its work of destruction. Some days ago a bomb filled with this explosive agent exploded by accident in Belfort arsenal, killing six persons, and severely wounding eleven.

A DINNER was lately given to Prof. de Lacaze-Duthiers by some forty or fifty of his pupils, who also presented him with a magnificent engraving of his own likeness. This was a well-deserved tribute of admiration for the good and useful work done in the department of zoology by Prof. de Lacaze-Duthiers. He has done great service to students of natural science by his personal labours, by the establishment of the two marine zoological stations of Roscoff and Banyuls-sur-Mer, and by the founding of the *Archives de Zoologie Expérimentale*.

THE zoological station of Cette, on the Mediterranean coast, founded by Prof. Sabatier, of Montpellier, has been recently attached to the École Pratique des Hautes Études. Cette is a very interesting place for zoologists, owing to the abundance of the fauna and its variety.

THE laboratories of the Paris Medical School will soon—that is, in the course of the spring or summer—be transferred to new buildings in front of the Medical School. The present laboratories are ugly and unhealthy.

SOUTHAMPTON, we are glad to see, is anxious to possess a University College of its own. On Wednesday, the 9th inst., a public meeting, over which the Mayor presided, was held to express the general opinion on the subject, and resolutions were unanimously carried in favour of the scheme. In one of these resolutions it was stated that, in the opinion of the meeting, "The Hartley Institution is admirably fitted, and has high claims, to form the nucleus of a University College for Southampton and the surrounding district."

SIR JOSEPH WHITWORTH'S will, dated December 1884, has now been proved. He leaves two hundred shares in Sir Joseph Whitworth and Company (Limited) to the Owens College, Manchester; eighty shares to the Institution of Civil Engineers, London; and forty to the Institution of Mechanical Engineers. By his will, after making certain bequests, he left the residue of his estate to the School Boards of Manchester, Salford, and Stockport, and to the Science and Department, South Kensington; but by codicils added last year he revokes his bequests to the School Boards and South Kensington, and leaves all his real estate and the residue of his personal estate to his executors and trustees absolutely for their own use and benefit, but in confidence that they will make such dispositions of his property for educational purposes as they know that he would have wished made.

WE regret to announce the death of M. Alexander Borodin, Professor of Chemistry at the Medico-Surgical Academy at St. Petersburg, and one of the most eminent Russian musical composers. He died on February 27.

THE death is announced of Dr. Gustav Heinrich Kirchenpauer, first Burgomaster of Hamburg, and a well-known naturalist. He died on March 4.

A DECREE has been signed by the King of Italy by virtue of which a new and complete edition of the works of Galileo will be published at the cost of the State. The Minister of Education, with the assistance of some eminent professors, will superintend the publication, which will fill twenty quarto volumes of 500 pages each.

BY the investigation of forty-two large North German lakes, the well-known zoologist Dr. Otto Zacharias has proved that the lower fauna occupies an intermediate position between that of the Scandinavian and that of the Swiss and Italian freshwater basins. Since it is supposed that during the Ice epoch gigantic glaciers stretched from the north of Europe to the foot of the Riesengebirge, it is interesting to learn that the North German lakes contain a number of lower Crustaceans that, till now, have only been found in Scandinavia.

THE Academy of Sciences at Berlin has granted the following sums for the furtherance of zoological research:—75*l.* to Dr. Karl Brandt (Königsberg) for investigations on Radiolaria; 50*l.* to Prof. Ludwig (Giessen) for the continuation of his work on Echinoderms; 100*l.* to Dr. Heinicke (Oldenburg) to continue his researches on the varieties of the herring. Besides these sums, 1950*l.* has been given for the printing of some important zoological works, viz. Prof. Dohrn's "Jahresbericht," Dr. Taschenberg's "Bibliothek," and Prof. Fritsch's work on "Electric Fishes."

THE total value of fish landed on the coasts of Scotland for the two months ending February 1887 was 190,068*l.*, being an increase over the corresponding period of last year of 8434*l.*

THE twenty-second volume of the Transactions and Proceedings of the Royal Society of Victoria has been sent to us. It contains the address of Prof. Kernot, the President, delivered on March 11, 1886; and among the papers are "The Atmosphere a Source of Nitrogen in Plant Economy," by Mr. E. Lloyd Marks; "Notes on some Evidences of Glaciation in the Australian Alps," and "The Cryptogamia of the Australian Alps," by Mr. James Stirling; "On an Apparatus for Utilising the Force of the Tides," by Mr. Lockhart Morton; and "On an Apparatus for Determining the Stability of Ships," by Mr. C. W. McLean.

WE have received Parts 21-25 of "Länderkunde des Erdteils Europa." The editor of this admirably illustrated work is Prof. Alfred Kirchhoff, and among the contributors are Profs. Penck, Egli, and Heim. The aim of the writers is not merely to describe the countries with which they deal, but to bring out the influence of geographical conditions upon material, political, and social progress.

IN reference to the acclimatisation of flat-fish in American waters, the latest Bulletin of the United States Fish Commission states that in April 1880 five soles sent from England reached New York, and were deposited outside Sandy Hook. In October 1881, out of a consignment of turbot and soles sent from England, three soles and six turbots survived. These were transferred to the Sheep's Head Bay. In order to ascertain whether any trace of these fish could be found, the Fish Commission in October last trawled in the vicinity of the spots mentioned, but did not succeed in capturing any flat-fish.

THE Botanical Museum of Hamburg will be rendered more generally serviceable to German commerce and industry by the addition of a commercial laboratory. For analyses and investigations a most moderate tariff has been set up.

IN an article in the *Entomologist's Monthly Magazine* for March, Mr. Herbert Goss raises the question whether *Aporia cratægi* is dying out in this country. At one time this butterfly was common in Kent, Sussex, Hampshire, Huntingdonshire, Northamptonshire, Herefordshire, Monmouthshire, and Glamorganshire. Now it has disappeared, apparently, from all these counties. Mr. Goss does not think that this can be attributed to the rapacity of collectors, and he holds that it can be accounted for only in some localities by cultivation and drainage. It seems to him more probable that the extreme scarcity or total extinction of the Black-veined White may be due to a succession of wet ungenial summers and mild winters.

THE investigations into the causes and nature of the species of elephantiasis known in Java as *beri-beri*, and in Japan as *kakké*, which have been conducted at Acheen, in Sumatra, by a medical officer delegated by the Japanese Government, and Dr. Cornelissen, Inspector of the Medical Service of the Netherlands India, have led to the following results: (1) *beri-beri* must be regarded as a disease produced by minute organisms; (2) these organisms are Bacilli, which bear most resemblance to the *anthrax* Bacilli, but not smaller; (3) they are found in the blood, lungs, heart, and nervous tissue of persons dying of the disease; (4) they can be reared independently; (5) the Bacilli, which can live as parasites in the human organism, can also live and multiply out of it. These facts, which are said to be established by the investigations, explain how *beri-beri* patients can infect particular places, and how healthy individuals coming from uninfected places contract the disease in infected ones.

MR. W. H. BEEBY has reprinted from the *Scottish Naturalist* some interesting notes on the flora of Shetland. They are the result of a visit of about eight days to the Shetland Islands at the latter end of July last. Four distinct districts were visited, the greater amount of time being spent in Unst. Mr. Beeby is of opinion that the flora of the Shetland Islands is well worthy of further attention. An explorer would, he thinks, be rewarded by finding plants which are at present known only in the Faroes and in Scandinavia.

THE contents of Part 2, No. 3, of vol. lv. of the Journal of the Asiatic Society of Bengal include a short paper by Dr. King, on two new species of holly from the Eastern Himalayas, but are otherwise purely entomological. Prof. Forel continues his critical examination of Indian ants in the Calcutta Museum. Mr. de Nicéville describes nine new species of Indian butterflies, chiefly from Sikkim (which are to be figured in a succeeding number). Mr. Doherty, of Cincinnati, U.S.A., communicates a paper on new or rare Indian butterflies, many of which are from the Nicobar Islands; and Mr. E. T. Atkinson, President of the Society, gives a compilation of what has been written concerning Indian Coccidæ, which may be taken as an introduction to the study of this obscure and injurious family of insects in India. The author has chiefly followed Signoret in the systematic arrangement. The collected information will prove useful in India, for some of these scale-insects have been most destructive to coffee and other plantations. Having a clue as to how and what to observe, Indian entomologists will, no doubt, soon show that legions of Coccidæ exist in India, as elsewhere, and many strange forms will be detected.

THE additions to the Zoological Society's Gardens during the past week include a Gray Ichneumon (*Herpestes griseus*) from India, presented by Mr. C. F. Hird; a Golden Eagle (*Aquila chrysaëtus*) from Scotland; a Chilian Sea-Eagle (*Geranoaëtus melanoleucus*) from South America; a Brazilian Caracara (*Polyborus brasiliensis*) from Brazil, presented by Mr. C. Czarnikow; a Bronze-winged Pigeon (*Phaps chalcoptera*) from Australia, presented by Mr. Malcolm Nicholson; two Red-crested Cardinals (*Paroaria cucullata*) from Brazil; two Cockateels (*Calopsitta novæ-hollandiæ*) from Australia, presented by Colonel F. D. Walters; two Crested Newts (*Molge cristata*), presented by Mr. Alban Doran; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa; two Blue-fronted Amazons (*Chrysotis æstiva*) from South America, deposited; a Hog Deer (*Cervus porcinus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

TELEGRAPHIC DETERMINATION OF AUSTRALIAN LONGITUDES.—A "Report on the Telegraphic Determination of Australian Longitudes," signed by Messrs. Ellery, Todd, and Russell, has recently been published by the Government of South Australia. This Report contains the final results of the operations connecting Singapore and Port Darwin, carried out in 1883 by Capt. Darwin, R.E., in concert with the Australian astronomers above mentioned. The Observatories of Melbourne, Sydney, and Adelaide were subsequently connected with Port Darwin. The preliminary results of these telegraphic longitude determinations were communicated by Mr. Todd in 1883 to Sir G. B. Airy, and published in the *Observatory* for October of that year. The longitude of Singapore adopted in forming the results given in the Report before us is that determined by Commander Green, U.S.A., in 1882, viz. 6h. 55m. 25·01s. East of Greenwich (for Capt. Darwin's station), assuming that of the Madras Observatory to be 5h. 20m. 59·42s. Hence the resulting longitudes are:—

	h.	m.	s.
Observatory, Port Darwin	8	43	22·49
,, Adelaide	9	14	20·30
,, Melbourne	9	39	54·14
,, Sydney	10	4	49·54
,, Wellington, N.Z.	11	39	6·52
,, Hobart	9	49	19·80

The observations for the purpose of connecting Singapore with the various points in Australia are given in sufficient detail in the Report to enable us to see that the determinations have been made with care and attention to detail, and appear to be deserving of every confidence. The New Zealand and Tasmanian results may perhaps require further correction.

COMETS AND ASTEROIDS.—Prof. Daniel Kirkwood has a brief note in the *American Journal* for January 1887, on the origin of comets, in which he points out the probability that two, at least, of recent short-period comets have had an origin in the zone of asteroids. Tempel's comet (1867 II.) has a period, inclination, and longitude of node approximately the same with those of Sylvia (Minor Planet No. 87), whilst its eccentricity is but little greater than that of Æthra (No. 132). Wolf's comet (1884 III.), before its last close approach to Jupiter, had an eccentricity which was exceeded by twelve known minor planets; its period was about 3619 days, and its mean distance 4·611, so that it would appear to have been simply a very remote asteroid. Its period was very nearly commensurable with that of Jupiter.

THE TAILS OF THE COMETS OF 1886.—Prof. Th. Bredichin has recently examined the curves of the tails of the three principal comets of last year in connection with his well-known theory as to the laws of formation of the tails of comets. The two first comets, those of Fabry and Barnard (1886 I. and II.), proved difficult to observe, the earth being nearly in the plane of the orbit of the former comet, so that the foreshortening greatly increased the errors of observations, whilst the tail of the latter was very short, and was diffused on one side. Both, however, were of the same type, the second, $1 - \mu$ being found to be equal to 1·3 for the first, and 1·9 for the second. The third comet referred to, that discovered almost simultaneously by Mr. Barnard and Prof. Hartwig, proved much more important for the purposes of Prof. Bredichin's theory, since it showed three tails. Of these the principal one plainly belonged to the first type, a value of 17·5 for $1 - \mu$ satisfying the observations very fairly. The shorter tail seen by a number of observers plainly belonged to the third type, $1 - \mu$ being very small, whilst a third tail, seen by Mr. Backhouse (NATURE, January 6, p. 224), and lying between the other two, evidently belonged to the second type.

MINOR PLANET NO. 265.—M. Bigourdan points out (*Comptes rendus*, vol. civ. No. 9) that the motion of R.A. of this body is unusually rapid, amounting to − 1m. 40s., or double the ordinary value for the other asteroids. As the planet is nearly exactly in opposition, it must be relatively near the earth, and may therefore be very advantageously employed in the future for the determination of the solar parallax.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 MARCH 20–26

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 20

Sun rises, 6h. 5m.; souths, 12h. 7m. 37·7s.; sets, 18h. 11m.; decl. on meridian, 0° 10′ S.: Sidereal Time at Sunset, 6h. 3m.

Moon (New on March 24) rises, 4h. 30m.; souths, 9h. 10m.; sets, 13h. 57m.; decl. on meridian, 15° 39′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	5 48	12 13	18 38	4 10 N.
Venus	6 51	13 43	20 35	9 22 N.
Mars	6 22	12 38	18 54	2 27 N.
Jupiter	21 18*	2 22	7 26	11 42 S.
Saturn	11 7	19 16	3 25*	22 30 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

March	h.	
20	22	Sun in equator.
22	3	Mercury in inferior conjunction with the Sun.

Variable Stars

Star	R.A. h. m.	Decl. ° ′		h. m.	
Algol	3 0·8	40 31 N.	Mar. 20,	4 36	*m*
			,, 23,	1 25	*m*
			,, 25,	22 14	*m*
ζ Geminorum	6 57·4	20 44 N.	,, 25,	19 0	*M*
U Monocerotis	7 25·4	9 33 S.	,, 24,		*M*
S Cancri	8 37·5	19 26 N.	,, 21,	22 42	*m*

R Aquarii	23 38·0	15 55 S.	,, 26,		*M*

M signifies maximum; *m* minimum.

Meteor-Showers

Near 55 Aurigæ, R.A. 98°, Decl. 45° N.; and on March 20, near θ Ursæ Majoris, R.A. 145°, Decl. 48° N.

GEOGRAPHICAL NOTES

OXFORD has decided to establish a Readership in Geography; candidates are invited to apply. Cambridge has postponed taking a similar step till 1888. While on this subject we may state that by a new Imperial ordinance geography has been raised to an equal footing with the most important subjects taught in German middle-class schools—*Realschulen* and *Gymnasien*. The programme for the examination of teachers desiring to make this one of their special subjects has been issued. There are three grades, and the standard in each is very high.

ACCORDING to advices received at Zanzibar from Uganda, Dr. Junker's caravan safely reached Emin Pasha, who was in good health. Intelligence has also been sent to Zanzibar that five months ago Emin Pasha visited Uganda, but that King M'wanga refused to allow him or his followers to pass through his territory. Emin Pasha then attempted to make arrangements for his passage through Karagwa, on the western shore of the Victoria Nyanza, but failed in this also, and afterwards returned to Wadelai, leaving a detachment of soldiers at Unyoro under the command of Capt. Casati, Emin Pasha's sole European companion.

WE learn on the best authority that Mr. Stanley, on his arrival at Stanley Falls with the first contingent of his Expedition, about 250, will proceed at once to Emin Pasha, without waiting for the rest of his party. No doubt he will be reinforced by some of Tippoo's men, and in this way there will not be a moment's delay. The main body will follow as soon as steamers are able to land them all at Stanley Falls, but first a camp will be established at some distance from the Falls as a base of operations. Dr. Junker gave an account of his seven years' exploring work, on February 26, to the Cairo Geographical Society. His magnificent maps were shown, one of them measuring 13 feet by 23 feet. Dr. Schweinfurth maintained the absolute accuracy of Junker's maps in all respects. Junker then gave a detailed account of his sojourn in the Niam-Niam country. Here he found extensive fertile plains, veritable savannahs, with grass over 3 feet high, and abundance of game. He then passed on to his exploration of the Wellé and the Mepoko, to within four days' journey of the Congo, concluding by giving some interesting details of the effect of the Mahdi revolt on these countries.

THE well-known African traveller, Dr. Zintgraff, who has been commissioned by the German Government to explore the Cameroon district, intends visiting the Cameroon Mountains. As large quantities of caoutchouc are said to be obtained there, Dr. Zintgraff will be accompanied by an expert in that material.

AN official publication of the Colonial Office (African, No. 332) contains a great deal of original information regarding the different districts and tribes of Sierra Leone and its vicinity.

ON Monday evening last a paper on "The Alpine Regions of Alaska" was read by Lieut. H. Seton-Karr at a meeting of the Royal Geographical Society. In the course of a description of a visit to this territory last year, the reader expressed the opinion that the St. Elias Alpine region offers one of the best places for the study of glacial phenomena under the most powerful conditions. According to Dall, the American surveyor, Mount St. Elias is 19,500 feet high. It is a mass of snow and ice from base to summit, and has always been marked in modern maps as exactly on the 141st meridian, which is the boundary line. If the shore line was correctly charted, he found that the summit was east of the meridian of longitude mentioned. It was therefore in the British Empire. Describing the ascent of the mountain, he stated that he proceeded to a point which the aneroid instruments gave as 7200 feet above the sea-level. There remained in the Alpine regions of the North Pacific a wide field for explorers. Mounts Crillon, Fairweather, and La Pérouse, respectively 15,900, 15,500, and 11,300 feet high, were not quite so striking as the one he described, but were much nearer to civilised settlements. There is a large blank space upon the map of Alaska, lying between Cook's Inlet and the great Yukon River. It is as unknown as any of the unexplored regions on the globe.

A JOURNEY of considerable interest is now being carried out in Central Asia by Mr. A. D. Carey, of the Bombay Civil Service. Mr. Carey left India in May 1885, and marched through Ladak into Northern Tibet (Chángtán) as far as the Mangtsa Lake, and then struck northward, descending on the plain of Turkestan, near Kiria. He thus traversed over 300 miles of country which had never before been visited by a European. The altitudes on this section of the journey were always very great, the track running usually at about 16,000 feet above the sea, while one at least of the passes crossed was calculated to reach 19,000 feet. After a stay at Kiria and Khotan, the Khotan River was followed to its junction with the Tarim; the route then lay along the latter river to Sarik, and then across a stretch of desert to Sháh-Yarand Kuchár. From the latter place the Tarim was followed down to a point where it turns southward towards Lake Lob. From this point the towns of Kurla and Kárástaber were visited, and about the end of the year the Tarim was struck again and tracked down to Lake Lob. Thus the whole length of the Tarim has been explored. The country along its banks is described as flat and reedy, and the people extremely poor and miserable. Mr. Carey pitched his camp at the village of Cháklik, some distance south of the lake, and close to the foot of the great range of mountains which forms the northern scarp of the Tibetan highlands. On April 30, 1886, Mr. Carey started from this village on a journey southward into Tibet, over a pass in the Altyn Tagh Range, and onward by a track occasionally used by the Kalmucks. Since this start nothing has been heard of Mr. Carey, but it is presumed that after spending the summer and autumn in travelling over the elevated region he has returned to Turkestan to winter.

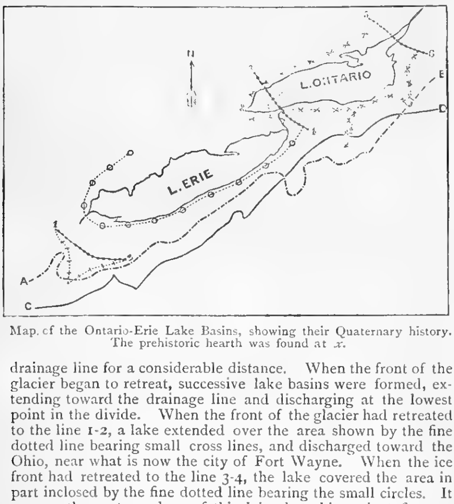
THE principal paper in the March number of *Petermann's Mitteilungen* is a special study of the basin of the Cachapoal in the province of Santiago, Chili, by Dr. A. Plagemann. There is also a short paper on the hydrography of Batanga Land, by Herr P. Langhaus. From the notes we are glad to learn that the Roumanian Government has adopted a plan for the triangulation of that country, which will be the means of filling up an important gap in the cartography of Europe. Ergänzungsheft No. 85 of *Petermann's* contains a detailed account, with map and diagram, of Dr. Gustav Radde's journeys in the Alpine region of Daghestan in the summer of 1885.

PREHISTORIC REMAINS IN AMERICA

At a recent meeting of the Washington Anthropological Society, Mr. G. K. Gilbert described a prehistoric hearth under the Quaternary deposits in Western New York. The speaker described the finding of the remains of a wood fire in the bottom of a well through the drift deposits near Gaines, a few miles south of Lake Ontario. The evidence in the matter rests almost entirely on the statements of a Mr. Tomlinson, a well-known and respected resident of the place, and who, personally, made the find upon his own farm. It was twenty years ago that the discovery was made, but Mr. Tomlinson has stated that his memory of all the essential details was very clear, and the speaker had every personal reason for believing the statements. The story is briefly that in sinking a well through 17 feet of gravel and clay, they found lying upon the rock at its bottom three large stones, partly inclosing a small space in which were about a dozen charred sticks, undoubtedly the remains of a fire started by human hands. Mr. Tomlinson gave some of these remains to neighbours, who still remember the matter, and the remainder he kept himself. In time, however, they have been lost, and the endeavour to find them did not meet with success.

The speaker then discussed at length the character of the beds under which the remains were found, and their geologic age, illustrating his statements by a map, of which a small copy is here reproduced.

The line A B shows the approximate southern limit of the lake drainage, and C D the approximate south-eastern extension of the second glacier, which, it will be noted, extends across the



Map of the Ontario-Erie Lake Basins, showing their Quaternary history. The prehistoric hearth was found at *x*.

drainage line for a considerable distance. When the front of the glacier began to retreat, successive lake basins were formed, extending toward the drainage line and discharging at the lowest point in the divide. When the front of the glacier had retreated to the line 1-2, a lake extended over the area shown by the fine dotted line bearing small cross lines, and discharged toward the Ohio, near what is now the city of Fort Wayne. When the ice front had retreated to the line 3-4, the lake covered the area in part inclosed by the fine dotted line bearing the small circles. It was on the eastern shore of this lake that this ancient fire was built, and by its shore wash that it was so gently covered as not to be disturbed during the process.

By further retreat of the glacier toward 5-6, a lower outlet was exposed in the valley of the Mohawk, and the surface of the glacial lake again fell—the Lake Erie portion to the level of the escarpment of Niagara limestone which still dams it back, and the Lake Ontario portion to a somewhat lower level. Further retreat of the icy dam to 5-6, and beyond, opened the St. Lawrence channel, and the present drainage was established.

From this explanation the comparative age of the hearth and its remains is indicated. It was near the end of the second glacial period, and at the time of separation of Lake Ontario from Lake Erie. At about this time, also, the Niagara River began its work of cutting through the escarpment of Niagara limestone, and at which it has been engaged ever since. Its rate of progress having recently been approximately determined, we are able to estimate the number of years as about 7000 since the lakes were separated and the gorge and falls begun. This estimate is based on comparisons of a recent survey by the U.S. Geological Survey with those made by the New York Survey forty years ago, and is open to some qualifications. In the first place, it is possible that some of the gorge was cut before the glacial period; then it has been found that the hardest stratum through which the river has to cut thins somewhat to the eastward, and thus offered less resistance to wear at an earlier date in the history of the gorge; and then, again, the possibility is presented of the volume of water having been vastly greater toward the close of the glacial period, and it is known that the erosive power of water increases very rapidly with increase of volume. These qualifications tend to reduce the time estimate; but on the other hand, evidence has been found that at one time the other lakes above Erie emptied by another means, and if this was so for any great length of time after the birth of the Niagara, it would tend to very greatly increase the time.

In the discussion following this paper, Mr. Murdock, of the Point Barrow Station, gave an account of the finding of a prehistoric relic under somewhat similar circumstances. Their station was near the extreme north-west corner of this continent, on a beach ridge a few yards from the Arctic Sea. This ridge was 9 or 10 yards in height, and extended along the coast for some distance. In making an excavation for an earth thermometer, they penetrated a 1-foot layer of turf which capped the ridge, and then frozen gravel and earth to a depth of 20 odd feet, where an Eskimo snow-goggle was found embedded in the frozen earth. The goggle was identical with those now in use, and consists of a piece of bone covering the eyes and bridging the nose, with small slits to admit a very limited amount of light and protect the eyes from snow-blindness. The specimen found had strings of braided sinew attached, but these were broken in removing them from the hard matrix. The speaker believed that the beds inclosing and covering this relic were the results of beach wash. The Eskimo of the region have a tradition that people used to live at the locality of the find, and a few remains of houses are found in the vicinity.

At the same meeting Mr. W. J. McGee read an informal paper on the finding of a spear-head in the Quaternary beds of Nevada.

The speaker described the geologic features of the Walker River cañon, in the lacustrine deposits in which the find was made. These deposits are those of the fossil Lake Lahontan, and were deposited in the old cañon during the Quaternary period. Since then the river has cut a new cañon through them, and they are now finely exposed. Beginning above, the beds consist of silt and loose materials for several feet, then comes a layer of calcareous tufa lying upon 20 to 30 feet of white marl, containing remains of extinct mammalia, and resting unconformably upon a somewhat similar series of beds of earlier date. It was in the white marl of the upper beds that the implement was found. The speaker described in detail the conditions under which the find was made. He was alone at the time, and far distant from camp or party; he had been carefully examining the face of the marl talus as he rode along, and was searching for occasional bone remains. At one point, 26 feet below the surface, he noticed a small projecting point which looked as if it was caused by a bone. Picking off some of the surface, he at once recognised the object to be a product of man's handicraft; and appreciating the importance of the find, and the necessity of a very thorough study of all the circumstances connected with it, framed some working hypotheses before removing the implement. At first it appeared probable that it was embedded in a superficial coating of the slime which is often washed over the surface of this loose marl. This was at once disproved by examination. Other possibilities were suggested, such as its having fallen into its position down a fissure or been shoved into the face of the cliff by man; but these were all found to be, if not impossible, extremely improbable, and the speaker had concluded that it was deposited with the marl. Extensive stratigraphic studies have been made of these lacustrine deposits by King, Russell, and Gilbert, and there can be no doubt but that these beds and the flint were deposited toward the close of the glacial period, and about at the same time as those covering the hearth described by Mr. Gilbert. The implement was a spear-head 3½ inches in length, finely made and well preserved.

In the discussion which followed this paper, several members called attention to the great value of the find from the fact that it was made by a well-trained observer, who appreciated the importance of his discovery before destroying the evidence, and then carefully studied every detail connected with it.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Mr. S. H. Vines, M.A., D.Sc. Lond., F.R.S., and Prof. J. H. Poynting, M.A., have been approved for the degree of Doctor in Science.

Fortunately for research in pathology, the opposition to the acceptance of the John Lucas Walker Studentship proved abortive, and it was accepted by a majority of nearly five to one last Thursday.

Dr. Michael Foster, Sec.R.S., has been appointed the University representative on the Council of the Marine Biological Association till the next annual meeting of the Association.

The following Entrance Scholarships and Exhibitions in Natural Science will be open for competition in the coming summer:—Downing College: Natural Science, June 1, 50*l.* per annum; Peterhouse: Mathematics, Chemistry, and Physics, 40*l.* to 60*l.* per annum; date to be announced in June; non-Collegiate students: Physical Science, July, in connection with Oxford and Cambridge Schools Examination Board, 50 guineas per annum for three years, tenable at Oxford or Cambridge, open to non-Collegiate students of not more than one term standing, or to persons not yet in residence. Apply to the Rev. F. G. Howard, Cambridge.

SCIENTIFIC SERIALS

American Journal of Mathematics, vol. ix. No. 2, January.—The number opens with a continuation of Mr. Greenhill's memoir, wave-motion in hydrodynamics, in which is discussed wave-motion in the following cases: § 21, across a channel with sides sloping at any angle; § 22, against a uniformly-sloping shore; § 24, in a cone; § 25, in a cylinder; and § 23 contains an algebraical solution of waves against a shore.—Prof. Sylvester's lectures on the theory of reciprocants give notes of lectures xvii. to xxiv., with an extract from a letter of M. Halphen in which the existence of *invariants* in general is established *a priori*; this is given as introductory to the theory of differential invariants.—A memoir in the theory of numbers, by A. S. Hathaway, contains an historical introduction of interest. The second part considers fundamental principles and definitions, then a problem and the consequences of its solution, and then turns the question of ideal solution of the problem into the question of the establishment of a given theory of ideals; the demonstrations are left for the reader to supply. The third part is occupied with a rigorous establishment of the theory of ideals indicated in the second part.—The next paper, on a theorem respecting the singularities of curves of multiple curvature, by H. B. Fine, is a generalisation of a portion of a previous paper (vol. viii. No. 2) by the same writer.—The number closes with two short notes—one on pencils of conics, by H. D. Thompson (let the eight points in which a conic intersects a quartic be divided into two groups of four, and a conic be passed through each group: the two residual—four-point—groups lie on a conic; an exceptional case in Cayley's theorem, which had been overlooked by the author, is mentioned and references given to where it is discussed); the other consists of observations on the generating functions of the theory of invariants, by Capt. P. A. Macmahon.

Notes from the Leyden Museum, edited by Dr. F. A. Jentink, vol. ix. No. 1, January 1887, contains, among other memoirs, the following:—J. Buttikofer, on a collection of birds made in the highlands of Padang, in West Sumatra, by Dr. C. Klaesi. This paper gives details of 189 birds in this collection, and is prefaced by a short history of the various published accounts of the birds of Sumatra from the first memoir by Sir Stamford Raffles in 1822. The only new species described is a swift (*Hirundinapus klaesii*).—Dr. R. Horst, descriptions of earthworms. Describes as new a gigantic earthworm from a coffee-plantation in Sumatra, *Moniligaster houtenii*; and also from the same country, *Rhinodrilus tenkatei*, n.sp.—Dr. Th. W. van Lidth Jeude, on a collection of reptiles and fishes from the West Indies. Describes three new lizards and a new fish taken during the Dutch Expedition to the West Indies.—There are also ten papers on new or little-known insects.

Rendiconti del R. Istituto Lombardo.—Results of the observations made by Dr. M. Rajna at the Brera Observatory on the diurnal oscillations of magnetic declination during the year 1886, communicated by E. G. V. Schiaparelli. These observations were taken as in previous years at 8 a.m. and 2 p.m., the diurnal variation being obtained by determining the difference in time between the two periods. The monthly averages thus determined and tabulated show for the whole year a mean of 6′·72.

Bulletin de l'Académie Royale de Belgique, January.—On some curious effects of molecular forces in contact with a solid and a liquid, by G. Van der Mensbrugghe. Some experiments are described tending to illustrate the expansive force possessed by the contact layer between a solid and a liquid, and the existence of which the author claims to have been the first to demonstrate.—On Fermat's last theorem, by P. Mansion. It is shown that, if there exist integers x, y, z, verifying Fermat's relation $x^n + y^n = z^n$, where $x < y < z$, then not only the middle term, y, as shown by de Jonquières, but also the largest, z, and the smallest, x, are compound numbers.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 3.—"Preliminary Note on a Balanoglossus Larva from the Bahamas." By W. F. R. Weldon.

A preliminary account was given of the degradation of a Balanoglossus larva, found during the latter half of last year in the deep waters round the Bahamas. Up to the period of the development of a pair of gill-slits, this larva resembled, except in its pelagic habit, the larva found in Carolina by Bateson. After this stage, degradation set in, resulting in the atrophy of the two posterior pairs of body cavities, and the reduction of that in the præoral lobe: the gills and notochord, together with the greater part of the nervous system, disappeared, and the trunk diminished in size. The result was a bell-shaped creature, with a large præoral lobe, on the sides of which was developed a curious arrangement of tentaculiferous grooves. The alimentary canal remained functional, but the creature gradually shrivelled up, and (probably) died.

"Studies of some New Micro-Organisms obtained from Air." By G. C. Frankland and Dr. Percy F. Frankland.

In previous communications to the Royal Society by one of the authors,[1] details have been given of a number of experiments on the presence of micro-organisms in the atmosphere. In these investigations a solid culture medium was employed, which not only greatly facilitated their enumeration, but also presented them in an *isolated* condition. In this manner the authors have met with a number of different varieties of aërial micro-organisms, which have hitherto remained either unknown or undescribed. They have therefore undertaken the characterisation of a number of these organisms by growing them in various cultivating media and observing the different appearances which they subsequently exhibit, by studying them microscopically in stained and unstained preparations, and by cultivating them on gelatine-plates, and describing the colonies to which they give rise. They have likewise made a number of drawings to illustrate the appearances which they present under the various examinations to which they have submitted them. To further facilitate their identification the authors have provisionally given them names, by which they have endeavoured to represent some of their most striking individualities.

The authors venture to hope that by thus characterising some of the organisms most prevalent in the atmosphere, they may prove of assistance in those investigations which have for their object the study of the particular physiological changes which are brought about by specific micro-organisms.

The following is a list of the micro-organisms described:—

Micrococcus carnicolor	Bacillus plicatus
,, albus	,, chlorinus
,, gigas	,, polymorphus
,, chryseus	,, profusus
,, candicans	,, pestifer vermicularis
Streptococcus liquefaciens	,, subtilis minor
Sarcina liquefaciens	,, subtilis cereus
Bacillus aurescens siccus	Saccharomyces rosaceus
,, aureus	,, liquefaciens
,, citreus	Mycelium fuscum.

[1] (1) "The Distribution of Micro-Organisms in Air," Roy. Soc. Proc. vol. xl. p. 509; (2) "A New Method for the Quantitative Estimation of the Micro-Organisms present in the Atmosphere," *ibid.* vol. xli. p. 443; (3) "Further Experiments on the Distribution of Micro-Organisms in Air by Hesse's method," *ibid.* p. 446.

In addition to these varieties a description has been given for the sake of comparison of some aërial micro-organisms which were obtained by one of the authors from Dr. Koch's laboratory in Berlin. These are—

Micrococcus rosaceus	Bacillus subtilis
Sarcina lutea	,, (Micrococcus) prodigiosus.
,, aurantiaca	

Linnean Society, March 3.—Mr. W. Carruthers, F.R.S., President, in the chair.—The following gentlemen were elected Fellows of the Society:—B. S. Dyer, Right Hon. Sir E. Fry, S. T. Klein, C. Mariès, E. S. Marshall, R. Morgan, J. B. Stone, and A. W. Tait.—A paper was read by Mr. Alfred W. Bennett on the genetic affinities and classification of the Algæ. He referred to Prof. Sachs's scheme as based on the mode of reproduction and degree of complexity of the sexual process alone; this being the most important factor in the life-history of the plant. Supporting Sachs to a certain extent, he nevertheless differs from him, and rather agrees with Prof. Fischer's view of Algæ and Fungi running in distinct series, while he diverges from both writers as to the descent, relations, and grouping of the Algæ. He believes arrest of development has had an important influence in many presumed deviations among the groups in question. He avers that retrogression may take the form of the suppression of either the vegetative or the reproductive organs, and whichever predominates or progresses leaves the other feeble or degenerate. If the principle advocated by the author holds good, it leads towards the almost abandoned divisions of the Algæ into the green, the red, and the brown,—Chlorosporeæ, Rhodosporeæ, and Phæosporeæ. It would appear as if at an early period in the development of the simplest form of vegetative life, three kinds of cell-contents were represented, a colourless, a blue-green, and a pure green. Based thereon are the author's three great divisions:—I. *Schizomycetes*, forms entirely destitute of chlorophyll, and adapted to carry on only a parasitic existence; II. *Chroococcaceæ*, unicellular organisms, with cell-contents composed of watery blue-green endochrome diffused through the protoplasm, without distinct chlorophyll grains, starch grains, or nucleus; III. *Protococcaceæ*, characterised by cells possessing a nucleus, starch grains, pure chlorophyll identical with that of higher plants, and in certain states a true cell-wall of cellulose. The (I.) Schizomycetes lead to the Fungi, which are not discussed by the author. The (II.) Chroococcaceæ pass through the Oscillarieaceæ to Nostocaceæ. The (III.) Protococcaceæ are the great derivatives of the Algal group. Hence three great lines of descent are indicated. (1) The Diatoms are regarded as of remote origin, very low in the scale. (2) The Cœobiæ comprise a series through Sorastreæ to Volvox and Allies. (3) The Eremobiæ as a line of descent pass to the Multinucleatæ, *e.g.* Siphoneæ with gigantic cells. Thence cell-division originating, proceeded to the Confervoideæ-isogamæ, the Conferva group. From these in three different lines have sprung: (*a*) the Conjugatæ, including Zygnemids and Desmids, a retrogressive group; (*b*) the brown seaweeds adapted to deep sea life, Phæosporeæ, terminating in Fucaceæ; and (*c*) the Confervoideæ-heterogameæ, at the extreme of which the Coleochætæ are reached. The Coleochætæ lead direct to the red seaweeds, or Florideæ, a natural group with great variety in development of the sexual organs. By arrest of development branches proceed on the one hand through Nemalieæ to the Ulvaceæ, while on the other at a tangent from true Algæ were evolved the Characes, the Mosses, the Gymnosperms, and lastly the higher Angiosperms, or flowering plants.—A paper was read on the disease of Colocasia in Jamaica, by Mr. G. Massee and Mr. D. Morris. The negroes of the West Indies give the name "Cocoes" to the main stem and shoots of a species of Aroid. This forms a wholesome food, and is said to be preferable to yams and sweet potatoes. A blight arises in the tubers similar to the potato-disease; and as shown by the authors this is produced by a fungus belonging to the genus Peronospora, a new species named by them *P. trichotoma*. Instructions are given as to remedial measures, an important one being the absolute necessity of badly affected plants being wholly destroyed.

Physical Society, February 26.—Prof. W. G. Adams, Vice-President, in the chair.—The resolution passed at the meeting on February 12, providing greater facilities to persons being abroad for qualifying for membership of the Society, was unanimously confirmed.—Prof. W. Stroud and Mr. A. S. Gulbenkian were elected Members of the Society.—Mr. James Swinburne read a note on Prof. Carey Foster's method of measuring the mutual induction of two coils. The author described an apparatus devised last summer for measuring mutual induction by a null method, thus dispensing with a ballistic galvanometer. The induction in the secondary coil is balanced by an opposite effect produced by a variable known fraction of the primary current passing through one wire of a double-wound coil of known mutual induction, the other wire of which is joined in series with the secondary coil and galvanometer. In a preliminary trial, using an ordinary reflecting galvanometer, it was found that instead of no deflection being observed, two kicks in opposite directions occurred when there was iron in the circuit. A new galvanometer, with heavy needle, is now being constructed to overcome this difficulty. A null method of finding the ohm by means of a differentially-wound, heavy-needle galvanometer is suggested in the latter part of the note. Prof. Ayrton pointed out that Prof. Foster's method does not require readings on a ballistic galvanometer, and mentioned that in practice it is greatly superior to those given in Maxwell and the ordinary text-books. The chief drawback is the necessity of having large condensers of accurately known capacity where large coefficients are concerned. A large number of experiments have been carried out at the Central Institution by Mr. Sumpner with very satisfactory results. Prof. Adams concurred in Prof. Ayrton's statement regarding the difficulties in using Maxwell's methods in practice, and expressed his satisfaction with the great simplicity of Prof. Foster's method.—On the determination of coefficients of mutual induction by means of the ballistic galvanometer and earth inductor, by R. H. M. Bosanquet. The methods described depend on two measurements of the throws of a ballistic galvanometer: (1) that produced by the sudden rotation of a coil (the constants of which are accurately known) through 180° about a vertical axis; and (2) that produced by the mutual induction to be measured when a current of known strength is started in the primary circuit. The earth induction-coil is permanently joined in series with the ballistic galvanometer and secondary coil, and the primary current measured by an absolute tangent galvanometer of the Helmholtz pattern. If Q_0 and Q be the quantities of electricity which pass through the ballistic galvanometer in the two experiments, then

$$Q_0 = \frac{2\,NAH}{R},$$

where NA is the effective area of the inductor, and

$$Q = \frac{MC}{R},$$

where $C = GH \tan\theta$.

Hence $$\frac{Q}{Q_0} = \frac{MG\tan\theta}{2\,NA} = \frac{\alpha}{\beta},$$

where α and β are the throws of the ballistic galvanometer. From the above we get

$$M = \frac{\alpha}{\beta}\,\frac{2\,NA}{G\tan\theta}.$$

A modification to be used when M or R are very large is also described. Numerical results obtained are given, from which it is inferred that Maxwell's formulæ for calculating the mutual induction of two circular coils cannot be applied where the distance between their central planes is at all comparable with their radii. Experiments on an A Gramme dynamo gave very irregular results when the currents were small, owing to the sub-permanent magnetism of the machine. Further uses of the method are suggested, such as the absolute determination of capacity and resistance. Remarks on the subject were made by Prof. Carey Foster and Mr. Swinburne, and Prof. Ayrton replied to Mr. Swinburne's contention that Prof. Foster's method was not independent of observations of a ballistic galvanometer (since capacities are determined by their means) by pointing out that where accurate standards exist it is quite legitimate to base other absolute measurements on them.—Prof. Reinold then read an abstract of a paper on the continuous transition from the liquid to the gaseous state of matter at all temperatures, by Prof. W. Ramsay and Dr. Sydney Young. The authors find the relation between pressure and temperature of gases and liquids at constant volume expressible by $p = bt - a$ where b and a are constants, and therefore conclude that the *isochors* (*i.e.* curves connecting p and t for constant volume) are straight lines. At temperatures below the critical point, the isotherm, during passage from the gaseous to the liquid state, is a serpentine curve intersected by the horizontal line of vapour-pressure corresponding with that temperature, the two areas between the curve and straight line being equal. By experiment and extrapolation the authors find the loci of the apices of the serpentine curves corresponding with different temperatures, to intersect at the critical point. The above results are proved for ether and carbon dioxide, and the authors believe them to be true for all stable substances. Prof. Rücker remarked that if similar relations hold for liquids and solids, the triple point of intersection would be of immense interest. Prof. Perry, whilst regarding the results as of vast importance, thought the curves and calculations should be very carefully discussed before being finally accepted.

Edinburgh

Royal Society, February 21.—Rev. Prof. Flint, Vice-President, in the chair.—In a paper on the effect of pressure on the maximum density point of water, Prof. Tait replied to criticisms made upon his results by Grimaldi.—Dr. J. Murray gave a re-determination of the mean height of the land of the globe above sea-level. He obtains a value higher than that obtained by previous observers.—Prof. Tait read a note on the effects of explosives. He pointed out that within a certain distance from the centre of explosion the speed of ejected matter (air, &c.,) is greater than that of sound. Hence within this distance there is great danger of damage to objects from impulsive pressure.—Dr. Traquair read a supplementary report on fossil Ganoidei collected in Eskdale and Tiddesdale.—Sir W. Thomson submitted a paper in continuation of his paper read before the last meeting on the equilibrium of a gas under its own gravitation alone.

Paris

Academy of Sciences, March 7.—M. Janssen in the chair.—Determination of the constant of aberration: first and second processes (concluded), by M. Lœwy. The relations being known between the ecliptical and equatoria lco-ordinates, the equation is here determined by means of which for a couple of stars without aberration, the epoch may be calculated, when both are at the same altitude above the horizon.—On a theorem of M. Liapounoff respecting the equilibrium of a fluid mass, by M. H. Poincaré. By considerations borrowed from electrostatics, a simplification is here offered of the demonstration recently published by M. Liapounoff in the *Mémoires* of the University of Kharkoff.—On the direct fixation of the gaseous nitrogen of the atmosphere by vegetable soils with the aid of vegetation, by M. Berthelot. Having already described the results of the experiments made at Meudon on the fixation of atmospheric nitrogen by certain argillaceous and vegetable soils, apart from the action of vegetation, the author here gives the results of the experiments simultaneously carried on with the aid of vegetation, and under the ordinary conditions suitable for the natural development of plants. In this case the amount fixed was only 4·67 and 7·58 grms., as compared with 12·7 and 23·15 in the absence of plants. From these experiments important conclusions are drawn with regard to the rapid exhaustion of the soil under the prevalent systems of forced culture.—On the great movements of the atmosphere, and on M. Mascart's second note of February 28, by M. Faye. The author replies to the objections urged against, and repeats the arguments already advanced by him in support of, the theory he has formulated on this subject based on fifteen years' observations of atmospheric phenomena.—On the magnetic effects of the recent earthquakes, by M. Mascart. A more careful study of the curves recorded at the Observatory of Nantes shows that the magnetic effects observed at Paris, Lyons, and Perpignan, were also felt in the west of France, although here the oscillations were much feebler.—On the determination of the poles in magnets, by M. Mascart. For the method here described it is claimed that it involves no hypothesis on the magnetic state of the bars, and is free from the objections urged against the other methods now in use.—On the nutritive properties of latex, and on the aquiferous apparatus of *Calophyllum* as described by M. Vesque, by M. A. Trécul.—On the frequency and duration of showers, by M. Hervé Mangon. The results are here tabulated of the pluviometric observations taken at Paris during the years 1860–70 with the pluvioscope invented by the author. The rainfall here recorded is higher than that indicated by other instruments, which mostly neglect slight showers under 0·10 or 0·15 mm., which nevertheless represent from 1000 to 1500 kgrms. of water per hectare.—Letter on atmospheric eddies (M. Weyher's experiments, &c.), by M. D. Colladon.—Report on M. Léon Roque's note respecting a new metronome, based on the isochronism of the slight oscillations of the pendulum, by M. Fizeau. The Commission appointed to examine this instrument reports favourably on the principle of its construction as at once simple and practical, and considers that it is likely to be of service to the art of music.—Report on MM. Bérard and Léauté's memoir on the means of diminishing momentary increase of velocity in machinery furnished with governors acting indirectly, by the Commissioners, MM. Lévy, Marcel Deprez, Sarrau, and Phillips. The report considers that MM. Bérard and Léauté have arrived at a simple and complete solution of the problem how best to control the irregular action of machinery, and that, while specially useful for the manufacture of gunpowder, their apparatus will be found generally applicable to all mechanical work.—Note on the earthquake of February 23 in Italy, by M. F. Denza. General conclusions are given regarding the character, extent, duration, intensity, &c., of this disturbance, derived from reports received from all quarters at the Observatory of Moncalieri.—Propagation of the earthquake in one of the mines at Anzin (Nord), by M. François. The *tromomètre* (seismometer) set up in this mine at a depth of 250 metres two months ago recorded, for the first time, extraordinary vibrations between 6.15 and 6.30 a.m. on February 23.—Reports on the same phenomenon, by MM. A. Issel (Porto Maurizio), M. E. de Rossi (Rome), and Perrotin (Nice).—Observations on M. Donnadieu's recent note on the winter incubations of Phylloxera, by M. Balbiani. In reply to M. Donnadieu, the author maintains his views regarding the hibernation of this parasite.—Observations of Barnard's Comet II. and of Palisa's new planet made at the Observatory of Algiers with the 0·50 m. telescope, by MM. Trépied and Rambaud.—Distribution in latitude of the solar phenomena during the year 1886, by M. P. Tacchini. From the tabulated results of the year's observations it appears that the eruptions, spots, and faculæ, were more numerous in the southern, and the protuberances in the northern, solar hemisphere. The latter occurred in all zones, whereas the other phenomena were almost entirely confined to the region between the equator and ± 40°.—On the rectifications of Maclaurin's trisector curve by means of the elliptical integrals, by M. G. de Longchamps.—On the laws of solution, by M. H. Le Chatelier. This is a reply to MM. Chancel and Parmentier's recent communication to the effect that the author's law of solution is not general, and in certain cases is opposed to observed facts.—On some formulæ relating to saline solutions, by M. Duhem.—On a particular case of solution, by M. F. Parmentier.—On an acid obtained by the action of potassa on a mixture of acetone and chloroform, by M. R. Engel. The compound substance here described has been obtained by M. Willgerodt by treating acetone with chloroform and a small quantity of solid potassa. Its formula is $C_4H_7OCl_3$, and it takes the name of acetone-chloroform.—Synthetical researches on some derivatives of diphenyl, by M. P. Adam.—Note on active camphene and ethyl-borneol, by MM. G. Bouchardat and J. Lafont.—Action of the bibromide of ethylene on the alkaline alcoholates: preparation of acetylene, by M. de Forcrand.—On the spores of *Bacillus anthracis*, by M. S. Arloing. It is shown that these spores are really killed by the light of the sun.—A new method of attenuating the virus of ovine pox, by M. P. Pourquier. The experiments here described yield an unlimited supply of an attenuated virus or vaccine, with which sheep may be safely and efficiently inoculated.—Researches on the structure and development of the cysts in *Echinorhynchus angustatus* and *E. proteus*, by M. R. Kœhler.—On the food of the sardine, by MM. G. Pouchet and J. de Guerne. It is shown that the food of the sardine varies according to circumstances, and does not depend, as recently asserted, on the animal refuse drifting from the Newfoundland fisheries.—New researches on the mode of formation of double monsters, by M. Camille Dareste.—On the variations of structure in the carboniferous porphyries of Renfrewshire, by M. A. Lacroix.—On the minerals associated with the basalt of Prudelles, near Clermont-Ferrand, by M. Ferdinand Gonnard. The prevailing mineral disseminated among these as among most of the Puy-de-Dôme basalts is a christianite apparently confused by the old mineralogists with mesotype, or vaguely described under the name of zeolite.—Researches on the contraction of the terrestrial radius since the formation of the solid crust, by M. A. de Lapparent. Several arguments are adduced against the general theory that the radius of the globe has diminished by one-half since the gneiss or oldest rock formation.

BERLIN

Physiological Society, February 11.—Prof. du Bois-Reymond in the chair.—Dr. König spoke on acuteness of hearing and its estimation by means of tuning-forks, the sound of which gradually died away. He laid stress on the distinction between acuteness of seeing and acuteness of hearing, the latter of which was represented by the time from the beginning of hearing a tuning-fork struck till no sound from it was any longer perceived. It was now customary to say when one person could hear a certain tuning-fork for 100 seconds after it had been struck, and another could hear the same tuning-fork, struck at the same intensity, for only 50 seconds, that the second had only half the acuteness of hearing possessed by the first. In point of fact, such a statement was not accurate, seeing that the amplitudes of a vibrating tuning-fork declined in geometrical progression. It was only in very special circumstances that the specification of the amount of acuteness of hearing, as commonly employed, could be correct. As an empirical method of measurement according to a conventional standard, the expressions a half, a quarter, or whatever be the measure, of acuteness of hearing would be permissible, if in such cases the same tuning-fork were always applied, and it was always struck with the same intensity. To come to an understanding on this point was the business of practical aurists. During the animated discussion which followed this address, Prof. du Bois-Reymond produced an apparatus in which an equal amplitude of vibration in a tuning-fork was obtained by placing between the prongs of the fork a revolving elliptical disk of such dimensions that the small axis left the prongs in their natural position, while the large axis forced them apart from one another. The large axis having been put in, and the disk rapidly turned through 90°, the fork commenced to vibrate, and with each impulse the amplitude was the same.—Prof. Zuntz reported the results of the experiments, partly instituted in conjunction with Herr Potthast, respecting the alimentary values of various albuminous substances. As a most important principle in conducting these experiments, the speaker laid down the maxim that the albuminous substance to be examined should not be administered in too large quantities. It was only with very small doses that the alimentary value of the different albuminous substances beside the same nourishment free of nitrogen could be determined. The dog was used for the purpose of the experiment. The proteine substances compared were: the albumen of lentils, that of lupines, that of gluten, and caseine. In the normal feeding, which regularly alternated with that of the albumen to be tested, the proteine of nourishment was imparted in the form of flesh-meal. The result of the long and laborious experiments was that the alimentary value of the albumen of lentils and that of gluten were each found to be equivalent to that of flesh-meal. That is to say, when to the food (which, apart from the additions to be specified, was the same in all the different cases) there were added equal quantities of albuminous nitrogen—in one case in the form of flesh-meal, in another in the form of gluten, and in a third in the form of lentils—in each such case a quantity of nitrogen was developed, and therefore a quantity of albumen withdrawn from the nourishment, which was equal in all three. The albumen of lupines had a lower alimentary value than the albumen of flesh-meal, seeing that from the lupines more albumen was decomposed than from the flesh-meal. Finally, from caseine, less albumen was decomposed, and therefore more was absorbed by the body and utilised, than in the case of any of the other albuminous classes. By means of this investigation two facts of general importance were established: first, it was ascertained that by changing the species of albumen employed by way of nourishment, a better utilisation of the nutritive albumen was obtained, *i.e.* less albumen was decomposed, than if one and the same species of albumen were given for a long period; second, the paradoxical observation was made that during lactation, when the animal made use of a large quantity of albumen for the formation of milk, more of the albumen administered in the food passed away in waste than would have been the case in the same circumstances at a time of non-lactation. The following explanation of these phenomena was given by the speaker. During lactation the animal used a certain quantity of albumen for the milk. The albumen of milk, as was known, was caseine. This caseine was not, however, administered in the food, but had first to be produced from the nutritive albumen (the various species of albumen being chemically different. Now, from the nutritive albumen only certain groups of molecules could be utilised for the formation of caseine. Far more albumen must therefore be decomposed than corresponded with the quantity of nitrogen in the caseine. Hence, therefore, the greater decomposition and the less utilisation of the albumen of the nourishment. Nor was the albumen which the animal needed for incorporation with the body offered to it in the albumen of the nourishment, but the albumen taken by the body was built up from the constituents of the albumen of the nourishment. If only one kind of albumen was given to the animal, it required to decompose a large quantity in order to obtain sufficient constituents for the albumen appropriated by the body. If, on the other hand, different sorts of albumen were given in the food, then the animal decomposed on the whole a less percentage, seeing that in the differently composed albuminous substances it sooner found the different molecular groups which it needed for the building-up of the albumen of the body.

THE NECESSITY FOR A MINISTER OF EDUCATION

IF we are justified in judging of the progress of right ideas on the importance to the nation of science and scientific instruction by the outcomes of one week, then certainly we may congratulate ourselves upon the fact that at last the views which we have for the last eighteen years, in season and out of season, been putting forward are beginning to attract public attention.

There can be no doubt that the general interest is now thoroughly aroused on this matter. In spite of the absolute block of anything like a debate upon education in Parliament, scientific and political leaders say their say elsewhere, and the manner in which these utterances are referred to and enlarged upon in the leading journals is a sure indication that the public interest is known to be growing, and that it is now generally acknowledged that our welfare as a nation depends upon a proper consideration of educational questions.

The first utterance we have to refer to is the admirable speech delivered by Lord Hartington on the night our last number went to press. Lord Hartington had consented to give away the prizes and make an address at the Polytechnic Young Men's Christian Institute, an organisation which now numbers nearly 7000 students, for the existence and endowment of which England is indebted to the munificence and clear-sightedness of one individual, Mr. Quintin Hogg.

It was not to be wondered at that Lord Hartington, with such an unaccustomed task before him, should have referred, in the course of his speech, to Prof. Huxley's recent address, in which the fact was emphasised that if peace has her victories, there must be some who are vanquished; that there is a death to the conquered in peace as in war, the victims of peace being starved as a result of continual depression of trade.

The interest of Lord Hartington's speech was that the question which Prof. Huxley had approached from the Darwinian point of view—the survival of the fittest, the destruction of the unfittest—was to him a question of possible contemporary politics which he had to consider, and the consideration he gave to it led him to emphasise Prof. Huxley's view of the situation. It is clear moreover that the opinion given was not one hastily formed, for the former paramount position of this country when she had a monopoly of iron, and coal, and other material resources, and when there was no science to speak of anywhere, either here or abroad, had been fully taken into consideration. We quote from the speech:—

"No doubt we should still have our material resources, our iron and steel, and the muscular energy of what would then be our superabundant population; but instead of being what we are now, we should be hewers of wood and drawers of water for the world. If ever our raw materials could be manufactured for the uses and wants of the world better in other countries than in our own, we should become the slaves and servants of the rest of the world, instead of its leaders and masters, as we have been hitherto."

Now, if a politician of Lord Hartington's eminence tells us that this may happen as a result of our being beaten in a campaign of peace, it is proper to consider whether we could be very much worse off in the event of a disastrous war. Certainly, to fend off this result by war, we, as a nation, would not hesitate to double the national debt.

Lord Hartington next went on to show that war also now depends upon science.

"There are some who go so far as to deprecate any large expenditure whatever, even when necessary for the efficiency of our services. These people point to the success which we have attained in former times when almost alone we have contended successfully against a whole continent; they point to the undiminished strength and courage of our soldiers and sailors, to the vast resources—industrial, manufacturing, and financial—of the country; and they tell us that if we only husband these resources they will pull us through in future emergencies as they have done in the past. But I would say that all these arguments are utterly vain and futile unless we can prove that the conditions under which we should have to fight are entirely similar to those under which we have fought in the past. If, on the other hand, it can be proved that wars are no longer decided by personal courage or endurance, but by the possession of scientific knowledge and all the most approved and perfected appliances, then we cannot afford to disregard the teaching and the experience of the rest of the world, and cannot afford to allow ourselves to be behindhand in the possession of the scientific knowledge and appliances that are demanded."

Lord Hartington then insists upon the importance of science both in peace and war.

"If undoubted success can only be gained by the possession of scientific knowledge and the application of the most scientific instruction to the masses of our people, then it follows that we shall fall behind in this industrial competition and warfare if we do not possess ourselves of these necessities."

He holds that the army of peace must be aided by the State as well as the other. We no longer think of keeping out an invasion by train-bands, and volunteers, and our merchant fleet. For peace purposes also, then, local effort alone will not do all that is necessary. We have found this out already, and we have the Science and Art Department as well as the Admiralty and War Office. Lord Hartington holds that the Science and Art Department must be strengthened so far as technical instruction is concerned.

We see, then, that at last we have one political leader who views science and scientific instruction in the true light, and has the courage of his opinion. Science is to be *aided* on precisely the same grounds that we *aid* the army and the navy. It is no longer a question of merely paying for Sweetness and Light, or of giving a poor dog a bone.

It was not to be expected that Prof. Huxley, who has so unceasingly done all in the power of a single individual to place the right views on this matter before the public, would rest content with the note of warning to which Lord Hartington, as we have seen, has so forcibly drawn attention.

Under the title of "The Organisation of Industrial

Education" a letter appeared in the *Times* of the 21st inst., which we print *in extenso* elsewhere. The main purpose of this second outcome is to show that at the present moment what is chiefly lacking in the army of peace is organisation and a proper headquarter staff—an Educational Commander-in-Chief. Reading between the lines of the letter, it is easy to see that one of the things "organisation" is expected to do, nay, must do, is to prevent so-called "economy" from thwarting every attempt at progress. "Economy does not lie in sparing money, but in spending it wisely," is a maxim that must be commended not only to the Treasury, but to local bodies.

It is probably the feeling that the proposals of a strong Minister of Education, with a full knowledge of his subject and in touch with all the most eminent educationalists of his time, would be sure to commend themselves to Parliament, and that the annual charge would be increased, which has induced successive Ministries to postpone the creation of such an office. It is now thirteen years since both the Duke of Devonshire's Commission and Parliament itself discussed the question; the latter on the motion of Mr. (now Sir Lyon) Playfair. Three years ago the Report of the Select Committee presided over by Mr. Childers unanimously recommended that a Minister of Education should be appointed. With the growing feeling on the part of the public on this matter, if an opportunity presents itself of again bringing forward this proposal it will not be allowed to be dropped.

It is clear from Prof. Huxley's letter that the present machinery is not adequate: it can only be strengthened and consolidated by the appointment of a Minister. One enormous advantage of such a Minister would be that we should have an acknowledged Department to apply to, absolutely in sympathy with those who wish to bring about any improvement in our educational machinery. Quite recently we have had two deputations on purely educational matters: one, for an endowment to the Victoria University, to the Chancellor of the Exchequer, and the other, for further aid to technical education, to the Lord President. It is very difficult for a plain man to understand why the Chancellor of the Exchequer should have been chosen in one case and the Lord President in the other: of course there is an official reason, but it only adds point to the grotesqueness of the present arrangements.

We have, however, to refer to these deputations from another point of view. The prayer of the Victoria University has been granted: that the needed assistance in the other matter—technical instruction—will be granted at once is by no means certain. However this may be, well-wishers of science must thank Mr. Mundella for his vigorous pleading of the cause they have at heart.

The object of the last deputation, as Mr. Mundella pointed out, was to ask the Government to take a very modest step in the direction of the organisation of industrial and commercial education. The education of the 4,600,000 on the books of the elementary schools is confined to education of a purely elementary character, and anything in the shape of manual or industrial education is treated in a way very disheartening to those interested in the question. At present our industrial classes are like badly drilled soldiers fighting a battle with antiquated weapons—it is like sending our soldiers into the field, armed with Brown Bess, to meet the best armed soldiers of Europe. Dr. Konrad, in a report on the Prussian system in its bearing on the national economy, said the superiority of the Western to the Eastern workman, and of the German to the Englishman, was well established; and he added that no doubt the Englishman by his enormous perseverance and his wonted diligence got through considerably more work in the sphere to which he had been long accustomed, but he was far behind the German in capacity for adapting himself to new circumstances. This was the result of the better and more general training which the Germans got in their schools. Mr. Mundella acknowledged that there had been repeated attempts to do something in England to improve the condition of things, but where public bodies had interfered they had acted beyond their powers and been punished accordingly. It was freedom from the restrictions under which these authorities laboured that the deputation sought. They asked also for increased powers to promote industrial, scientific, and technical training, and that for this purpose they should be put in connexion with the Science and Art Department. The cost of executing what they proposed would be trifling.

Sir Lyon Playfair contended that a short Act of three clauses would do all that is wanted. We hope soon to see it. Sir B. Samuelson, as Chairman of the Associated Chambers of Commerce, presented a memorial from that body, and Mr. Howell hit the nail on the head by stating that for "unemployed," in connexion with our industrial population, now so often used, the word "unskilled" should be substituted.

We are bound to say that Lord Cranbrook's answer was sympathetic, but he is clearly of opinion that the Government can do nothing because "Parliament has not really pronounced on the subject of technical instruction"!

ROSENBUSCHS "PETROGRAPHY"

Mikroskopische Physiographie der massigen Gesteine. Von H. Rosenbusch. I. Abtheilung. Zweite gänzlich umgearbeitete Auflage. (Stuttgart, 1886.)

THE first part of the second edition of this important work has at length appeared, the author having wisely decided not to keep back this instalment until the whole has been completed. Petrography advances nowadays with such gigantic strides, and so quickly are new facts accumulated and new theories elaborated, that as soon as the last chapters of a treatise on this science have been written it is almost time to begin re-writing the first.

This book has been looked forward to by petrographers with a certain amount of pardonable impatience, in the hope that it would do something towards clearing away the mists that envelop rock-classification and nomenclature. Since the introduction of the polarising microscope into petrographical research, old familiar names—like greenstone, trap, felstone, trachyte, &c.—have either been discarded or materially modified in their use; and we now talk with Gümbel of lamprophyre, proterobase, picrophyre, palæophyre, palæopicrite, leucophyre, and the like; or we use names manufactured from the localities where the rocks are found, such as tonalite, ortlerite, or palatinite; or, lastly, following in the wake of the organic chemists, we construct complex names by stringing together those of the component minerals, as, for example, quartz-augite-diorite or hornblende-augite-mica-andesite. The result is that either different petrographers call the same rock by different names, or use the same name to designate different rocks. At the same time, so many views have arisen as to the fundamental elements of petrographical classification, that there are almost as many systems of classification as there are petrographers.

Up to the present time Continental geologists have been in the habit of making geological age a primary factor in classification. Now, although this may apply to Germany, it certainly will not hold for other countries. In England and America it has been shown conclusively that rocks identical in structure and composition have been formed in pre-Tertiary and Tertiary times.

The new edition of Rosenbusch's work would, it was hoped, bring order into this chaos, and give us a classification and nomenclature which, without being too rigid, would allow of referring any particular rock to its family. Such a classification, agreeing with all the known facts, would doubtless readily be accepted by all geologists in this country, were it only for the sake of uniformity and unanimity.

A brief review, or epitome, of Prof. Rosenbusch's book may not be unwelcome here. Any criticism had best be reserved until the work is completed. We owe, indeed, such a debt of gratitude to the author for collecting, collating, and arranging the vast quantity of facts which have been accumulating within the last few years, that it would be almost presumptuous to attempt to find fault with a work so excellent, so invaluable in every way.

In the introduction Prof. Rosenbusch gives us his views on classification. These differ very materially from those expressed in the former edition. "A natural system of classification must," he writes, "in the first place lay stress on the geological mode of occurrence (*geologische Erscheinungsform*), as determining structure and the mineral components. In the second place comes chemical composition, and, lastly, geological age." Secondary alteration in structure or mineralogical composition can have no classificatory value.

It is the geological mode of occurrence that almost exclusively determines the structure of an eruptive rock. Eruptive masses of the same chemical and mineralogical composition possess a totally different structure, according as they were poured out at the earth's surface in the form of lava, or consolidated in the deeper regions of the earth's solid crust. This may, of course, also be expressed by saying that the structure of a rock depends, *cæteris paribus*, only on the differences of temperature and pressure to which it has been subjected during its formation.

Classified, then, according to their mode of occurrence, eruptive rocks may be divided into two great groups: (1) the *Plutonic* rocks (*Tiefengesteine*); and (2) the *Volcanic* or *effusive* rocks (*Ergussgesteine*). Occupying an intermediate position between these two chief groups is a third—that of the rocks occurring in the form of dykes (*Ganggesteine*). Both plutonic and volcanic rocks are often found as dykes; but this group comprises those rocks which are found occurring alone in this form, and which possess certain structural peculiarities entitling them to be considered apart from the plutonic and effusive rocks. With regard to the latter it may be remarked that it is in this group that Prof. Rosenbusch does not feel justified in dropping altogether geological age as a classificatory factor. Accordingly these rocks are subdivided by him into *palæovolcanic* and *neovolcanic*; the former embracing those erupted in pre-Tertiary times, the latter those of Tertiary age.

In the introductory chapter to the plutonic rocks Prof. Rosenbusch treats of the structure and order of crystallisation of the mineral components of these rocks. In this chapter he embodies the substance of his paper on the granular and porphyritic structure of massive rocks, published some time since in the *Neues Jahrbuch*. In that paper he showed how in an eruptive silicate-magma the minerals separate in the order of decreasing basicity, so that at any given moment the uncrystallised magma is more acid than the sum of the separated compounds. Further, that the relative masses of the compounds present in such a magma act only in so far on the order of their separation, that generally those present in less quantity crystallise out first. To facilitate petrographical expression, Prof. Rosenbusch has proposed a couple of words which appear to be worthy of general acceptation. He calls those mineral components which occur in individuals, bounded on all sides by crystallised faces, *idiomorphic*; *allotriomorphic*, those which owe their boundaries to causes other than an internal arrangement of the molecules composing them. Applying this to the plutonic rocks, he points out that, whereas certain rocks, occurring as dykes, possess a "panidiomorphic granular" structure, the plutonic rocks are characterised by a granular structure essentially "hypidiomorphic" (a part of the minerals only possessing their own crystallographic form).

The group of the Plutonic rocks is subdivided by Prof. Rosenbusch as follows:—

(*a*) Family of the granitic rocks.
(*b*) Family of the syenitic rocks.
(*c*) Family of the elæolite syenites.
(*d*) Family of the diorites.
(*e*) Family of the gabbros and norites.
(*f*) Family of the diabases.
(*g*) Family of the theralites.
(*h*) Family of the peridotites.

Among these we notice a new name—the *theralites*. Under this head are included the plagioclase-nepheline rocks, formerly represented by the teschenites. The latter have been shown by Rohrbach (Tschermak's *Min und Pet. Mitt.*, 1885, ii. 1-63) to contain no nepheline, and have consequently been referred by him partly to the diorites, partly to the diabases. Still, plutonic rocks representing this mineralogical combination appear to exist (*e.g.* in the Crazy Mountains in Montana, U.S.); and thus the gap left by the removal of the teschenites is filled up. Prof. Rosenbusch derives the name theralite from θηρᾶν (to seek eagerly).

The group that embraces the rocks occurring in the form of dykes, is subdivided, according to mineralogical and chemical composition, into a *granitic*, a *syenitic*, and a *dioritic* series.

Looking at the rocks, however, from the point of view of habit and structure, three types, independent of mineralogical composition, may be established, namely: a "*granitic*," only known to occur among the more acid representatives; a "*granito-porphyritic*," which is represented in each of the above series; and a "*lamprophyric*," which appears to be unrepresented in the more acid subdivisions. The following classification is accordingly proposed for the "dyke-rocks":—

(*a*) Granitic dyke-rocks (aplite, tourmaline-granite, &c.).

(*b*) Granito-porphyritic dyke-rocks (granite-porphyry, syenite-porphyry, elæolite-porphyry, diorite-porphyrite).

(*c*) Lamprophyric dyke-rocks.

This last family may perhaps be best designated as a refuge for certain classes of rocks, such as the kersantites and kersantons, the minettes, and the lamprophyres, which have been long wandering about in the various systems of classification without finding any fixed abode. It is further subdivided into the syenitic lamprophyres (minettes and vogesites) and the dioritic lamprophyres (kersantite and camptonite).

Passing on to the group of the true Volcanic rocks, we note an important distinction between them and those of the Plutonic group, contained in a general law laid down by the author in this chapter. A volcanic (effusive) rock is always more acid and specifically lighter than its plutonic equivalent. To explain this the author suggests that an eruptive magma, during its slow ascent along cracks in the earth's crust, differentiates according to specific gravity, the heavier part, which ultimately gives rise to the plutonic rocks that consolidate within the earth's crust, being more basic, poorer in alkalies, and richer in alkaline earths and iron, than the specifically lighter part which reaches the earth's surface.

The author then proceeds to discuss the recurrence of phase in the crystallisation of the effusive rocks, and defines porphyritic structure as that structure which is produced by the recurrence of the same or similar minerals at two distinct periods of crystallisation. It is this structure which is the most essential characteristic of the effusive rocks. It may, however, be developed in very different ways. When the ground-mass is holocrystalline, the structure is "holocrystalline-porphyritic"; it is "vitro-porphyritic" when the ground-mass is glassy, and "hypocrystalline-porphyritic" when the ground-mass consists partly of vitreous, partly of crystalline elements.

Of the Volcanic group only the palæovolcanic series is discussed in the present volume. It is subdivided as follows:—

(*a*) Family of the quartz porphyries (palæovolcanic equivalents of the granites).

(*b*) Family of the quartzless porphyries (equivalents of the syenites).

(*c*) Family of the porphyrites (equivalents of the diorites).

(*d*) Family of the augite-porphyrites and melaphyres equivalents of the gabbros and diabases).

(*e*) Family of the picrite-porphyrites (equivalents of the peridotites).

The neovolcanic rocks (rhyolites, trachytes, andesites, basalts, phonolites, tephrites, &c.) are reserved for the Second Part, which is promised for Easter of this year, and will contain the plates to the whole volume. Thus completed, the work will form a most valuable addition to petrographical literature. One of its important features is the full collation of literature under each head. Students of petrographical science will thank Prof. Rosenbusch for the inestimable boon he has conferred upon them in indexing almost all the papers dealing with petrographical subjects which had appeared up to the date of publication of his book.

FREDERICK H. HATCH

LOCH CRERAN

Loch Creran: Notes from the Western Highlands. By W. Anderson Smith. (Paisley and London: Alexander Gardner, 1887.)

THE amateur naturalist who has leisure, a genuine interest in his subject, and abundant opportunities of exercising his observation, ought to be an exceptionally happy person; but he is not always well-advised in rushing into print with the result of his fugitive studies. That, however, is one of the foibles of the hour. The public are supposed to welcome somewhat bald catalogues of the common objects of the way-side, the heath, and the sea-shore; the newspaper reporter is glad to be temporarily withdrawn from the Divorce Court and sent to describe the chestnut-trees in Bushey Park; and young ladies, who have got the length of distinguishing between *Ranunculus Ficaria* and *R. acris* narrate in the evening papers the story of their exploration of the hedgerows. The result is harmless enough. It is not science; it is not literature; but it serves to teach a few people here and there to keep their eyes open; and that is something. And perhaps a world groaning under a load of books need not mind an additional volume or two—which it is not compelled to read.

Mr. W. Anderson Smith does not inform us whether these "Notes from the Western Highlands" have been, like some other of his writings, reprinted from a provincial journal; but if they are so, he has done himself injustice in not stating the fact; for carelessness that is comparatively venial in the columns of a newspaper becomes vexatious in a book. And truth compels us to say that Mr. Smith's style is slovenly in the extreme. Mis-spellings abound; the few scraps of French or Latin quoted are almost invariably mangled; there is an occasional lapse of grammar; and now and again the heedless composition provokes a smile, as when he says, "Into the luxurious beds we sink up to the knees, many of them at present with dainty seed-vessels ripe and full." And yet there is a chatty simplicity here and there in the book that is not without attraction. The ways and humours of certain domestic pets are described in a kindly fashion which recommends itself; and there are incidental glimpses of winter life and winter occupations in the West Highlands that are sufficiently pleasant. As for the bulk of the volume, that is devoted to marine zoology; and marine zoology, to be made interesting, not to say intelligible, to the general reader, should be accompanied by illustrations; while, on the other hand, the trained scientific student is not likely to concern himself much with the unmethodical investigations here noted down.

But in merely making incidental memoranda of the every-day experiences of life in his northern home, Mr. Smith has mentioned not a few interesting things; and for these one soon begins to be grateful in reading a volume that is otherwise none too lively. He tells us, for example, how a heron was suspected of stealing ducklings, was watched, and finally caught in the act of devouring one of the birds—which seems a singular occurrence. On the other hand, the appearance of a bat in January, when the West Highlands happen to be visited by a spell of mild weather, is by no means the rare phenomenon he supposes it to be. There are some interesting remarks on the incubation of the cuckoo's egg (pp. 13 and 16) which seem to suggest a need for further inquiry. But we cannot say that we place implicit faith in Mr. Anderson Smith as an observer. His story of how, on one occasion, in passing through a wood, he startled a number of fallow-deer and roebuck may be forgiven on account of the darkness prevailing at the time: we should prefer to wait for some daylight notes before believing that the fallow-deer and the roe have agreed to lay aside their long-standing and mutual antipathy. "The pheasant is an unwieldy bird and of no great power of flight." Did the writer of that sentence ever try to "stop" a rocketer well on the wing and coming down wind; and what was the expression of his face when he wheeled round to find the "unwieldy" bird already disappearing into the next parish? Mr. Smith in this volume revives a controversy in which, as it appears, he has been engaged before, with regard to the lower animals committing suicide; and remarks that it may be assumed they know what death is from the fact that many of them can simulate it with marvellous accuracy. It is no doubt true that the young of certain animals, when confronted with danger, will suddenly become motionless, and remain so until the danger is removed—just as it is a common trick among street arabs for a small boy, when pursued by a bigger boy, to throw himself down in the roadway and lie perfectly still, prepared for the worst. But to assume that the young curlew or the young rat that suddenly stiffens itself and shuts its eyes is aware that it is simulating death, or has any understanding of such a state, is a far jump. Mr. Smith cites the case of a terrier belonging to a friend of his which, having the distemper, deliberately went off and drowned itself. Clearly the verdict here must be temporary insanity; the dog did not know what it was doing. The chief reason for concluding that the lower animals are not aware that they possess the liberty of suicide is that so few of them (or none of them) take advantage of it; if they did know, the overworked cart-horse, the mangy cur, the long-enduring donkey, would forthwith knock their heads against the nearest wall—unless, indeed, it is to be supposed that these animals are so highly intelligent as to have heard of the significant French proverb: "Quand on est mort, c'est pour longtemps." But this question of suicide among animals has always been a stumbling-block. Prof. Edward Forbes accused a whole tribe of star-fish of having a suicidal instinct on no better grounds than that they, on being brought into the air, or put in fresh water, went to bits. He even describes one of them as rejoicing in its power of eluding scientific scrutiny:—"I saw its limbs escaping through every mesh of the dredge. In my despair I seized the largest piece, and brought up the extremity of an arm with its terminal eye, the spinous eyelid of which opened and closed with something exceedingly like a wink of derision." After this we shall not be surprised to hear of a body of scientific experts meeting to consider the question of suicide among animals—with Mark Twain as President of the Committee.

"Loch Creran" is not a vivacious book; but it is unpretentious; and the author, in a rambling and hap-hazard fashion, contrives to give us some idea of his surroundings and pursuits. Indeed, the dweller in towns, who has the patience to follow this somewhat prolix writer, will probably part company with him with no slight feeling of envy.

OUR BOOK SHELF

The Encyclopædic Dictionary. Vol. VI. Part I. (London: Cassell and Co., 1887.)

THE work to which this volume belongs is much more than a mere dictionary in the ordinary sense. It includes the description of things as well as of words, special attention being given to objects and processes indicated by scientific and technical terms. The information offered is never, of course, exhaustive, but it is sufficient for the purposes the compilers have had in view, and generally it has the merit of being clear, concise, and, as far as it goes, accurate. As a dictionary the work deserves high praise. It contains all the English as well as all the Scotch words now in use, with their significations re-investigated, re-classified, and re-illustrated by examples. A large number of obsolete words have also been introduced. The etymology is inclosed within brackets immediately following each word; and the pronunciation is indicated by diacritical marks, a key to which is given at the foot of the several pages. The present volume includes all words from "quoi" to "shipp," and, so far as we have been able to test it, we have found it lucidly arranged and thoroughly trustworthy.

Descriptive Catalogue of the General Collection of Minerals in the Australian Museum. By A. Felix Ratte. Printed by order of the Trustees. (Sydney: Thomas Richards.)

THIS Catalogue has been carefully compiled, and no doubt it has already been of considerable service to persons making use of the Australian Museum. For the classification of silicates the compiler has taken as a guide Dana's "System of Mineralogy"; for the classification of metallic minerals, Roscoe's "Chemistry." But these authors' systems have not been entirely followed, especially where rare mineral products are concerned. The notes, although generally brief, are adequate, and there is a valuable appendix on gems and ornamental specimens.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

West Indian Meteorological Confederation

IN the leading article in NATURE, vol. xxxv. p. 241, remarks were made respecting the advantages which would accrue to the West Indian Islands, and to the Meteorological Council of the

Royal Society, if those islands were confederated for meteorological purposes."

The writer was apparently unaware that in the year 1879 those islands agreed to confederation. It was not restricted to the British colonies—Guadaloupe, for instance, passed a vote of credit through its chamber before the decision of the British Meteorological Council was received—but all the work broke down when the Meteorological Council insisted upon Antigua as the central station.

It is unnecessary to say that unmitigated failure was the result.

The advantages to the United States of any West Indian system, however poor, are palpable to the lowest stratum of scientific intelligence; yet we find that Congress disestablished the whole of their West Indian stations without the slightest reason, as far as I have been able to discover. But the words of the Chief Signal Officer have a thousand times the weight of mine, and I quote them accordingly:—

"Among the objects for which appropriations were refused were 'foreign reports.' A request was made for 4000 dollars to pay for these warnings of tropical hurricanes, which, last year, were instrumental in saving millions of dollars of property. Two storms of great fury swept up from the Gulf, one in September and one in October. Warnings of the coming of these storms were given from the West India stations, so that the indications officer on duty in each month was able to give at least two days' notice of the coming of the storm to every port in the Gulf and on the Atlantic coast. The result was an immense saving of valuable property and of human life. The statistics were gathered as fully as possible from all the stations passed over by the cyclones, and the names of the vessels, their value, and the value of their cargoes, remaining in port in obedience to the storm warnings of this service, were ascertained. The reports were not wholly satisfactory, because accurate information could not be obtained from the largest places of the country, such as New York, Philadelphia, Baltimore, and Boston. These cities lie at the head of large harbours that have safe anchorages near their openings, and vessels delayed by a storm almost invariably go down the harbour to there await its conclusion. But, without these great ports, it was ascertained that 6,460,586 dollars of property remained safe in harbour during the September cyclone, and 6,051,393 dollars in October. The failure to appropriate the 4000 dollars asked for for the current fiscal year has reduced the warnings received from the West Indies, and made it less possible to predict with certainty the approach of tropical hurricanes." (Report for 1883, p, 4.)

The anticipations of the Chief Signal Officer have been fully confirmed.

In the face of such opposition I would ask what is the use of proposing schemes of confederation requiring the support of the authorities? There is no doubt that if meteorological confederation is to obtain in the West Indies, it must be done among the British colonies themselves; but who will come forward to undertake such a task? Should anyone attempt it, he will at least have the support of Jamaica.

MAXWELL HALL,
Jamaica Government Meteorologist

February 15

Units of Weight, Mass, and Force

YOUR reviewer, of the well-known initials "P. G. T.," has taken exception to some of the terminology employed by Mr. Anderson in his book "On the Conversion of Heat into Work," particularly to the expressions of "pounds on the square inch" and "tons on the square inch," which he says would define a superficial density if used in their proper sense; and it is this opinion I wish, with your permission, to dispute, as I think "P. G. T." and mathematicians generally, are at present in this endeavour to avoid one ambiguity in dynamical language only creating greater confusion.

I presume that "P. G. T." would have been satisfied with the above expressions provided the word "weight" had been introduced somewhere; but let us examine carefully what is implied by "weight" as used in ordinary language.

Turning to the chapter on elementary dynamical principles in Maxwell's "Theory of Heat," we find that "the word *weight* must be understood to mean the *quantity of the thing as determined by the process of weighing against standard weights.*" And again:— "In a rude age, before the invention of means for overcoming friction, the weight of bodies formed the chief obstacle to setting them in motion. It was only after some progress had been made in the art of throwing missiles, and in the use of wheel-carriages and floating vessels, that men's minds became practically impressed with the idea of mass as distinguished from weight."

The language we employ, including the use of the ambiguous word "weight," was formed in this rude age before the discovery of true dynamical principles and before the theory of gravitation, and now, in order to avoid ambiguity, the mathematician uses, *wherever it is possible*, the word "mass" for greater precision, where an ordinary person would use the word weight.

But unfortunately for his principle the rules of language do not permit him to be consistent, and he is compelled to speak of "*weights* and measures" and of "bodies *weighing* so many pounds or tons" instead of "bodies *massing* so many pounds," or "*masses* and measures," which might be mistaken for a political phrase.

The word "weight" will, then, be found to be used in ordinary language in most cases in the same sense as the word "mass," introduced with laudable intention by the mathematicians to avoid confusion; but unfortunately some mathematicians introduce greater confusion than they remove by appropriating the word "weight" to the subsidiary sense of the word, undistinguishable by those ignorant of dynamics, namely, the force with which the earth attracts the weight.

Thus we find in ordinary treatises on dynamics, after an effort at the definition of the mass, the weight of a body defined as "the force with which it is attracted by the earth."

As Maxwell says, "The only occasions in common life in which it is required to estimate weight considered as a force is when we have to determine the strength required to lift or carry things, or when we have to make a structure strong enough to support their weight." Herein is comprised in general terms the whole province of the theory of engineering, and consequently the engineer always employs the gravitational measure of forces.

The force with which the earth attracts the standard weight is taken as the gravitation unit of force; and for brevity the force with which the earth attracts a pound weight (the mathematician would say a pound mass) is called the force of a pound, abbreviated again to "a pound." Hence we have steam pressures, gunpowder pressures, moduli of elasticity, tenacities, &c., as well as the expressions objected to by "P. G. T." in Mr. Anderson's book, expressed in pounds or tons on the square inch, without creating any confusion in the mind of the practical man; and we find the words "pound" or "ton" used side by side, now in the sense of weight or mass, and now in the sense of force; as, for instance, in the statement, "A train, weighing 100 tons moving against a resistance of 20 pounds a ton, is drawn by an engine exerting a pull of 2 tons, &c."

But when the practical man opens the ordinary text-book on dynamics, then the confusion begins. Take, for instance, the familiar equation $W = Mg$: what does it mean? The writers tell us that W means the weight and M the mass of the body. Having defined "weight" as the force with which the body is attracted by the earth, the writer implies that he is keeping to the statical gravitational unit of force, and therefore his unit of mass is the mass of g pounds, if W, the weight, is measured in pounds. But, after defining a pound as a unit of mass, he ought to take M as the weight in pounds, and then the equation $W = Mg$ means that the earth attracts M pounds with a force of W poundals where $W = Mg$.

The confusion is intolerable ("most tolerable, and not to be endured"), and entirely due to the erroneous mathematical definition of the word "weight," combined with straining the units of mass and force so as to fit into the equation $P = Mf$, when absolute units are not employed.

To show the absurdity of the definition that "the weight of a body is the force with which it is attracted by the earth," take the question, "What is the weight of the earth?" According to this definition, the answer is "Zero," but ordinary people would calculate the result in millions of tons, from the data of the mean radius and the mean density.

Take again a question of a similar nature: "Prove that 288 pounds at the pole weigh the same as 289 pounds at the equator." To realise this question we must imagine a balance constructed of which the arm is curved into a quadrant of the earth, reaching along a meridian from the pole to the equator, and supported by a fulcrum in latitude 45°; then 288 pounds at the pole will equilibrate 289 pounds at the other end of the balance at the equator. Without requiring a balance with so long an arm, we can have 289 pounds at the bottom of the shaft of a mine weighing the same as 288 pounds at the surface, provided the shaft is of sufficient depth.

Some years ago, being troubled myself with this confusion of language, I wrote to Prof. Maxwell to ask him for a good illustrative example of the correct and incorrect use of the word "weight," and received the following characteristic reply on a postcard:—"Compare St. John xix. 39, ὡσεὶ λίτρας ἑκατόν, with the A.V. (authorised version), and keep to the original Greek." The translation in the authorised version is "about a hundred pounds *weight*."

Here we see that Maxwell recognised the ambiguous nature of the word "weight," and advised its omission wherever possible; but the exigencies of language compel us to use it; and in fact we shall generally find writers, even after the above incorrect definition of weight, proceed subsequently to use the word in its ordinary meaning of daily life.

I wish to repeat that writers on dynamics only create confusion in appropriating the word "weight" to the sense of the force of attraction of the earth on a body, as we never speak of "a force *weighing* so many pounds"; and I wish to support the language in ordinary use by engineers and practical men as perfectly correct in using the words "pound" or "ton" side by side in two senses, first as meaning the weight (or mass) of a body, and secondly as meaning the force with which the body is attracted by the earth; one being sometimes distinguished as a pound weight, and the other as a pound force.

If we use Prof. James Thomson's admirable word "poundal" for the British absolute unit of force, this slight confusion of terms will disappear, although engineers will still continue to think in gravitation units of force, as gravity is the one universal force from which there is no escape; and I fear it will be impossible ever to persuade them to think in C.G.S. units like the centimetre, gramme, dyne, erg, &c., which, though admirably adapted for the minute measurements of experiments in physics, are unsuitable for large magnitudes.

In conclusion, let the equation $W = Mg$ be dismissed from the text-books, as leading to statements such as "The mass of a body weighing W pounds is $\frac{W}{g}$;" the true equivalent equation being $W = M$, and therefore unnecessary; and with it let the confusing "astronomical unit of mass" disappear, and introduce instead the "constant of gravitation" in our equations. Let us also recognise that the primary idea of "weight" is the same as "mass," and form our dynamical definitions on the usages of ordinary language.

Woolwich, February 28

Mr. Herbert Spencer's Definition of Life

I have read with much interest the report in Nature of Prof. Judd's address to the Geological Society, in which he attempts to show that Mr. Herbert Spencer's definition of life is not restricted to those cases only which display the ordinarily acknowledged characteristics of vitality; a certain correspondence between internal and external changes being displayed by minerals.

I write to draw attention to what I think tends to show that the mass of evidence brought forward really tells *in favour* of the definition; bearing in mind that the hypothesis of evolution "implies insensible modifications and gradual transitions, which render definition difficult—which make it impossible to separate absolutely the phases of organisation from one another" ("Principles of Biology," vol. ii. p. 10), and that consequently there can be no "absolute" commencement of life.

The fact, treated by Mr. Spencer when seeking a definition of life, that there is a correspondence between life and its circumstances gives the clue showing us that the "vitality of minerals" is a misnomer; a fallacy he himself exposes when he treats of the internal actions—the feathery crystallisation—displayed by the misnamed storm glass in correspondence with external changes. Using his own words, we see that:—

"Subtle as is the dependence of each internal upon each external change, the connection between them does not, in the abstract, differ from the connection between the motion of a straw and the motion of the wind that disturbs it. In either case a change produces a change, and there it ends. The alteration wrought by some environing agency on an inanimate object, does not tend to induce in it a secondary alteration, that anticipates some secondary alteration in the environment. But in every living body [in a living body, mark!] there is a tendency towards secondary alterations of this nature; *and it is in their production that the correspondence consists.* The difference may be best expressed by symbols. Let A be a change in the environment; and B some resulting change in an inorganic mass. Then A having produced B, the action ceases. Though the change A in the environment, is followed by some consequent change a in it; no parallel sequence in the inorganic mass simultaneously generates in it some change b that has reference to the change a. But if we take a living body of the requisite organisation, and let the change A impress on it some change C; then, while in the environment A is occasionally a, in the living body C will be occasioning c: of which a and c will show a certain concord in time, place, or intensity. . . ." (vol. i. p. 78).

"That the word *correspondence* will not include, without straining, the various relations to be expressed by it," is best met by the reply "that we have no word sufficiently general to comprehend all forms of this relation between the organism and its medium, and yet sufficiently specific to convey an adequate idea of the relation; . . . The fact to be expressed in all cases, is, that certain changes, continuous or discontinuous, in the organism, are connected after such a manner that, in their amounts, or variations, or periods of occurrence, or modes of succession, they have a reference to external actions, constant or serial, actual or potential—a reference such that a definite relation among any members of the one group, implies a definite relation among certain members of the other group; and the word *correspondence* appears the best fitted to express this fact." (vol. i. p. 79).

In deer-stalking we see a realisation of these symbols. In the deer the primary internal change—the perception of odour, or, as I believe it is called, "winding"—is followed by that secondary internal change which induces a desire to increase the distance between the living organism and the inferred source of danger, a change differing not only in degree, but in kind, differing *toto cœlo* from any of those actions which take place in minerals and crystals.

That the address contains many valuable facts furthering not only Mr. Spencer's view of life, but also his views of evolution, becomes apparent when we consider how it carries out and develops these ideas to an extent which would have been impossible at the time when the "Principles of Biology" were first published, now twenty years since. I say "furthering," for I wish now to touch upon a very important point, which I cannot but think has been much enlarged and amplified by Prof. Judd. It is to the much more expanded meaning which can now be attached to the fact *that the degree of life varies as the degree of correspondence between internal and external relations.*

For the correspondence displayed by a crystal or mineral is shown to be of a very much lower degree than that displayed by the simplest plant or animal. These latter present correspondences of greater complexity, greater rapidity, and greater length in the series of them than the former, which, during its long "millions of years," can respond only to the two or three forms of molar and molecular forces alluded to. The changes in the mineral simply respond to changes in the environment; whereas in an organism it is a *relation* between changes in it which responds to a *relation* between changes in the environment.

Churchfield, Edgbaston F. Howard Collins

An Equatorial Zone of almost Perpetual Electrical Discharge

The recent reference in your columns to Edlung's theory of the aurora borealis, recalls a very curious observation that I have made in my travels of a zone of almost perpetual electrical discharge in the belt of the "doldrums" all round the world.

Anywhere in that belt, a more or less intermittent display of sheet lightning commences the moment the twilight of sunset has sufficiently faded away, and continues with varying intensity till the light of morning prevents further observation.

The localisation of this belt of lightning is very obvious as we run a section across the equator on board ship. There is very little electrical discharge in the high-pressure belt of anti-cyclones which encircle the earth approximately under the lines of the tropics; but as we approach the low-pressure band of the "doldrums," where the two trade-winds, or the two monsoons meet, then the display of lightning is of nightly occurrence, even if there are no actual thunderstorms.

This electric discharge has a diurnal period like every other meteorological element; for night after night, as I have slept on deck in Malaysia during the change of the monsoons, I have noticed a very marked diminution of the lightning after 1 or 2 a.m. If a total eclipse of the sun could last for twelve hours, I have no doubt that we should see more or less lightning all the time, with a regular set of diurnal variations.

Edlung and others have noticed the gradual decrease in the frequency of thunderstorms as we recede from the equator; but I wish to show now, not only that the discharge is of nightly occurrence, but that the locality of maximum effect is not so much on the equator as in the "doldrums." The sheet lightning may be the reflection of distant thunderstorms, or it may be the silent discharge of electricity. Meteorologists are much divided as to the possibility of the latter; but it is certain that the amount of sheet lightning is out of all proportion to the frequency of actual thunderstorms.

Is it not possible that we may find in this perpetual lightning, some clue to the origin of earth-currents everywhere? and in the diurnal variation in the discharge, some probable reason for the hourly variation of the aurora, and of some magnetic elements? No doubt it is at present difficult to connect the electricity of lightning with the electro-magnetic effects of terrestrial magnetism or the aurora; and though Edlung's theory is defective in this respect, I cannot help thinking that he is right in collating thunderstorms on the equator with the glow discharge of electricity on the Arctic circle; and it is in the hope that the discovery of the constancy of electrical discharge in the "doldrums" may perhaps assist in the evolution of a true theory of the aurora, that I have penned this short notice.

RALPH ABERCROMBY

21 Chapel Street, London, March 15

Scorpion Virus

PROF. BOURNE'S experiments, related in the Proceedings of the Royal Society of January 6, 1887, seem to establish the fact that although the scorpion may be provoked to strike and wound itself or another scorpion, it is incapable, in either case, of causing any toxic action, however active the virus may prove in respect of other creatures. That it is, in short, with the scorpion as it is with the cobra or viper: they poison other creatures, but not themselves or each other.

Some years ago an exhaustive series of experiments brought me to the conclusion that a cobra is not poisoned by cobra virus, whether inoculated by its own fangs, by those of another cobra, or by a hypodermic syringe. The same in the case of daboia and other viperine snakes.

It seemed, however, that the bungarus, a less deadly snake than the cobra, occasionally is affected, though slowly, by the cobra virus, but that it escapes more frequently than it suffers; and when it does suffer the effect of the poison is greatly diminished. On the other hand, non-venomous snakes, lizards, frogs, fish, mollusca, and other low forms of life, all rapidly succumb to snake poison.

The details of these experiments are to be found in the "Thanatophidia of India," published in 1872, and in referring to them Prof. Bourne remarks: "They show conclusively that the cobra poison will not affect a cobra, and will not even affect the viperine ptyas." I would correct the latter part of the quotation so far as to say that the ptyas is a colubrine harmless snake, not a viperine snake, and that it rapidly succumbs to the cobra virus.

Prof. Bourne has helped to dispel another of the popular delusions which cling round venomous creatures.

March 14 J. FAYRER

THE RELATION OF TABASHEER TO MINERAL SUBSTANCES

MR. THISELTON DYER has rendered a great service, not only to botanists, but also to physicists and mineralogists, by recalling attention to the very interesting substance known as "tabasheer" (NATURE, vol. xxxv. p. 396). As he truly states, very little fresh information has been published on the subject during recent years, a circumstance for which I can only account by the fact that botanists may justly feel some doubt as to whether it belongs to the vegetable kingdom, while mineralogists seem to have equal ground for hesitation in accepting it as a member of the mineral kingdom.

It is very interesting to hear that so able a physiologist as Prof. Cohn intends to investigate the conditions under which living plants separate this substance from their tissues. That unicellular Algæ, like the Diatomaceæ, living in a medium which may contain only one part in 10,000 by weight of dissolved silica, or even less than that amount, should be able to separate this substance to form their exquisitely ornamented frustules is one of the most striking facts in natural history, whether we regard it in its physiological or its chemical aspects.

Sir David Brewster long ago pointed out the remarkable physical characters presented by the curious product of the vegetable world known as "tabasheer," though so far as I can find out it has not in recent years received that attention from physicists which the experiments and observations of the great Scotch philosopher show it to be worthy of.

Tabasheer seems to stand in the same relation to the mineral kingdom as do ambers and pearls. It is in fact an *opal* formed under somewhat remarkable and anomalous conditions which we are able to study; and in this aspect I have for some time past been devoting a considerable amount of attention to the minute structure of the substance by making thin sections and examining them under the microscope. It may be as well, perhaps, to give a short sketch of the information upon the subject which I have up to the present time been able to obtain, and in this way to call attention to points upon which further research seems to be necessary.

From time immemorial tabasheer has enjoyed a very high reputation in Eastern countries as a drug. Its supposed medicinal virtues, like those of the fossil teeth of China and the belemnites ("thunderbolts") of this country, seem to have been suggested by the peculiarity of its mode of occurrence. A knowledge of the substance was introduced into Western Europe by the Arabian physicians, and the name by which the substance is generally known is said to be of Arabic origin. Much of the material which under the name of "tabasheer" finds its way to Syria and Turkey is said, however, to be fictitious or adulterated.

In 1788 Dr. Patrick Russell, F.R.S., then resident at Vizagapatam, wrote a letter to Sir Joseph Banks in which he gave an account of all the facts which he had been able to collect with respect to this curious substance and its mode of occurrence, and his interesting letter was published in the Philosophical Transactions for 1790 (vol. lxxx. p. 273).

Tabasheer is said to be sometimes found among the ashes of bamboos that have been set on fire (by mutual friction?). Ordinarily, however, it is sought for by splitting open those bamboo stems which give a rattling sound when shaken. Such rattling sounds do not, however, afford infallible criteria as to the presence or absence of tabasheer in a bamboo, for where the quantity is small it is often found to be closely adherent to the bottom and sides of the cavity. Tabasheer is by no means found in all stems or in all joints of the same stem of the bamboos. Whether certain species produce it in greater abundance than others, and what is the influence of soil, situation, and season upon the production of the substance are questions which do not seem as yet to have been accurately investigated.

Dr. Russell found that the bamboos which produce tabasheer often contain a fluid, usually clear, transparent, and colourless or of greenish tint, but sometimes thicker and of a white colour, and at other times darker and of the consistency of honey. Occasionally the thicker varieties were found passing into a solid state, and forming tabasheer.

Dr. Russell performed the interesting experiment of drawing off the liquid from the bamboo-stem and allowing it to stand in stoppered bottles. A "whitish, cottony sediment" was formed at the bottom with a thin film of the same kind at the top. When the whole was well shaken together and allowed to evaporate, it left a residue of a whitish-brown colour resembling the inferior kinds of tabasheer. By splitting up different joints of bamboo Dr. Russell was also able to satisfy himself of the gradual deposition within them of the solid tabasheer by the evaporation of the liquid solvent.

In 1791, Mr. James Louis Macie, F.R.S. (who afterwards took the name of Smithson), gave an account of his examination of the properties of the specimens of tabasheer sent home by Dr. Russell (Phil. Trans. vol. lxxxi., 1791, p. 368). These specimens came from Vellore, Hydrabad, Masulipatam, and other localities in India. They were submitted to a number of tests which induced Mr. Macie to believe that they consisted principally of silica, but that before calcination some vegetable matter must have been present. A determination of the specific gravity of the substance by Mr. Macie gave 2·188 as the result; another determination by Mr. Cavendish gave 2·169.

In this same paper it is stated that a bamboo grown in a hot-house at Islington gave a rattling noise, and on being split open by Sir Joseph Banks yielded, not an ordinary tabasheer, but a small pebble about the size of half a pea, externally of a dark brown or black colour, and within of a reddish-brown tint. This stone is said to have been so hard as to cut glass, and to have been in parts of a crystalline structure. Its behaviour with reagents was found to be different in many respects from that of the ordinary tabasheer; and it was proved to contain silica and iron. The specimen is referred to in a letter to Berthollet published in the *Annales de Chimie* for the same year (October 1791). There may be some doubt as to whether this specimen was really of the nature of tabasheer; if such were the case, it would seem to have been a tabasheer in which a crystalline structure had begun to be set up.

In the year 1806, MM. Fourcroy and Vauquelin gave an account of a specimen of tabasheer brought from South America in 1804 by Humboldt and Bonpland (*Mém. de l'Inst.*, vol. vi. p. 382). It was procured from a species of bamboo growing on the west of Pichincha, and is described as being of a milk-white colour, in part apparently crystalline in structure, and in part semi-transparent and gelatinous. It was seen to contain traces of the vegetable structure of the plant from which it had been extracted. On ignition it became black, and emitted pungent fumes.

An analysis of this tabasheer from the Andes showed that it contained 70 per cent. of silica, and 30 per cent. of potash, lime, and water, with some organic matter. It would, perhaps, be rash to conclude from this single observation that the American bamboo produced tabasheer of different composition from that of the Old World; but the subject is evidently one worthy of careful investigation.

It was in the year 1819 that Sir David Brewster published the first account of his long and important series of observations upon the physical peculiarities of tabasheer (Phil. Trans., vol. cix., 1819, p. 283). The specimens which he first examined were obtained from India by Dr. Kennedy, by whom they were given to Brewster.

Brewster found the specimens which he examined to be perfectly *isotropic*, exercising no influence in depolarising light. When heated, however, it proved to be remarkably *phosphorescent*. The translucent varieties were found to transmit a yellowish and to reflect a bluish-white light—or, in other words, to exhibit the phenomenon of *opalescence*. When tabasheer is slightly wetted, it becomes white and opaque; but when thoroughly saturated with water, perfectly transparent.

By preparing prisms of different varieties of tabasheer, Brewster proceeded to determine its refractive index, arriving at the remarkable result that tabasheer "has a lower index of refraction than any other known solid or liquid, and that it actually holds an intermediate place between water and gaseous bodies!" This excessively low refractive power Brewster believes to afford a complete explanation of the extraordinary behaviour exhibited by tabasheer when wholly or partially saturated with fluids. A number of interesting experiments were performed by saturating the tabasheer with oils of different refractive powers, and by heating it in various ways and under different conditions, and also by introducing carbonaceous matter into the minute pores of the substance by setting fire to paper in which fragments were wrapped.

The mean of experiments undertaken by Mr. James Jardine, on behalf of Brewster, for determining the specific gravity of tabasheer, gave as a result 2·235. From these experiments Brewster concluded that the space occupied by the pores of the tabasheer is about two and a half times as great as that of the colloid silica itself!

From this time forward Brewster seems to have manifested the keenest interest in all questions connected with the origin and history of a substance possessing such singular physical properties. By the aid of Mr. Swinton, Secretary to the Government at Calcutta, he formed a large and interesting collection of all the different varieties of tabasheer from various parts of India. He also obtained specimens of the bamboo with the tabasheer *in situ*. In 1828 he published an interesting paper on "the Natural History and Properties of Tabasheer" (*Edinburgh Journal of Science*, vol. viii., 1828, p. 288), in which he discussed many of the important problems connected with the origin of the substance. From his inquiries and observations, Brewster was led to conclude that tabasheer was only produced in those joints of bamboos which are in an injured, unhealthy, or malformed condition, and that the siliceous fluid only finds its way into the hollow spaces between the joints of the stem when the membrane lining the cavities is destroyed or rent by disease.

Prof. Edward Turner, of the University of London, undertook an analysis of tabasheer, the specimens being supplied from Brewster's collection (*Edinburgh Journal of Science*, vol. viii., 1828, p. 335). His determinations of the specific gravities of different varieties were as follows:—

Chalky tabasheer	2·189
Translucent tabasheer	2·167
Transparent tabasheer	2·160

All the varieties lose air and hygroscopic water at 100° C., and a larger quantity of water and organic matter (indicated by faint smoke and an empyreumatic odour) at a red heat. The results obtained were as follows:—

	Loss at 100° C.	Loss at red heat
Chalky tabasheer	0·838 per cent.	1·277 per cent.
Translucent tabasheer	1·620 ,, ,,	3·840 ,, ,,
Transparent tabasheer	2·411 ,, ,,	4·518 ,, ,,

Dr. Turner found the ignited Indian tabasheer to consist almost entirely of pure silica with a minute quantity of lime and vegetable matter. He failed to find any trace of alkalies in it.

In 1855, Guibourt (*Journ. de Pharm.* [3], xxvii. 81, 161, 252; *Phil. Mag.* [4], x. 229) analysed a specimen of tabasheer having a specific gravity of 2·148. It gave the following result:—

Silica	=	96·94
Potash and lime	=	0·13
Water	=	2·93
Organic matter	=	trace

Guibourt criticised some of the conclusions arrived at by Brewster, and sought to explain the source of the silica by studying the composition of different parts of the bamboo. While the ashes of the wood contained 0·0612 of the whole weight of the wood, the pith was found to contain 0·448 per cent., the inner wood much less, and the greatest proportion occurred in the external wood. On these determinations Guibourt founded a theory of the mode of formation of tabasheer based on the suggestion that at certain periods of its growth the bamboo needed less silica than at other times, and that when not needed, the silica was carried inwards and deposited in the interior.

In the year 1857, D. W. Rost van Tonningen, of Buitenzorg, undertook an investigation of the tabasheer of Java, which is known to the natives of that island under the name of "singkara" (*Naturkundig Tijdschrift voor Nederlandsch Indie*, vol. xiii., 1857, p. 391). The specimens examined were obtained from the *Bambusa apus* growing in the Residency of Bantam; it is described as resembling in appearance the Indian tabasheers. Its analysis gave the following result:—

Silica	=	86·387
Iron oxide	=	0·424
Lime	=	0·244
Potash	=	4·806
Organic matter	=	0·507
Water	=	7·632
Total ...		100·000

Apart from the question of its singular mode of origin, however, and its remarkable and anomalous physical properties, tabasheer is of much interest to mineralogists and geologists. All the varieties hitherto examined, with the exception of the peculiar one from the Andes, are in composition and physical characters true opals; this is the case with all the Indian and Java varieties. They consist essentially of silica in its colloidal form, the water, lime, potash, and organic matter being as small and variable in amount as in the mineral opals; and, as in them, these substances must be regarded merely as mechanical impurities.

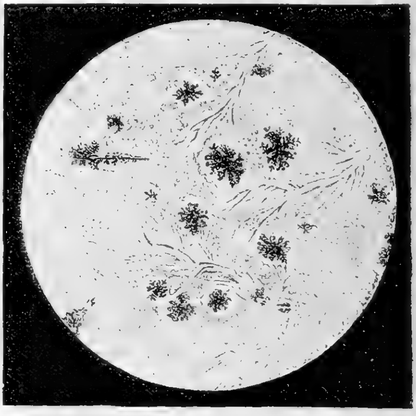
The tabasheers must be studied in their relations on the one hand with certain varieties of the natural semi-opals, hydrophanes, beekites, and floatstones, some of which they closely resemble in their physical characters, and on the other hand with specimens of artificially deposited colloid silica formed under different conditions. Prof. Church, who has so successfully studied the beekites, informs me that some of those remarkable bodies present singular points of analogy with tabasheer.

By the study of thin sections I have, during several years, been endeavouring to trace the minute structure of some of these substances. In no class of materials is it more necessary to guard one's self against errors of observation arising from changes induced in the substance during the operations which are necessary to the preparation of transparent sections of hard substances. Unfortunately, too, it is the custom of the natives to prepare the substance for the market by an imperfect calcination, and hitherto I have only been able to study specimens procured in the markets which have been subjected to this process. It is obviously desirable, before attempting to interpret the structures exhibited under the microscope, to compare the fresh and uncalcined materials with those that have been more or less altered by heat.

Tabasheer would seem, from Brewster's experiments, to be a very intimate admixture of two and a half parts of air with one part of colloidal silica. The interspaces filled with air appear, at all events in most cases, to be so minute that they cannot be detected by the highest powers of the microscope which I have been able to employ. It is this intimate admixture of a solid with a gas which probably gives rise to the curious and anomalous properties exhibited by this singular substance.

The ultra-microscopical vesicles filled with air in all probability give rise to the opalescence which is so marked a property of the substance. Their size is such as to scatter and throw back the rays at the blue end of the spectrum and to transmit those at the red end.

When the vesicles of the substance are filled with Canada balsam, and a thin slice is cut from it, this opalescence comes out in the most striking manner; very thin sections are of a rich orange-yellow by transmitted light, and a delicate blue tint by reflected light.



Section of Indian tabasheer, seen with a magnifying power of 250 diameters.

I do not know of any substance which in such thin films displays such striking opalescence.

That the excessively low refractive power of tabasheer is connected with the mechanical admixture of the colloidal silica with air seems to be proved by the experiments of Brewster, showing that with increase of density there was an increase in the refractive index, from 1·111 in specimens of the lowest specific gravity, to 1·182 in those of the highest specific gravity. Where the surface was hard and dense, Brewster found the refractive index to approach that of semi-opal. The wonderful thing is that a substance so full of cavities containing gas should nevertheless be transparent.

By the kindness of Mr. F. Rutley, F.G.S., I am able to supply a drawing taken from one of my sections of tabasheer.

The accompanying woodcut gives some idea of the interesting structures exhibited in some sections of tabasheer, though much of the delicacy and fidelity of the original drawing has been lost in transferring it to the wood.

In this particular case, the faint punctation of the surface may possibly indicate the presence of air-vesicles of a size sufficiently great to be visible under the microscope. But in many other instances I have failed to detect any such indication, even with much higher powers. The small ramifying tubules might at first sight be taken for some traces of a vegetable tissue, but my colleague Dr. Scott assures me that they do not in the least resemble any tissue found in the bamboo. I have myself no doubt that it is an inorganic structure. It is not improbably analogous to the peculiar ramifying tubules formed in a solution of water-glass when a crystal of copper sulphate is suspended in it, as shown by Dr. Heaton (Proc. Brit. Assoc., 1869, p. 127). Similar forms also occur on a larger scale in some agates, and the artificial cells of Traube may probably be regarded as analogous phenomena.

The aggregates of globular bodies seen in the section so greatly resemble the globulites of slags and natural glasses, and in their arrangement so forcibly recall the structures seen in the well-known pitchstone of Corriegills in Arran, that one is tempted to regard them as indicating the beginnings of the development of crystalline structure in the tabasheer. But I have good grounds for believing the structure to have a totally different origin. They seem in fact to be the portions of the mass which the fluid Canada balsam has not succeeded in penetrating. By heating they may be made to grow outwards, and as more balsam is imbibed they gradually diminish, and finally disappear.

I must postpone till a future occasion a discussion of all the structures of this remarkable substance and of the resemblances and differences which they present to the mineral opals on the one hand, and to those of the opals of animal origin found in sponge spicules, radiolarians, and the rocks formed from them, some of which have recently been admirably investigated by Dr. G. J. Hinde (Phil. Trans., 1885, pp. 425–33).

I cannot, however, but think that it would be of the greatest service to botanists, physicists, and mineralogists alike, if some resident in India would resume the investigations so admirably commenced by Dr. Patrick Russell nearly a century ago; and it is in the hope of inducing someone to undertake this task that I have put together these notes. There are certain problems with regard to the mode of occurrence of this singular substance which could only be solved by an investigator in the country where it is found.

Most parcels of the commercial tabasheer appear to contain different varieties, from the white, opaque, chalk-like forms, through the translucent kinds to those that are perfectly transparent. It would be of much interest if the exact relation and modes of origin of these different varieties could be traced. It would also be important to determine if Brewster was right in his conclusion that the particular internodes of a bamboo which contain tabasheer always have their inner lining tissue rent or injured. The repetition of Dr. Russell's experiment of drawing off the liquids from the joints of bamboos and allowing them to evaporate is also greatly to be desired. My colleague Prof. Rücker, F.R.S., has kindly undertaken to re-examine the results arrived at by Brewster in the light of more recent physical investigations, and I doubt not that some of the curious problems suggested by this very remarkable substance may ere long find a solution.

JOHN W. JUDD

EXHIBITION OF MARINE METEOROLOGICAL INSTRUMENTS

THE eighth Annual Exhibition of the Royal Meteorological Society was held in the Library of the Institution of Civil Engineers, 25 Great George Street, Westminster, from Tuesday, March 15th, to Friday, the 18th. The exhibition was specially devoted to marine meteorological instruments and apparatus, and such new instruments as have been invented and first constructed during the past twelve months.

A very interesting and valuable collection of instruments from the *Challenger* Commission, the Scottish Marine Station at Granton, the Scottish Meteorological Society, and Mr. J. Y. Buchanan, were brought from Edinburgh under the charge of Dr. H. R. Mill, who showed several in action. This set included various forms of deep-sea thermometers, from the early pattern of the Miller-Casella to the Scottish frame for Negretti and Zambra's reversing thermometer, which has been adapted from Magnaghi's by Dr. Mill. Two specimens of the Miller-Casella thermometer, after four months' immersion in brackish water, were shown, with the following results: in No. 1, which was placed at the surface, the copper case was clean, but the scale figures were entirely obliterated from the porcelain; in No. 2, which was suspended in 9 fathoms, and at 1 foot above the bottom, the copper was entirely covered with a green crust, but the scale figures were not rendered illegible. Various forms of piezometers for ascertaining the depth when the temperature is known, or the temperature when the depth is known, were also exhibited. These were nearly all constructed by Mr. Buchanan on board the *Challenger*. Water-bottles for obtaining samples of water at the bottom, or any required depth below the surface, were suspended from the gallery to show their action when in use. The most interesting were Buchanan's sounding-rod and water-bottle for great depths, and Mill's self-locking slip water-bottle for moderate depths.

The Meteorological Council contributed sets of instruments as supplied to merchant ships and the Royal navy; the Royal Meteorological Institute of the Netherlands exhibited a set as supplied to the Dutch navy; and the Deutsche Seewarte sent a set as issued to the German navy.

The Rev. C. J. Steward exhibited a set of instruments as used at the Lochbuie Marine Institute, Isle of Mull, which, among others, included a dimenuion thermometer in a box for river temperatures, the box being suitable for the bottoms of pools, or rough stony bottoms; and a large disk for ascertaining the transparency of the sea.

In connexion with the deep-sea thermometers Mr. Casella showed some apparatus originally employed in testing these instruments for the Admiralty and the Royal Society, and damaged during the experiments; viz., a bottle broken at a pressure corresponding to 2½ miles of sea-water, a steel bar bent at 3 miles, and an iron plug broken at 4 miles. Specimens of almost every pattern of deep-sea thermometer were exhibited, including Johnson's registering metallic, the records of which are obtained by the varying expansion of brass and steel bars acting upon indices; Miller-Casella maximum and minimum; and Negretti and Zambra's turnover thermometer.

The barometers exhibited included patterns used in the British, Dutch, French, and German navies. The English marine barometer has an iron cistern and contracted scale, and the gun barometer is mounted with india-rubber packing to prevent breakage caused by gun-firing. MM. Richard Frères, of Paris, sent one of their self-recording aneroids, for use on board ship; and Mr. Abercromby showed several curves taken at sea by one of these instruments in various parts of the world.

The anemometers shown were: Sir Snow Harris's, which is an improved form of Lind's; Hagemann's, Robinson's, Black's pressure, and Whipple's maximum pressure, the latter being quite a new instrument. Dr. Black exhibited his marine rain-gauge and evaporator. Among the miscellaneous instruments were various forms of patent logs, current meters, clinometers, and a model of a section of a vessel fitted with lightning conductor.

In addition to the instruments, a number of charts diagrams, &c., were exhibited, showing the meteorological conditions prevailing over the various oceans of the globe. The advance made in synoptic meteorology over the North Atlantic was clearly shown by comparing Leverrier's charts (1864) with the daily synchronous weather charts just published by the Meteorological Council. The specimens exhibited of the latter were (1) August 1-6, showing the meteorological conditions in the summer; (2) February 9-14, showing the conditions in the winter; and (3) February 24 to March 4, showing the conditions in early spring, and the persistence of the European anticyclone, producing cold dry winds over England. The Meteorological Council also exhibited a set of large charts showing the mean temperature of the sea surface round the coasts of the British Isles for each month. Dr. Mill had several interesting diagrams showing the distribution of temperature in a section of the Clyde sea area at seven periods from April 1886 to February 1887. Mr. Abercromby exhibited forty-six photographs and diagrams of clouds taken in various parts of the world; and Mr. Dyason showed a number of coloured drawings of clouds, &c. The Astronomer Royal sent the photographic registers of magnetic declination and horizontal force at the Royal Observatory, Greenwich, showing the earthquake shock which occurred on the morning of February 23.

The most interesting of the new instruments was the Watkin aneroid with open scale, by Mr. Hicks. Instead of the usual one-circle of figures, the scale of this instrument consists of a spiral of three complete turns. On the aneroid being put under an air-pump or taken up a mountain, the point of the index is gradually drawn *towards* the centre, so that it follows the *decreasing* spiral scale; but when the index moves in the opposite direction, the point moves *away* from the centre, thus following the *increasing* spiral. This is effected by the index-hand being made to slide in and out, so that one end may advance or recede from the centre, and thus follow the spiral scale. Attached to the spindle is a cross-piece, in which the index slides, and a hollow drum fixed to the dial-plate has a flexible chain or cord wound round it, the ends being fastened on the projecting pins riveted to the index. Consequently, if the spindle and the piece attached to it are revolved, one portion of the chain or cord winds off the drum, the other is wound on to the same extent, and the index is caused to slide through the cross-piece, the direction of motion being controlled by the direction in which the spindle is revolved.

MM. Richard Frères sent specimens of their self-recording thermometer, hygrometer, dry and wet bulb thermometers, and rain-gauge.

GEOGRAPHY AT THE UNIVERSITIES

At last, after years of apparently fruitless labour, the Royal Geographical Society have been eminently successful in persuading almost simultaneously the two great English Universities to recognise geography as a University study, and to make definite provision for teaching it. In pursuance of a proposal made by the President and Council of the Royal Geographical Society to the Vice-Chancellors of the two Universities, and of the replies thereto, a deputation of a few members of their Council visited Oxford and Cambridge in turns, to meet delegates appointed by those Universities, in order to explain their proposal more fully, and to discuss any modifications that might be suggested. The main features of the proposal were, that the Royal Geographical Society offered to give 150*l.* annually to each University if they would establish a Lectureship or Readership in Geography, giving the Lecturer an adequate University status, and contributing, on their part, an equal sum, so as to raise the stipend of each Lectureship to 300*l.* They also offered to give the two Universities a Scholarship or Exhibition of 100*l.* in alternate years for geographical students. The Royal Geographical Society was to be represented on the Board that selected the Examiners, and on that which adjudged the Scholarship.

The meeting at Oxford with delegates from that University, including the present and past Vice-Chancellors, took place five weeks ago, at which the proposal was well discussed and favourably entertained, subject to the foreseen difficulty of finding adequate funds from the University resources; nevertheless everything seemed in train for its being eventually carried out, though after a little delay, in the intended manner. An unexpected incident, however, gave a new and collateral impulse, and has hurried the Lectureship into existence at once. It happened that the Readership in Ancient History became vacant, and it seems to have occurred to those with whom the election of a successor rested, that as there was a great difficulty in finding funds for geography, and as a Professorship of Ancient History was already in existence, and, again, as ancient history was taught by most classical tutors, the Readership in Ancient History might be abolished without much loss, and one in geography might be with propriety established in its place. There was a nearly even division of opinion on the matter, but the vote for geography prevailed and carried the day, and the advertisement inviting candidates has already been published. So Oxford now takes an independent line, and accepts only the offer of the Scholarship.

The Cambridge meeting took place about three weeks ago. The proposal was carefully discussed, and modifications were asked for. At Cambridge, as at Oxford, the University funds are seriously embarrassed by engagements already entered into, chiefly connected with building operations; and there seemed no way, so narrow was the available surplus, of raising the whole of the annual amount of 150*l.* in a direct form, but only 50*l.* of it However, it appeared that indirect means existed by which this nominal sum would indirectly and eventually be raised to even something more than the proposed amount, and an amendment specifying only 50*l.* was therefore provisionally accepted. After this had received the approval of the Council of the Royal Geographical Society, it was submitted to the Council of the University of Cambridge, and adopted by them in the terms of the following recommendation:—

"That the approval of the Senate be given to the delivery in the University in the ensuing academical year of one or more courses of lectures on geography by lecturers selected by the Royal Geographical Society, that a teacher of geography be appointed by a Committee on which the Royal Geographical Society is represented, and that the Senate accept the proposal of the Royal Geographical Society to award in alternate years an Exhibition of 100*l.* or prizes of 50*l.* and 25*l.* That before the end of the Easter Term, 1888, a University Lecturer in Geography be appointed, for a period of five years, at a stipend of 200*l.* a year, of which sum 50*l.* is to be paid out of the common University fund and 150*l.* by the Royal Geographical Society. The appointment of the Lecturer to be made by a joint Committee of the representatives of the Royal Geographical Society and of the Council of the Senate, subject to the confirmation of the Senate; the Lecturer to submit his scheme of lectures to the Committee of Management; and power is to be given to the Council of the Senate, with the concurrence of the Committee of Management, to cancel the appointment of the Lecturer at any time."

This recommendation has to be submitted to the Senate at the beginning of next term, but its ultimate acceptance is placed almost beyond doubt through the very favourable reception given to the proposals of the Royal Geographical Society by the Council of the University.

THE ORGANISATION OF INDUSTRIAL EDUCATION

THE following is the letter by Prof. Huxley to which reference is made in our leading article (p. 482):—

"When a statesman of Lord Hartington's authority concurs with and enforces the opinions I ventured to express some little time ago, I have every reason for private and personal satisfaction. But the circumstance has a public importance as evidence that our political chiefs and leaders are giving their serious attention to those social questions which lie far above the region of party strife, and are of infinitely greater moment than the topics which ordinarily absorb the attention of politicians.

"The organisation of industrial and commercial education is not the least of these great problems. That it has to be solved, under penalty of national ruin, proves to be no mere alarmist fancy, but the belief of an experienced man of affairs, whose imperturbable coolness and strong common-sense are proverbial.

"It is an interesting question for us all, therefore, How do we stand prepared for the task thus imperatively set us? My conviction is that we are in some respects better off than most people imagine, in others worse. I conceive that two things are needful: on the one hand, a machinery for providing instruction and gathering information; on the other hand, a machinery for catching capable men wherever they are to be found and turning them to account. Now, I apprehend that both these kinds of machinery are to be found, though in a fragmentary and disconnected condition, in several organisations which, though independent, supplement one another.

"The first of these is that of the School Boards, which provide elementary education, and sometimes, though too rarely, have at their disposal scholarships by which capable scholars can attain a higher training. The second is the organisation of the Department of Science and Art. The classes, now established all over the country in connexion with the Department, not only provide elementary instruction, accessible to all, but offer the means whereby the pick of the capable students may obtain in the schools at South Kensington as good a higher education in science and art as is to be had in the country. It is from this source that the supply of science and art teachers, who in turn raise the standard of elementary instruction, is derived. The third organisation is that of the technical classes connected with the City and Guilds Institute, or with the Society of Arts, or with provincial Universities and Colleges, which provide special technical instruction for those who have, or ought to have, already acquired the elements of scientific and artistic knowledge in the science and art classes.

"A fourth organisation for the advancement of the interests of industry and commerce, of the nature of that which I imagined it was the intention of the founders of the Imperial Institute to create, and such as is, I believe, now actually in course of creation in the City of London, will complete the drill-grounds of the army of industry, and, so far as I can judge, omit nothing of primary importance. But, leaving the last aside as still in the embryonic condition, these excellent organisations are all mere torsos, fine—but fragmentary.

"The ladder from the School Boards to the Universities, about which I dreamed dreams many years ago, has not yet acquired much more substantiality than the ladder of Jacob's vision.

"The Science and Art Department has done, and is doing, admirable work, which I regret to see more often made the subject of small and carping criticism than of the praise which is its due. I trust it may not be diverted from efficiently continuing that work by having duties for which it is unfit forced upon it. That which the Department needs, in my judgment, is nothing but the means of doing that which Commission after Commission, Royal and departmental, have declared to be its proper business.

"As Dean of the Normal School I may be permitted to declare that it is impossible for us to perform the functions allotted to us unless the recommendations made by impartial and independent authority are carried into effect.

"The school exists, and common-sense surely suggests either make it efficient or abolish it. The alternative of abolition is not likely to be adopted, as that step would be equivalent to striking the keystone out of the edifice of scientific instruction for the masses of the people which it has taken a quarter of a century to raise, and which is the essential foundation for any sound system of technical education. The alternative of efficiency means spending a few thousand pounds on additional buildings; but the guardians of the national purse do not seem to feel the force of the adage about 'spoiling a ship for a halfpennyworth of tar.'

"The state of affairs in regard to that which ought to be the centre of our system of technical education is nearly the same. The Central Institute is undoubtedly a splendid monument of the munificence of the City. But munificence without method may arrive at results indistinguishably similar to those of stinginess. I have been blamed for saying that the Central Institute is 'starved.' Yet a man who has only half as much food as he needs is indubitably starved, even though his short rations consist of ortolans and are served up on gold plate. And I have excellent authority for saying that little more than one-half of the plan of operations of the Institute, drawn up by the Committee of which I was a member, has been carried out, or can be carried out, if the funds allotted for the maintenance of the Institute are not largely increased. At the same time, the Institute is doing all that could be rationally expected of it. Some of the guilds and many provincial towns are making admirable provision for elementary technical education. Such work, in my judgment, ought to be left to local administrators, whatever aid it may be thought desirable to give them. But the local schools should be brought into relation with the Central Institute, and this should be put upon such a footing as to subserve its proper purpose of training teachers and giving higher technical instruction.

"Economy does not lie in sparing money, but in spending it wisely. And it is, to my mind, highly necessary that some man or body of men, whom their countrymen trust, should consider these various organisations as a whole and determine the manner in which they should be correlated and in which it is desirable that the resources, public and private, which are available should be distributed among them.

"Lord Hartington has many claims on the gratitude and respect of his countrymen. I venture to express the wish that he would add to them by taking up this great work of organising industrial education and bringing it to a happy issue."

AUGUST WILHELM EICHLER

THE death of Dr. August Wilhelm Eichler, briefly announced in a previous number, is a great loss to botanical science, and especially to systematic botany. Year by year we are losing men of wide and consequently sound knowledge of plants without their places being adequately filled. We have doubtless arrived at a stage in botany where specialists are necessary; yet we venture to assert that men of general attainments are better qualified than specialists, in a narrow sense, for the head of large botanical establishments, such as the one over which the late Dr. Eichler presided, and which greatly extended its reputation during the nine years he was Director.

Dr. Eichler was barely forty-eight years of age, but before entering upon the absorbing duties connected with the University and Botanic Garden of Berlin he had already made a name as a botanical author.

For some years he was assistant to Von Martius at Munich, and succeeded him as editor of the colossal "Flora Brasiliensis," now nearly completed. This was in 1868, but he had previously been a considerable and excellent contributor to this work, having elaborated several difficult families in a masterly manner. The work by which he is more generally known is the "Blüthendiagramme," in which he admirably illustrates and explains the morphology and organogeny of the Phanerogamia. His labours were chiefly in the direction of morphology. His continued careful study of the female flower of the Coniferæ may be regarded as having finally settled the homologies of the different elements of the inflorescence of that family. One of his later contributions to science, if not his last, is entitled "Zur Entwickelungsgeschichte der Palmenblätter," in which the author fully elucidates the development of the various types of leaf in the Palmæ.

As a lecturer Dr. Eichler was exceedingly popular and successful; and he was regarded as an able administrator of the Botanic Garden. He was successively Professor of Botany at Munich, Gratz, Kiel, and Berlin, having been appointed to the last post in 1878. Two years later, "at the comparatively youthful age of thirty-nine," he was chosen a member of the Berlin Academy of Sciences; and in 1881 he was elected Foreign Member of the Linnean Society of London. He was also honorary and corresponding member of many other learned societies; and all who knew him, however slightly, will join in regretting his early death.

NOTES

BARON EGGERS, commissioned by Dr. Urban and assisted by the Royal Academy of Sciences of Berlin, is about to undertake the botanical investigation of the hitherto unexplored higher mountains of St. Domingo. The specimens collected for distribution will be arranged (under corresponding numbers) in two series. One will consist only of species which have not yet been distributed in Baron Eggers' West Indian collections; the other and larger series will include everything except the commonest tropical species. The first-named series will be disposed of at forty shillings per century, the latter at thirty shillings. Dr. J. Urban, assisted by other systematists, will determine the collections and receive the names of subscribers. As the expense and difficulty of transit in the island must limit the number of collections for sale, early application to Dr. Urban is desirable. Dr. Urban's address is Friedenau, bei Berlin.

A CONVERSAZIONE given by the Council of the City and Guilds of London Institute was held at the Central Institution, Exhibition Road, on Wednesday evening, the 16th inst., and was attended by about 1300 visitors. Lord Selborne received the guests. A large number of interesting objects of scientific and artistic interest were exhibited, and during the evening demonstrations were given by the Professors in the various departments, as well as by several gentlemen who are associated with the work of the Institute.

ON the 15th inst. a meeting was held at Grimsby to consider the expediency of establishing there an Institution for Technical Education with regard to Fish and Fisheries, and a Marine Fish-Culture Station. Mr. W. Oldham Chambers, Secretary of the National Fish-Culture Association, pointed out to the meeting the advantages of the proposed Station and Institute. Resolutions in support of the scheme were unanimously adopted, and an influential local Committee was appointed to further the object in view. Letters have been received from the various Fish Trade Associations and other bodies, heartily approving of the undertaking. The Manchester, Sheffield, and Lincolnshire Railway Company are prepared to grant a site for the Institute, and to erect a building, free of cost, at Cleethorpe, near Grimsby.

WE are sorry to see that the income of the Mason Science College, Birmingham, during the year ending "Founder's Day," February 23, fell short of the expenditure by the sum of 1646*l.* After deducting what may be termed extraordinary expenditure, there remained a deficiency of 1074*l.* The Council, in their last report, remind the Trustees that the annual deficits, which since 1881 have been charged against the accumulated surplus, have now reduced this fund to the sum of 1419*l.*, and that the estimates for the current financial year anticipate that the balance of the fund will be required. It is not creditable to the well-off citizens of Birmingham that an institution capable of doing great work for their town and district should have to meet these constantly recurring deficiencies.

THE spring meeting of the Institution of Mechanical Engineers, under the presidency of Mr. E. H. Carbutt, will take place on Monday, May 16, and the following day. On Tuesday, May 17, the Duke of Cambridge will dine with the members of the Institution.

IN order to determine between the rival sites for the Sedgwick Memorial Museum at Cambridge, and at the same time advance the chances of proceeding early with a portion at least of the building, the Council of the Senate propose to submit a grace next term to settle the question of site. The grace will take the form of authorising negotiations with Downing College for a site opposite the old Botanic Garden. If this be rejected, the latter affords the only practicable site.

MISS GORDON has presented to the Museum of the Royal Gardens, Kew, the collections and drawings made by her late brother, General Gordon, illustrative of the Coco de Mer (*Lodoicea seychellarum*), a palm peculiar to the Seychelles, and remarkable, among other things, for possessing the largest known seed in the vegetable kingdom. The seeds are well known in European museums. One amongst General Gordon's specimens is a model which he had made of the fruit in its mature state, before the external fibrous but perishable husk had become detached. Some of the specimens are placed, with others already possessed by Kew, in No. 2 Museum. The rest will be shown, with the drawings made by his own hand, in No. 3 Museum.

THE Cambridge University Local Examination Report for the past year states that in zoology and physiology the answers showed very inefficient teaching. Botany is somewhat better done; but many senior candidates had not been taught the use of floral diagrams. In physical geography, while the answering was generally good, many had used antiquated text-books. Chemistry was fairly done, the candidates choosing, out of the alternative questions, the practical rather than the theoretical. Qualitative analysis was well done, both by seniors and juniors. The seniors showed general ignorance about the laws of multiple proportion, and combination by volume. Heat was badly done by both seniors and juniors. Many seemed never to have read any text-book, and to have presented themselves on the strength of a few isolated facts. Statics was very unequally mastered. There was better acquaintance with the mathematical than with the practical part of the subject. Electricity (senior subject) had not been studied seriously enough to warrant its inclusion in the examination. The mathematical subjects of the examination are reported on much more favourably.

The botanical collections of the late Thomas Moore, F.L.S. Curator of the Botanic Garden at Chelsea, belonging to the Society of Apothecaries, have been acquired for the Herbarium of the Royal Gardens, Kew. The most important portions are:—(1) The general fern herbarium, which contains the types of the numerous species described by Moore, especially those introduced into European cultivation. (2) The collection of forms and varieties of British ferns, which is probably unique in richness and completeness; it is especially interesting as the basis of Mr. Moore's well-known and beautifully illustrated works on the fern flora of the British Isles. (3) The fern herbarium of R. Heward, F.L.S., which is especially strong in West Indian species.

British field botanists will be glad to learn that the Scottish Rights of Way Society has been successful in its action brought in the Court of Session against the proprietor of Glen Doll in Clova. Lord Kinnear has found that "the pursuers had established a sufficient use and possession of the road for more than forty years to entitle them to a judgment." There is probably no portion of the Highlands of Scotland from which botanists would feel it a greater hardship to be excluded. For years it has been so well watched by keepers that access to it has been impossible, except to such botanists as are swift and sure of foot. The present owner is the first who has denied a right of way through it, and, if we are not mistaken, the action only concerns this right to use the road. It is to be feared that efforts will not be wanting to confine the public to the road, and to deny all access to those parts so interesting to the field botanist.

A series of charts showing the surface temperatures of the Atlantic coast waters, from the eastern coast of Maine to the extreme southerly coast of Florida, is being prepared by the United States Fish Commission. The Commission is aided in this important undertaking by the Lighthouse Board and the Signal Service. Observations have thus far been made at twenty-four lighthouse stations, showing the surface temperatures at these localities during the past five years. The temperatures at each station are shown in detail for each year by ten-day means, and the facts are combined with those brought out on a series of isothermal charts giving the relations of the different stations. The results are likely to be of great value in connexion with the study of the migration of the mackerel, menhaden, shad, and other migratory fishes.

An interesting discussion has just been started in the Paris Academy of Medicine, concerning the bad results of mental straining in young persons. Attention has especially been called to the fact that many French girls, under the pressure of competition, are injuring their health by over-work at school. About 12,000 of them are trying to get the superior diploma which would confer upon them the right of getting an appointment in Government schools. Only 2000 will be able to get appointments.

An excellent address on the physical training of girls was lately given by Dr. Rayner W. Batten to the Gloucestershire branch of the British Medical Association. It is printed in the *British Medical Journal*. Speaking of ladies' Colleges, Dr. Batten says he does not know of more than one that has such a thing as a proper playground, whilst a leading College, if not the first in the country, with abundant means and ample opportunities, makes no pretence of having any playground at all. Dr. Batten urges that drill and calisthenic exercises are not enough. There must be recreation as well, "and at present, in our ladies' Colleges," he says, "the exercise, with the exception of tennis, has little of the recreative element in it." Dr. Batten is of opinion that all Colleges should have playgrounds—large spaces, open to the fresh air and sunlight—that every girl should be made to play, two half-holidays a week at least being given for that purpose, and that the games should be varied, so that girls may not have to go on doing what they are conscious of not doing well. "Every girl will soon find out her strong and weak points in play as well as in work, and if the game is to be a recreation she must be allowed to choose her own form, the only obligation being that she is to play, and that no books or work are to be brought on the playground."

At the meeting of the Essex Field Club on Saturday next, the 26th inst., Prof. Sylvanus P. Thompson will read a paper on William Gilbert, the founder of the science of electricity, and an Essex worthy entitled to rank with Ray among the pioneers of science. Those wishing to attend the meeting should communicate with the Secretary, Buckhurst Hill, Essex.

On the night of March 7, about 11.30, a brilliant meteor was seen in Dalcarlia, in Central Sweden. It was first seen in the north-west, going in a southerly direction, but soon afterwards it changed its course more easterly. Its colour was a brilliant white, and its greatest size about that of the moon. It was lost to sight behind the horizon, leaving only a faint trail behind.

From a recent official French Report on oyster-culture in France we learn that the two principal centres are at Arcachon in the south-west and Auray in the north-west. The Bay of Arcachon has since 1854 held a foremost place in oyster-breeding. In 1857 there were twenty parks, or district oyster-beds: in 1865 the number had increased to 297, with an output of over 10,000,000 oysters. At the present time the little bay, which has a total area of 37,500 acres, has oyster-beds covering an area of 15,000 acres, which provide annually about 300,000,000 oysters for consumption. With regard to the oyster-beds at Auray, on the coast of Brittany, these, though not so important as those of Arcachon, have still a considerable output, and, from being exhausted and unproductive when their rehabilitation was first undertaken, have become full to overflowing. In 1876–77 we find that 7,000,000 oysters were placed on the market from Auray; in 1885 the number had risen to over 70,000,000.

The ideas of M. Victor Meunier with regard to the domestication of apes are discussed in the new number of the *Revue d'Anthropologie* by Madame Clémence Royer, the French translator of Darwin. Madame Royer does not doubt that, under a proper system of training, apes might be made good workers. They lack perseverance, indeed, but in general intelligence they are, she thinks, superior to the dog, the horse, or even the elephant. She points out, however, that it would be necessary to feed domesticated apes with great quantities of fruit, bread, and eggs, that the process of educating them would be costly, and that for many generations they would probably be injuriously affected by the climate of Europe. Her opinion is that, if the experiment is to be made, it should be made first of all in tropical countries, where apes might be taught to labour in connexion with the cultivation of coffee, cocoa, and cotton.

An interesting paper on "The Application of Gems to the Art of the Goldsmith" was read to the Society of Arts on Tuesday, the 15th inst., by Mr. Alfred Phillips. It is printed in the Society's Journal. Mr. Phillips gives a very favourable account of the capacity of English workmen employed by goldsmiths at the present day. When masters encourage them to depart from the beaten track, they readily adapt themselves, Mr. Phillips says, to work which, ten years ago, would have been sent as a matter of course to specialists on the Continent.

A HEALTH EXHIBITION will be opened in Warsaw on May 15 next.

AN International Agricultural Exhibition of Tools and Implements will be held at Parma in September next.

THE Royal Bavarian Academy of Sciences is collecting the numerous treatises of Joseph Fraunhofer, hitherto dispersed in numberless serials, and is about to publish them in one volume.

PROF. VERNEUIL AND L. H. PETIT have issued the first number of a periodical publication called "Études expérimentales et cliniques sur la Tuberculose." It is published by means of a fund especially raised for the promotion of the study of tuberculosis.

M. H. GADEAU DE KERVILLE has just published a work on evolution. It is entitled "Causeries sur le Transformisme," and contains an exposition of the facts and theories upon which the doctrine of evolution is based.

A BOOK on therapeutics, by M. G. Hayem, Professor in the Paris Medical School, has just been published.

THE February number of the Italian Geographical Bulletin contains a detailed account, by Dr. G. A. Colini, of the rich ethnological collection recently presented to the Prehistoric and Ethnographic Museum of Rome by General Genè, Commander of the Italian possessions on the East Coast of Africa. The collection includes a great variety of objects, such as arms, costumes, implements, ornaments, utensils from Abyssinia, Somali Land, and the Afar (Danakil) country. Amongst them are baking-ovens, braziers, incense-burners, cooking-utensils, pestles for grinding coffee, pepper, durrha, &c.; baskets, matting, veils, robes, loin-cloths, wooden sandals, lamps, swords, matchlock guns, knives, hairpins, &c., illustrating the arts and industries of the East African peoples.

WE have received the four latest Bulletins of the U.S. Geological Survey (Nos. 30–33). No. 30 contains Mr. C. D. Walcott's second contribution to "Studies on the Cambrian Faunas of North America." A systematic review of our present knowledge of fossil insects, including myriapods and arachnids, by Mr. S. H. Scudder, is presented in No. 31; and an elaborate account of mineral springs of the United States, by Dr. A. C. Peale, in No. 32. No. 33 is made up of notes, by Mr. J. S. Diller, on the geology of Northern California.

MR. EDWARD COOKWORTHY ROBINS, whose collected papers on technical education and applied science, buildings and fittings, &c., were reviewed in NATURE some time ago, is now engaged on a general work of reference on the same subject. It will appear shortly under the title of "Technical School and College Buildings," in a quarto volume of about 250 pages, with upwards of 100 full-page illustrations, plates, and maps.

IN the Proceedings of the American Antiquarian Society (vol. iv. p. 62) Mr. Frederick W. Putnam gives an account of twelve jade objects found in Nicaragua and Costa Rica, ten of which were ornaments made by cutting celts into halves, quarters, or thirds, a portion of the cutting edge of the celt remaining on each piece. Mr. O. W. Huntington, who was asked to report upon the nature and source of the material of these ornaments, is of opinion that the specimens "are unquestionably Chinese jade." They have, he says, "all the characters of that mineral, although the largest specimen from Costa Rica is rather unusual in its colour, and would not be taken for jadeite at sight." The *American Naturalist*, which calls attention to these facts, thinks "it will now be in order to collate during the next ten years the evidence for and against contact between the Orient and the western shores of America."

SOME interesting notes from Venezuela have lately been contributed by Dr. Ernst, of Caracas, to the Proceedings of the Berlin Anthropological Society. The writer brings together much valuable information as to the manners and customs of the aboriginal population, and about their food, ornaments, implements, weapons, and canoes.

THE additions to the Zoological Society's Gardens during the past week include a Mauge's Dasyure (*Dasyurus maugæi* ♀) from Australia, presented by Mr. W. Miller; two White-crowned Pigeons (*Columba leucocephala*) from the West Indies, presented by Lieut.-Colonel Dawkins; two Long-tailed Grass Finches (*Poephila acuticauda*) from Australia, presented by Mr. Walter Burton; an Algerian Tortoise (*Testudo mauritanica*) from North Africa, presented by Mr. J. M. Green; a European Pond Tortoise (*Emys europæa*), South European, presented by Mr. Henry Garle; five European Tree Frogs (*Hyla arborica*), European, presented by Mr. F. W. Green; an Axis Deer (*Cervus axis* ♀), a Collared Fruit Bat (*Cynonycteris collaris*), sixteen Puff Adders (*Vipera arietans*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

RESEARCHES ON THE DIAMETER OF THE SUN.—Herr Auwers has published in the *Sitzungsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin*, 1886, No. l., the first part of an elaborate investigation of the value of the sun's diameter as found from meridian observations, and of the apparent variations thereof. The discussion now published refers to variations in the mean annual values only of the diameter. The series of observations discussed are the meridian observations of the sun made at Greenwich, 1851–83; at Washington, 1866–82; at Oxford (Radcliffe Observatory), 1862–83; and at Neuchâtel (transit observations only), 1862–83. The "personal equations" of the various observers are first determined on the supposition that there may be periodic annual variations, both in the horizontal and vertical diameters of the sun, such for instance as have been supposed by Secchi and others to exist, with a period corresponding to the sunspot cycle. The first determination of "personal equation" is therefore made by comparing observations taken in each year with others taken in the same year only. The resulting diameters are, however, such as to convince Herr Auwers that, although inequalities exist in each of the series of observations discussed, their comparison with each other and with the sunspot curve is sufficient to show that they have no connexion either with the latter or with a progressive change, but are most probably due to uncorrected "personal equations." A second determination of these on the assumption that, for some observers at least, they are liable to change, but that the sun's diameter is not subject to annual variation, leads to much more satisfactory results, and is regarded by Herr Auwers as the correct solution of the problem. The effect of personality on the deduced solar diameter, which on the average, for an individual observer, amounts to about 1″ (sometimes 3″, 4″, and even 10″), may be inferred from the fact that the values of the horizontal and vertical diameters of the sun, deduced from thirty-three years' observation with the Greenwich transit-circle, and referred to the mean of Dunkin, Ellis, Criswick, and J. Carpenter, as standard, are respectively 32′ 2″·48 and 32′ 2″·00; whilst, referred to the mean of fifty-four observers, the same observations give, for the horizontal and vertical diameters respectively, the values 32′ 1″·99 and 32′ 2″·73.

COMET 1887 *b* (BROOKS, JANUARY 22).—The following ephemeris for Berlin midnight, is by Dr. R. Spitaler (*Astr. Nach.* No. 2776).

1887		R.A. h. m. s.		Decl. ° ′		Brightness
March 24	...	4 18 8	...	35 46·5 N.	...	0·72
26	...	4 21 20	...	34 26·1	...	
28	...	4 24 26	...	33 8·9	...	0·66
30	...	4 27 26	...	31 54·9	...	
April 1	...	4 30 21	...	30 43·9	...	0·61
3	...	4 33 11	...	29 35·7 N.	...	

The brightness on January 24 is taken as unity.

MINOR PLANET NO. 262.—This object has received the name of Valda.

HARVARD COLLEGE OBSERVATORY.—The late Uriah A. Boyden having left proprety to the value of 230,000 dollars in trust for the purpose of astronomical research, the Trustees of the fund have transferred the property to the President and Fellows of Harvard College, in order that the researches proposed by Mr. Boyden may be directed at the Harvard College Observatory. These researches will be supported by a portion of the means of the Observatory, in addition to the trust fund itself. By the terms of the will the money is to be devoted to observations "at such an elevation as to be free, so far as practicable, from the impediments to accurate observations which occur in the observatories now existing, owing to atmospheric influences."

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *MARCH* 27—*APRIL* 2

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 27

Sun rises, 5h. 49m.; souths, 12h. 5m. 30·1s.; sets, 18h. 22m.; decl. on meridian, 2° 35′ N.: Sidereal Time at Sunset, 6h. 41m.

Moon (at First Quarter on April 1) rises, 7h. 19m.; souths, 14h. 12m.; sets, 21h. 16m.; decl. on meridian, 9° 44′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	5 19	11 26	17 33	0 40 N.
Venus	6 38	13 47	20 56	12 41 N.
Mars	6 3	12 30	18 57	4 37 N.
Jupiter	20 47*	1 52	6 57	11 28 S.
Saturn	10 39	18 48	2 57*	22 30 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

Occultations of Stars by the Moon (visible at Greenwich)

M signifies maximum; *m* minimum.

GEOGRAPHICAL NOTES

IN a recently-issued Colonial Office Report on the Gambia will be found some useful data on the climate of that colony which completely upset the results of previous observations and greatly reduce the temperatures hitherto accepted. The mean temperature, according to these latest observations, varies from 68°·5 in January to 80° in July at 7 a.m., and from 73°·7 in January to 82°·5 in July at noon. The same Report contains some interesting statements relating to the ethnology of the colony.

THE principal paper in the just-issued Bulletin (only No. 4 of 1885) of the American Geographical Society is on the historical and geographical features of the Rocky Mountain Railways, by Mr. James Douglass. There is also a translation of Baron Nordenskjöld's reply to criticisms on the "Voyage of the *Vega*." The criticisms relate to points of minor importance.

THE new number of the "Antananarivo Annual and Madagascar Magazine" (Christmas, 1886), consists, besides a reprint of Mr. A. R. Wallace's chapter on the fauna of Madagascar, mainly of papers on linguistic topics and on Malagasy folk-lore. M. Grandidier's paper on the channels and lagoons of the east coast of the island is translated with some interesting remarks by Mr. Sibree appended. Mr. Sibree points out that it would only require about thirty miles of canals to connect all these lagoons and so create a safe and extensive internal waterway of the greatest commercial value. The Rev. W. Montgomery contributes a paper on the Malagasy game of "Fanerana," in many respects resembling chess.

IN the new number (Heft i. Band 10.) of the *Deutsche Geographische Blätter*, we find a useful and careful, if rather too favourable, study of the trade-routes of Mexico, old and new, and their commercial importance, by Herr A. Scobel. From a scientific point of view the most valuable paper is that of Dr. Otto Finsch on his visit three years ago to the atoll of Diego Garcia in the Chagos Archipelago, about half-way between the Seychelles and Ceylon. Dr. Finsch was only a few hours on the islands, but his notes on the people (mostly of the Negro type from the Mauritius) and the richness of the bird life are interesting. An open space in the little east island was covered with "millions" of birds, whose combined cry was deafening. Eggs, also in "millions," lay about everywhere, unprotected by any nest. The commonest among these birds was the sooty tern (*Sterna fuliginosa*). Next to the Laccadives, the Chagos Islands seem to be the favourite breeding-place of this bird in the Indian Ocean. The variety in the colouring of the eggs was unprecedented in Dr. Finsch's experience, especially considering the fact that they all belonged to birds of the one species named above. The only other species noticed in the island by Dr. Finsch was the noddy (*Anous stolidus*). The birds arrive in the islands in the month of June, and stay till the young are fledged; by November they have all taken their departure. As on most coral islands, the animal world generally is very poor.

THE same number contains an account of Fontana's exploration of Eastern Patagonia in 1885, and also a short biography of Emin Pasha. From the latter we learn that Edward Schnitzer was born at Oppeln, in Silesia, in 1840; received his early education at Neisse, in Upper Silesia, and studied medicine at Breslau, Berlin, and Königsberg. From his earliest years he had a special taste for natural history, and especially ornithology, and in the latter department he has all along been a diligent collector. In 1864 we find Schnitzer at Antivari, in Albania, as a surgeon in the Turkish service. In 1870 he accompanied Ismail Pasha to Syria and Arabia, and afterwards to Trebizond, Erzeroum, and Epirus. At Ismail's death in 1874, Schnitzer came to Constantinople, and in 1875 made a short visit to his German home. Entering the Egyptian service, he, in 1876, followed Gordon Pasha from Cairo into the Soudan, where, under the title of Emin Effendi, he was appointed chief surgeon, and in 1878 Governor-General of the Equatorial Province, with the title of Bey. His work as administrator, scientific explorer, and collector, since then is well known. To Bremen and Vienna he has sent some 2000 bird-skins, carefully labelled with all necessary information, and including some twenty-five new species.

SINCE the time of Herodotus travellers in Africa have brought home reports of pygmy tribes scattered about in various regions of Africa. Readers of Schweinfurth will remember the Akkas whom he met in the Monbuttu country, and now Dr. Ludwig Wolf, who, with Wissmann, recently explored the Sankuru, the great southern tributary of the Congo, gives us many details of a similar pygmy race among whom he sojourned for some time, in the district to the north-west of the station Luluaburg. He found entire villages inhabited by tiny men and women, of a height of not more than 1·40 metre. Among their neighbours they are known as Batua. These are nomad tribes devoting themselves exclusively to the chase and the manufacture of palm wine. Their villages, consisting of huts, are met with in clearings in the forests which cover the greater part of the country. Each district thus possesses a village of pygmies. As is the case of the Akkas among the Monbuttus, so the Batua among the Bakubu are regarded as little benevolent beings whose special mission is to provide the tribes among whom they sojourn with game and palm-wine. In exchange, manioc, maize, and bananas are given to the pygmies. Generally they live apart, but sometimes they unite themselves with races of larger stature. They excel in the art of scaling palm-trees to collect the sap, and in setting traps for game. Their agility is almost incredible. In hunting they bound through the high grass like grasshoppers, facing the elephant, antelope, and buffalo with the greatest audacity, shooting their arrows with rare precision, following up rapidly with a stroke of the lance. Physically the Batua are very well made, having absolutely no deformity. They are simply little men, well proportioned, very brave, and very cunning. Their mean height is 1·30 metre. Their skin is a yellow-brown, less dark than that of larger races. Their hair is short and woolly. Neither the Akkas nor the Batua have any beard.

SUNLIGHT COLOURS[1]

SUNLIGHT is so intimately woven up with our physical enjoyment of life that it is perhaps not the most uninteresting subject that can be chosen for what is — perhaps somewhat pedantically—termed a Friday evening "discourse." Now, no discourse ought to be possible without a text on which to hang one's words, and I think I found a suitable one when walking with an artist friend from South Kensington Museum the other day. The sun appeared like a red disk through one of those fogs which the east wind had brought, and I happened to point it out to him. He looked, and said, "Why is it that the sun appears so red?" Being near the railway station, whither he was bound, I had no time to enter into the subject, but said if he would come to the Royal Institution this evening I would endeavour to explain the matter. I am going to redeem that promise, and to devote at all events a portion of the time allotted to me in answering the question why the sun appears red in a fog. I must first of all appeal to what everyone who frequents this theatre is so accustomed, viz. the spectrum; I am going not to put it in the large and splendid stripe of the most gorgeous colours before you with which you are so well acquainted, but my spectrum will take a more modest form of purer colours some twelve inches in length.

I would ask you to notice which colour is most luminous. I think that no one will dispute that in the yellow we have the most intense luminosity, and that it fades gradually in the red on the one side and in the violet on the other. This then may be called a qualitative estimate of relative brightnesses; but I wish now to introduce to you what was novel last year, a quantitative method of measuring the brightness of any part.

Before doing this I must show you the diagram of the apparatus which I shall employ in some of my experiments.

RR are rays (Fig. 1) coming from the arc light, or, if we were using sunlight, from a heliostat, and a solar image is formed by a lens, L_1, on the slit S_1 of the collimator C. The parallel rays produced by the lens L_2 are partially refracted and partially reflected. The former pass through the prisms P_1P_2, and are focused to form a spectrum by a lens, L_3, on D, a movable ground glass screen. The rays are collected by a lens, L_4, tilted at an angle as shown, to form a white image of the near surface of the second prism on F.

Passing a card with a narrow slit, S_2, cut in it in front of the spectrum, any colour which I may require can be isolated. The consequence is that, instead of the white patch upon the screen, I have a coloured patch, the colour of which I can alter to any hue lying between the red and the violet. Thus, then, we are able to get a real patch of very approximately homogeneous light to work with, and it is with these patches of colour that I shall have to deal. Is there any way of measuring the brightness of these patches? was a question asked by General Festing and myself. After trying various plans, we hit upon the method I shall now show you, and if anyone works with it he must become fascinated with it on account of its almost childish simplicity—a simplicity, I may remark, which it took us some months to find out. Placing a rod before the screen, it casts a black shadow surrounded with a coloured background. Now I may cast another shadow from a candle or an incandescence lamp, and the two shadows are illuminated, one by the light of the coloured patch and the other by the light from an incandescence lamp which I am using to-night. [Shown.] Now one stripe is evidently too dark. By an arrangement which I have of altering the resistance interposed between the battery and the lamp, I can diminish or increase the light from the lamp, first making the shadow it illuminates too light and then too dark compared with the other shadow which is illuminated by the coloured light. Evidently there is some position in which the shadows are equally

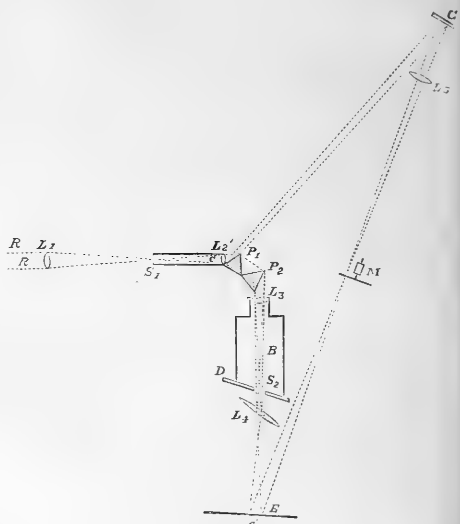

Fig. 1.—Colour Photometer.

luminous. When that point is reached, I can read off the current which is passing through the lamp, and having previously standardised it for each increment of current, I know what amount of light is given out. This value of the incandescence lamp I can use as an ordinate to a curve, the scale number which marks the position of the colour in the spectrum being the abscissa. This can be done for each part of the spectrum, and so a complete curve can be constructed which we call the illumination curve of the spectrum of the light under consideration.

Now, when we are working in the laboratory with a steady light, we may be at ease with this method, but when we come to working with light such as the sun, in which there may be constant variation owing to passing, and maybe usually imperceptible, mist, we are met with a difficulty; and in order to avoid this, General Festing and myself substituted another method, which I will now show you. We made the comparison light part of the light we were measuring. Light which enters the collimating lens partly passes through the prisms and is partly reflected from the first surface of the prism; that we utilise, thus giving a second shadow. The reflected

[1] Lecture delivered by Capt. W. de W. Abney, R.E., F.R.S., at the Royal Institution, on February 25, 1887.

rays from P_1 fall on G, a silver-on-glass mirror. They are collected by L_5, and form a white image of the prism also at F. The method we can adopt of altering the intensity of the comparison light is by means of rotating sectors, which can be opened or closed at will, and the two shadows thus made equally luminous. [Shown.] But although this is an excellent plan for some purposes, we have found it better to adopt a different method. You will recollect that the brightest part of the spectrum is in the yellow, and that it falls off in brightness on each side, so, instead of opening and closing the sectors, they are set at fixed intervals, and the slit is moved in front of the spectrum, just making the shadow cast by the reflected beam too dark or too light, and oscillating between the two till equality is discovered. The scale number is then noted, and the curve constructed as before. It must be remembered that, on each side of the yellow, equality can be established.

This method of securing a comparison light is very much better for sun work than any other, as any variation in the light whose spectrum is to be measured affects the comparison light in the same degree. Thus, suppose I interpose an artificial cloud before the slit of the spectroscope, having adjusted the two shadows, it will be seen that the passage of steam in front of the slit does not alter the relative intensities; but this result must be received with caution. [The lecturer then proceeded to point out the contrast colours that the shadow of the rod illuminated by white light assumed.]

I must now make a digression. It must not be assumed that everyone has the same sense of colour, otherwise there would be no colour-blindness. Part of the researches of General Festing and myself have been on the subject of colour-blindness, and these I must briefly refer to. We test all who come by making them match the luminosity of colours with white light, as I have now shown you; and as a colour-blind person has only two fundamental colour-perceptions instead of three, his matching of luminosities is even more accurate than is that made by those whose eyes are normal or nearly normal. It is curious to note how many people are more or less deficient in colour-perception. Some have remarked that it is impossible that they were colour-blind, and would not believe it, and sometimes we have been staggered at first with the remarkable manner in which they recognised colour to which they ultimately proved deficient in perception. For instance, one gentleman when I asked him the name of a red colour patch, said it was sunset colour; he then named green and blue correctly, but when I reverted to the red patch he said green. On testing further he proved totally deficient in the colour-perception of red, and with a brilliant red patch he matched almost a black shadow. The diagram shows you the relative perceptions in the spectrum of this gentleman and myself. There are others who only see three-quarters, others half, and others a quarter the amount of red that we see, whilst some see none. Others see less green and others less violet, but I have met with no-one that can see more than myself or General Festing, whose colour-perceptions are almost identical. Hence we have called our curve of illumination the "normal curve."

We have tested several eminent artists in this manner, and about one-half of the number have been proved to see only three-quarters of the amount of red which we see. It might be thought that this would vitiate their powers of matching colour, but it is not so. They paint what they see, and although they see less red in a subject, they see the same deficiency in their pigments; hence they are correct. If totally deficient, the case of course would be different.

Let us carry our experiments a step further, and see what effect what is known as a turbid medium has upon the illuminating value of different parts of the spectrum. I have here water which has been rendered turbid in a very simple manner. In it has been very cautiously dropped an alcoholic solution of mastic. Now mastic is practically insoluble in water, and directly the alcoholic solution comes in contact with the water it separates out in very fine particles, which, from their very fineness, remain suspended in the water. I propose now to make an experiment with this turbid water.

I place a glass cell containing water in front of the slit, and on the screen I throw a patch of blue light. I now change it for turbid water in a cell. This thickness much dims the blue; with a still greater thickness the blue has almost gone. If I measure the intensity of the light at each operation, I shall find that it diminishes according to a certain law, which is of the same nature as the law of absorption. For instance, if one inch diminishes the light one-half, the next will diminish it half of that again, the next half of that again, whilst the fourth inch will cause a final diminution of the total light of one-sixteenth. If the first inch allows only one-quarter of the light, the next will only allow one-sixteenth, and the fourth inch will only permit 1/256 part to pass. Let us, however, take a red patch of light and examine it in the same way. We shall find that, when the greater thickness of the turbid medium we used when examining the blue patch of light is placed in front of the slit, much more of this light is allowed to pass than of the blue. If we measure the light we shall find that the same law holds good as before, but that the proportion which passes is invariably greater with the red than the blue. The question then presents itself:—Is there any connection between the amounts of the red and the blue which pass? Lord Rayleigh, some years ago, made a theoretical investigation of the subject; but, as far as I am aware, no definite experimental proof of the truth of the theory was made till it was tested last year by General Festing and myself. His law was that for any ray, and through the same thickness, the light transmitted varied inversely as the fourth power of the wave-length. The wave-length 6000 lies in the red, and the wave-length 4000 in the violet. Now 6000 is to 4000 as 3 to 2, and the fourth powers of these wave-lengths are as 81 to 16, or as about 5 to 1. If, then, the four inches of our turbid medium allowed three-quarters of this particular red ray to be transmitted, they would only allow $(\frac{3}{4})^5$, or rather less than one-fourth, of the blue ray to pass. Now this law is not like the law of absorption for ordinary absorbing media, such as coloured glass for instance, because here we have an increased loss of light running from the red to the blue, and it matters not how the medium is made turbid, whether by varnish, suspended sulphur, or what not. It holds in every case, so long as the particles which make the medium turbid are small enough; and please to recollect that it matters not in the least whether the medium which is rendered turbid is solid, liquid, or air. Sulphur is yellow in mass, and mastic varnish is nearly white, whilst tobacco-smoke when condensed is black, and very minute particles of water are colourless: it matters not what the colour is, the loss of light is *always* the same. The result is simply due to the scattering of light by fine particles, such particles being small in dimensions compared with a wave of light. Now, in this trough is suspended 1/1000 of a cubic inch of mastic varnish, and the water in it measures about 100 cubic inches, or is 100,000 times more in bulk than the varnish. Under a microscope of ordinary power it is impossible to distinguish any particles of varnish: it looks like a homogeneous fluid, though we know that mastic will not dissolve in water. Now a wave-length in the red is about 1/40,000 of an inch, and a little calculation will show that these particles are well within the necessary limits. Prof. Tyndall has delighted audiences here with an exposition of the effect of the scattering of light by small particles in the formation of artifical skies, and it would be superfluous for me to enter more into that. Suffice it to say that when particles are small enough to form the artificial blue sky they are fully small enough to obey the above law, and that even larger particles will suffice. We may sum up by saying that very fine particles scatter more blue light than red light, and that consequently more red light than blue light passes through a turbid medium, and that the rays obey the law prescribed by theory. I will exemplify this once more by using the whole spectrum and placing this cell, which contains hyposulphite of soda in solution in water, in front of the slit. By dropping in hydrochloric acid, the sulphur separates out in minute particles; and you will see that, as the particles increase in number, the violet, blue, green, and yellow disappear one by one and only red is left, and finally the red disappears itself.

Now let me revert to the question why the sun is red at sunset. Those who are lovers of landscape will have often seen on some bright summer's day that the most beautiful effects are those in which the distance is almost of a match to the sky. Distant hills, which when viewed close to are green or brown, when seen some five or ten miles away appear of a delicate and delicious, almost of a cobalt, blue colour. Now, what is the cause of this change in colour? It is simply that we have a sky formed between us and the distant ranges, the mere outline of which looms through it. The shadows are softened so as almost to leave no trace, and we have what artists call an atmospheric effect. If we go into another climate, such as Egypt or amongst the high Alps, we usually lose this effect. Distant mountains stand out crisp with black shadows, and the want of atmosphere is much felt. [Photographs showing these differences were shown.] Let us ask to what this is due. In such climates as England there is always a certain amount of moisture present in the atmosphere, and this moisture may be present as very minute particles of water—so minute indeed that they will not sink down in an atmosphere of normal density—or as vapour. When present as vapour the air is much more transparent, and it is a common expression to use, that when distant hills look "so close" rain may be expected shortly to follow, since the water is present in a state to precipitate in larger particles; but when present as small particles of water the hills look very distant, owing to what we may call the haze between us and them. In recent weeks everyone has been able to see very multiplied effects of such haze. The ends of long streets, for instance, have been scarcely visible though the sun may have been shining, and at night the long vistas of gas lamps have shown light having an increasing redness as they became more distant. Everyone admits the presence of mist on these occasions, and this mist must be merely a collection of intangible and very minute particles of suspended water. In a distant landscape we have simply the same or a smaller quantity of street-mist occupying, instead of perhaps 1000 yards, ten times that distance. Now I would ask, What effect would such a mist have upon the light of the sun which shone through it?

It is not in the bounds of present possibility to get outside our atmosphere and measure by the plan I have described to you the different illuminating values of the different rays, but this we can do:—First, we can measure these values at different altitudes of the sun, and this means measuring the effect on each ray after passing through different thicknesses of the atmosphere, either at different times of day, or at different times of the year, about the same hour. Second, by taking the instrument up to some such elevation as that to which Langley took his bolometer at Mount Whitney, and so to leave the densest part of the atmosphere below us. Now, I have adopted both these plans. For more than a year I have taken measurements of sunlight in my laboratory at South Kensington, and I have also taken the instrument up to 8000 feet high in the Alps, and made observations *there*, and with a result which is satisfactory in that both sets of observations show that the law which holds with artificially turbid media is under ordinary circumstances obeyed by sunlight in passing through our air: which is, you will remember, that more of the red is transmitted than of the violet, the amount of each depending on the wave-length. The luminosity of the spectrum observed at the Riffel I have used as my standard luminosity, and compared all others with it. The result for four days you see in the diagram.

I have diagrammatically shown the amount of different colours which penetrated on the same days, taking the Riffel as ten. It will be seen that on December 23 we have really very little violet and less than half the green, although we have four-fifths of the red.

The next diagram before you shows the minimum loss of light which I have observed for different air thicknesses. On the top we have the calculated intensities of the different rays outside our atmosphere. Thus we have that through one atmosphere, and two, three, and four; and you will see what enormous absorption there is in the blue end at four atmospheres. The areas of these curves, which give the total luminosity of the light, are 761, 662, 577, 503, and 439; and if observed as astronomers observe the absorption of light, by means of stellar observations, they would have had the values, 761, 664, 578, 504, and 439—a very close approximation one to the other.

Next notice in the diagram that the top of the curve gradually inclines to go to the red end of the spectrum as you get the light transmitted through more and more air, and I should like to show you that this is the case in a laboratory experiment. Taking a slide with a wide and long slot in it, a portion is occupied by a right-angled prism, one of the angles of 45° being towards the centre of the slot. By sliding this prism in front of the spectrum I can deflect outwards any portion of the spectrum I like, and by a mirror can reflect it through a second lens, forming a patch of light on the screen overlapping the patch of light formed by the undeflected rays. If the two patches be exactly equal, white light is formed. Now, by placing a rod as before in front of the patch, I have two coloured stripes in a white field, and though the background remains of the same intensity of white, the intensities of the two stripes can be altered by moving the right-angled prism through the spectrum. The two stripes are now apparently equally luminous, and I see the point of equality is where the edge of the right-angled prism is in the green. Placing a narrow cell filled with our turbid medium in front of the slit, I find that the equality is disturbed, and I have to allow more of the yellow to come into the patch formed by the blue end of the spectrum, and consequently less of it in the red end. I again establish equality. Placing a thicker cell in front, equality is again disturbed, and I have to have less yellow still in the red half, and more in the blue half. I now remove the cell, and the inequality of luminosity is still more glaring. This shows, then, that the rays of maximum luminosity must travel towards the red as the thickness of the turbid medium is increased.

The observations at 8000 feet, here recorded, were taken on

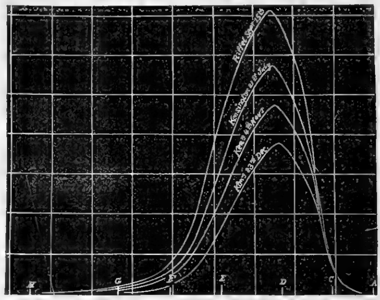

FIG. 2.—Relative Luminosities.

September 15 at noon, and of course in latitude 46° the sun could not be overhead, but had to traverse what would be almost exactly equivalent to the atmosphere at sea-level. It is much nearer the calculated intensity for no atmosphere intervening, than it is for one atmosphere. The explanation of this is easy. The air is denser at sea-level than at 8000 feet up, and the lower stratum is more likely to hold small water particles or dust in suspension than is the higher.

For, however small the particles may be, they will have a greater tendency to sink in a rare air than in a denser one, and less water vapour can be held per cubic foot. Looking, then, from my

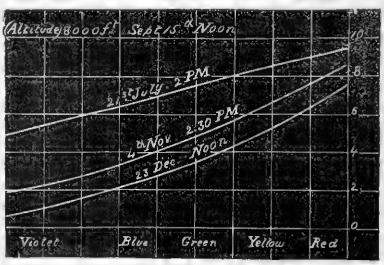

FIG. 3.—Proportions of Transmitted Colours.

laboratory at South Kensington, we have to look through a proportionately larger quantity of suspended particles than we have at a high altitude when the air thicknesses are the same; and consequently the absorption is proportionately greater at sea-level that at 8000 feet high. This leads us to the fact that the real intensity of illumination of the different rays outside the atmosphere is greater than it is calculated from observations near sea-level. Prof. Langley, in this theatre, in a remarkable and interesting lecture, in which he described his journey up Mount Whitney to about 12,000 feet, told us that the sun was really blue outside our atmosphere, and at first blush the amount of extra blue which he deduced to be present in it would, he thought, make it so; but though he surmised the result from experiments made with rotating disks of coloured paper, he did not, I think, try the method of using pure colours, and consequently, I believe, slightly exaggerated the blueness which would result. I have taken Prof. Langley's calculations of the increase of intensity for the different rays, which I may say do not quite agree with mine, and I have prepared a mask which I can place in the spectrum giving the different proportions of each ray as calculated by him, and this when placed in front of the spectrum will show you that the real colour of sunlight outside the atmosphere, as calculated by Langley, can scarcely be called bluish. Alongside I place a patch of light which is very closely the colour of sunlight on a July day at noon in England. This comparison will enable you to gauge the blueness, and you will see that it is not very blue, and, in fact, not bluer perceptibly than that we have at the Riffel, the colour of the sunlight at which place I show in a similar way. I have also prepared some screens to show you the value of sunlight after passing through five and ten atmospheres. On an ordinary clear day you will see what a yellowness there is in the colour. It seems that after a certain amount of blue is present in white light the addition of more makes but little difference in the tint. But these last patches show that the light which passes through the atmosphere when it is feebly charged with particles does not induce the red of the sun as seen through a fog. It only requires more suspended particles in any thickness to induce it.

In observations made at the Riffel, and at 14,000 feet, I have found that it is possible to see far into the ultra-violet, and to distinguish and measure lines in the sun's spectrum which can ordinarily only be seen by the aid of a fluorescent eye-piece or by means of photography. Circumstantial evidence tends to show that the burning of the skin, which always takes place in these high altitudes in sunlight, is due to the great increase in the ultra-violet rays. It may be remarked that the same kind of burning is effected by the electric arc light, which is known to be very rich in these rays.

Again, to use a homely phrase, "You cannot eat your cake and have it." You cannot have a large quantity of blue rays present in your direct sunlight, and have a luminous blue sky. The latter must always be light scattered from the former. Now, in the high Alps you have, on a clear day, a deep blue-black sky, very different indeed from the blue sky of Italy or of England; and as it is the sky which is the chief agent in lighting up the shadows, not only in those regions do we have dark shadows on account of no intervening—what I will call—mist, but because the sky itself is so little luminous. In an artistic point of view this is important. The warmth of an English landscape in sunlight is due to the highest lights being yellowish, and to the shadows being bluish from the sky-light illuminating them. In the high Alps the high lights are colder, being bluer, and the shadows are dark, and chiefly illuminated by reflected direct sunlight. Those who have travelled abroad will know what the effect is. A painting in the Alps, at any high elevation, is rarely pleasing, although it may be true to Nature. It looks cold, and somewhat harsh and blue.

In London we are often favoured with easterly winds, and these, unpleasant in other ways, are also destructive of that portion of the sunlight which is the most chemically active on living organisms. The sunlight composition of a July day may, by the prevalence of an easterly wind, be reduced to that of a November day, as I have proved by actual measurement. In this case it is not the water particles which act as scatterers, but the carbon particles from the smoke.

Knowing, then, the cause of the change in the colour of sunlight, we can make an artificial sunset, in which we have an imitation light passing through increasing thicknesses of air largely charged with water particles. [The image of a circular diaphragm placed in front of the electric light was thrown on the screen in imitation of the sun, and a cell containing hyposulphite of soda placed in the beam. Hydrochloric acid was then added: as the fine particles of sulphur were formed, the disk of light assumed a yellow tint, and as the decomposition of the hyposulphite progressed, it assumed an orange and finally a deep red tint.] With this experiment I terminate my lecture, hoping that in some degree I have answered the question I propounded at the outset: why the sun is red when seen through a fog.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—From the University accounts for 1886, just issued, we learn that the Mathematical Tripos Examiners are paid 348*l.*; Examiners in Natural Science, 575*l.*; in Medicine and Surgery, 210*l.*; all extremely moderate payments.

Science Professors received 3725*l.* from the University Chest, 1800*l.* from the Common University Fund (derived from tax on the Colleges), besides payments from special endowments; Readers, Demonstrators, and other officers connected with Science and Medicine, 2100*l.* from the University Chest; 1800*l.* from the Common University Fund. Total, 9425*l.* for teachers mainly.

The University Observatory cost 786*l.*, in addition to 164*l.* from the Sheepshanks Fund. The Botanic Garden cost 1223*l.*; the Museums and Lecture Rooms, 4221*l.*, including 100*l.* for Dr. Guillemard's collection of bird-skins from the voyage of the *Marchesa*, 11*l.* for bird-skins bought by Prof. Newton at the Jardine sale, and 8*l.* 10*s.* for a skeleton of a European elk. The Pathological Laboratory cost 167*l.* out of the foregoing amount; the Department of Human Anatomy, 356*l.*; the Woodwardian Museum, 498*l.*; the Chemical Laboratory, 517*l.*; the Cavendish Laboratory, 274*l.*, including 60*l.* for instruments. The new dissecting-room (iron) for Human Anatomy cost 350*l.*, an additional class-room for Physiology 10*l.*, charged to the Museums Reserve Fund.

At Gonville and Caius College, Dr. Shuttleworth's Scholarship of 60*l.* for three years, open to medical students of the University of not less than eight terms' standing, given for proficiency in Botany and Comparative Anatomy, has been awarded to Francis Henry Edgeworth, B.A., Scholar of the College.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 3.—"On the Limiting Distance of Speech by Telephone." By William Henry Preece, F.R.S.

The law that determines the distance to which speaking by telephone on land-lines is possible, is just the same as that which determines the number of currents which can be transmitted through a submarine cable in a second.

It is dependent on a time-constant varying with the conditions of the circuit, invariable for the same uniform circuit, but differing for different circuits. It represents the time that elapses from the instant contact is made at the sending-end to the instant that the current begins to appear at the receiving-end. It is given by the following equation:—

$$a = \mathrm{B}krl^2,$$

B being a constant dependent principally on the units used; k the inductive capacity per unit length (mile or knot); r the resistance per unit length, and l the lengths in miles or knots.

The number of reversals which can be produced at the end of a wire per second is quite independent of the impressed E.M.F., and therefore of the strength of the current. But it depends upon the sensitiveness of the apparatus used to receive the currents. This is why such discordant results are obtained by different observers who attempt to measure the velocity of currents of electricity. It is also why the telephone is such an admirable instrument for research—for it is sensitive to the least increment or decrement of current.

The inductive capacity of overhead and underground wires was measured with great care on very dry days in different parts of the country.

The results come out as follows:—

	Capacity per mile, microfarads	Resistance per mile, B.A. ohms
No. 7½ iron wire	0·0168 ...	12·0
No. 12½ copper wire	0·0124 ...	5·7
Gutta-percha-covered wire in iron pipes	0·2500 ...	23·0
Gutta-percha-covered wire in cables	0·2900 ...	10·25

It then became necessary to determine the speed of the current through wires of different lengths, resistances, and capacities.

It was found that, for mixed wires, the speed was given by the equation

$$t = 32 \times 10^{-8}\ \mathrm{KR},$$

but for copper alone the constant was 22×10^{-8}.

The limiting distance through which it is possible to speak varies inversely with the speed of the current, and that the speed of the current varies inversely with the product of the total resistance and the total capacity of the circuit. Hence the number of reversals that it is possible to send through any circuit varies inversely with the product of the total resistance (R) and the total capacity (K), or the limiting distance—

$$S = KR \times \text{constant} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

This is only another form of Thomson's law for $K = lk$, and $R = lr$, and

$$\therefore S = krl^2 \times \text{constant}.$$

If the equation (1) be put into this form,

$$A = krx^2, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and A be given the following values :—

Copper (overhead)	15,000
Cables and underground	12,000
Iron (overhead	10,000

the limiting distance (x) through which speech is possible is

$$x^2 = A/kr.$$

There is an interesting consequence of Thomson's law which comes out of these experiments, and that is, whether the line be a single wire completed by the earth, or a double wire making a metallic circuit, the rate of speed between the two ends is exactly the same, and therefore the distance we can speak through is just the same whether we use a single or double wire circuit. This is owing to the fact that though in the latter case we double the total resistance, we halve the total capacity, and therefore the product remains the same.

The difference between copper and iron is clearly due to self-induction, or to the electro-magnetic inertia of the latter, and the difference between copper overground and copper underground is due to the facility that the leakage of insulators offers to the rapid discharge to earth, at innumerable points, of the static charge, which in gutta-percha-covered wire can find an exit only at the ends.

It is also evident that there is no difficulty in working telephones through underground wires, even though they attain fifty miles in length, and in fact it would be better to work underground with proper copper wire from London to Brighton, than to use iron wires along the railway telegraph poles, owing to the absence of external disturbances in the former case.

March 17.—"Second Note on the Geometrical Construction of the Cell of the Honey Bee (Roy. Soc. Proc. vol. xxxix. p. 253, and vol. xli. p. 442)." By Prof. H. Hennessy, F.R.S.

The author deduces from the results established in his communications as above cited that, while the trihedral pyramid at the apex of the cell may be inscribed in a sphere whose diameter, D, is equal to the sum of the three edges of the pyramid, another sphere may be inscribed within the cell touching all of its nine faces and whose diameter, D', is equal to the diameter of the cell, and that between these diameters the following relation exists :—

$$\frac{D}{D'} = \left(\frac{3}{2}\right)^{\frac{3}{2}}.$$

The connexion between the geometrical cell and its inscribed and circumscribing spheres is pointed out as possibly bearing on the mode of formation of the actual cells.

"A Coal-dust Explosion." By W. Galloway. Communicated by R. H. Scott, M.A., F.R.S.

Zoological Society, March 1.—Prof. W. H. Flower, F.R.S., President, in the chair.—Prof. Jeffrey Bell read extracts from a communication sent to him by Mr. Edgar Thurston, Superintendent of the Government Central Museum, Madras, containing observations on two species of Batrachians of the genus *Cacopus*.—Mr. O. Salvin (on behalf of Mr. F. D. Godman) exhibited a pair of a large and rare Butterfly (*Ornithoptera victoriæ*), the male of which had been hitherto undescribed. These specimens were obtained at the end of May 1886 by Mr. C. M. Woodford, at North-West Bay, Maleita Island, one of the Solomon group.—Mr. E. B. Poulton read a paper containing an account of his experiments on the protective value of colourand markings in insects (especially in Lepidopterous larvæ) in their relation to Vertebrata. It was found that conspicuous insects were nearly always refused by birds and lizards, but that they were eaten in extreme hunger: hence the unpleasant taste failed as a protection under these circumstances. Further, conspicuous and unpalatable insects, although widely separated, tended to converge in colour and pattern, being thus more easily seen and remembered by their enemies. In the insects protected by resembling their surroundings it was observed that mere size might prevent the attacks of small enemies. Some such insects were unpalatable, but could not be distinguished from the others. In tracing the inedibility through the stages, it was found that no inedible imago was edible in the larval stage; in this stage therefore the unpleasant taste arose.—Mr. G. A. Boulenger read a paper descriptive of the fishes collected by the late Mr. Clarence Buckley in Ecuador. The set of all the species in the collection acquired by the British Museum in 1880 contained a large number of highly interesting and well-preserved specimens. Amongst them were representatives of ten species described as new to science.—Mr. Richard S. Wray, read a note on a vestigial structure in the adult Ostrich representing the distal phalanges of the third digit.—Mr. John H. Ponsonby communicated (on behalf of Mr. Andrew Garrett) the second and concluding part of a paper on the Terrestrial Mollusks of the Viti or Fiji Islands.—Mr. Edgar A. Smith gave an account of a small collection of shells from the Loo-Choo Islands, made by Mr. H. Pryer.

Geological Society, February 18.—Annual General Meeting. —Prof. J. W. Judd, F.R.S., President, in the chair.—Having presented the various medals, and the proceeds of the Donation Funds in the gift of the Society, the President read his Anniversary Address, which we have already printed.—The ballot for the Council and Officers was taken, and the following were duly elected for the ensuing year :—President: Prof. J. W. Judd, F.R.S. Vice-Presidents: H. Bauerman, Prof. T. G. Bonney, F.R.S., A. Geikie, F.R.S., Henry Woodward, F.R.S. Secretaries: W. T. Blanford, F.R.S., and W. H. Hudleston, F.R.S. Foreign Secretary: Warington W. Smyth, F.R.S. Treasurer: Prof. T. Wiltshire. Council: H. Bauerman, W. T. Blanford, F.R.S., Prof. T. G. Bonney, F.R.S., A. Champernowne, Thomas Davies, Prof. P. M. Duncan, F.R.S., A. Geikie, F.R.S., Henry Hicks, F.R.S., Rev. Edwin Hill, W. H. Hudleston, F.R.S., J. W. Hulke, F.R.S., Prof. T. McKenny Hughes, Prof. T. Rupert Jones, F.R.S., Prof. J. W. Judd, F.R.S., R. Lydekker, J. E. Marr, E. T. Newton, Prof. H. G. Seeley, F.R.S., Warington W. Smyth, F.R.S., J. J. H. Teall, Prof. T. Wiltshire, Rev. H. H. Winwood, Henry Woodward, F.R.S.

February 23.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—On the origin of dry chalk valleys and of Coombe rock, by Mr. Clement Reid. Whilst engaged in examining the Pleistocene deposits of Sussex, for the Geological Survey, the author observed that the Coombe rock differs from anything commonly seen in the strongly glaciated districts of the Yorkshire and Lincolnshire Wolds. As in these localities, the seaward slope of the South Downs is broken by the line of a partially buried sea-cliff before passing under the low-lying drift areas. Subsequent to the formation of this sea-cliff a mass of angular flint and chalk detritus spread out from the Downs over the low lands, being seldom found far up the valleys. This is the Coombe rock, which passes further on into a worthless mixture of angular flint and loam, and at a still greater distance into almost clean brick-earth. It is not of glacial origin, neither is it marine, nor is it a gravel formed by ordinary fluviatile action. The rolling outline of the Downs, and the steep-sided dry valleys point to conditions which have passed away. However much rain may fall, the upper parts of these valleys are always dry, and no running water can be found where the incline of the bottom of the valley exceeds the slope of the plane of saturation—never more than 60 feet per mile. The author discussed the various explanations which have been offered. In suggesting an origin for the dry valleys and Coombe rock, he considers that the fauna and flora, both at Fisherton and Bovey Tracey, point to a great degree of cold, from 20° to 30° lower than what now prevails in the South of England. The ground would thus be frozen to the depth of several hundred feet, and the drainage system of the chalk entirely modified. There would be no underground circulation. The summer rains would immediately run off any steep slope, often in violent torrents. These would tear up the layer of rubble already loosened by the frost, carrying down masses of unthawed chalk too rapidly for solvents to have much effect. No Coombe rock is found in valleys that have a greater slope than 100 feet per mile. There is no need of excessive rainfall; it might have been a dry period corresponding to that of the loess. If the time had not been short, all soft rocks in the South of England would have been planed down to one gently undulating surface like the plains of Russia and Siberia. Such tundra-conditions may have occurred more than once.—Probable amount of former glaciation of Norway, as demonstrated by the present condition of rocks upon and near the western coast, by Mr. W. F. Stanley.

Mathematical Society, March 10.—Sir James Cockle, F.R.S., President, in the chair.—The following communications were made:—A metrical property of plane curves, by R. Lachlan.—Note on the Weierstrass functions, by Mr. A. G. Greenhill.—Second paper on the change of the independent variable; with applications to some functions of the reciprocant kind, by C. Leudesdorf.—A note on knots, by Mr. A. B. Kempe, F.R.S.

Chemical Society, March 3.—Dr. Hugo Müller, F.R.S., President, in the chair.—The following papers were read:—Tartaric and racemic acids and the magnetic rotatory power of their ethyl salts, by Dr. W. H. Perkin, F.R.S.—Anhydracetonebenzil, by Mr. Francis R. Japp, F.R.S., and Mr. Cosmo Innes Burton.—Condensation compounds of benzil with ketones, by the same.—Constitution of glycosine, by Mr. Francis R. Japp, F.R.S., and Mr. E. Cleminshaw.—Diphenylglyoxaline and methyldiphenylglyoxaline, by Mr. Francis R. Japp, F.R.S.—Dehydracetic acid, by Dr. W. H. Perkin, Jun.—The colouring-matter of *Drosera Whittakeri*, by Prof. E. H. Rennie.—Further notes on the di-haloid derivatives of thiocarbamide, by Dr. George McGowan.

Anthropological Institute, March 8.—Mr. Francis Galton' F.R.S., President, in the chair.—Mr. A. L. Lewis read a paper on stone circles near Aberdeen. In this paper Mr. Lewis described in detail two circles near Dyce and Portlethen respectively, and drew particular attention to the fact that they differ in two important particulars from the circles of Southern Britain. In former papers on stone circles the author had insisted on the presence of a special reference to the north-east, but in these circles the main direction is north and south. They are further distinguished from the southern circles by the existence of an oblong stone flanked by two upright stones, which is indeed their principal feature, and which exists nowhere except in the Aberdeen district, where it is almost universal. Mr. Lewis regarded the Aberdeen circles as having more affinity to the "giants' graves" found in the north of Ireland, than to the English circles to which it has always been sought to ally them.—The following papers were also read:—Palæolithic implements from the drift-gravels of the Singrauli Basin, South Mirzapore, by Mr. J. Cockburn.—Stone implements from Perak, by Mr. Abraham Hale.

Entomological Society, March 2.—Dr. D. Sharp, President, in the chair.—Mr. Slater exhibited, with the object of showing the effect of food in causing variation in Lepidoptera, two specimens of *Arctia caja*, one of which was bred from a larva fed on lime-leaves, and the other from a larva fed on low plants, the ordinary pabulum of the species.—Capt. H. J. Elwes exhibited a large number of Lepidoptera-Heterocera, caught by him at Darjeeling, in Sikkim, at an elevation of 7000 feet, on the night of August 4, 1886, between 9 p.m. and 1 a.m. The specimens exhibited represented upwards of 120 species, belonging to Bombyces, Noctuæ, Geometræ, Crambidæ, &c., many of which were believed to be undescribed. Capt. Elwes stated that Mr. A. R. Wallace's observations on the conditions most favourable for collecting moths in the tropics were fully confirmed by his own experience during four months' collecting in Sikkim and the Khasias. The conditions referred to were a dark wet night in the rainy season; a situation commanding a large extent of virgin forest and uncultivated ground; and a whitewashed veranda with powerful lamps in it. He also made some remarks on the Khasia Hills, the southern slopes of which he believed to be the true habitat of the greater part of those insects described many years ago by Prof. Westwood and others as coming from Sylhet. A discussion ensued, in which Mr. McLachan, Dr. Sharp, Mr. Champion, Mr. Kirby, and others took part.—The Rev. W. W. Fowler exhibited a specimen of *Cathormiocerus socius*, taken at Sandown, Isle of Wight.—Mr. S. Stevens exhibited specimens of *Cathormiocerus maritimus* and *Platytarsus hirtus*.—Mr. F. Grut said he was requested by M. Péringuey, of Cape Town, to announce that the latter was engaged on a monograph of the genus *Hipporrhinus*, and that he would be glad to receive specimens and other assistance from British entomologists.—Mr. Gervase F. Mathew, R.N., communicated a paper entitled "Descriptions of new species of Rhopalocera from the Solomon Islands."—Mr. G. T. Baker communicated the following papers: "Description of a new species of the Lepidopterous genus *Carama*, together with a few notes on the genus"; and "Description of a new genus of Rhopalocera allied to *Thecla*."

Institution of Civil Engineers, February 22.—Mr. Edward Woods, President, in the chair.—A paper was read on irrigation in Lower Egypt, by Mr. William Willcocks.

March 1.—Mr. Edward Woods, President, in the chair.—A paper was read on dredging-operations and appliances, by Mr. John James Webster. The author described the objects for which dredging-operations are generally carried out, and spoke of the advantage of obtaining the aid of natural scour, when possible, for supplementing or dispensing with dredging. The various kinds of appliances used were fully described.

March 15.—Mr. Edward Woods, President, in the chair.—A paper was read on the treatment of gun-steel, by Colonel Eardly Maitland, R.A.

PARIS

Academy of Sciences, March 14.—M. Janssen, President, in the chair.—Reply to M. Houzeau's additional note, by M. Lœwy. It is argued that M. Houzeau's mistake lies in the arrangement proposed by him in 1871, which is practically that of a sextant with fixed opening. The principle of the sextant is based on the combination of two mirrors, which in virtue of known optical conditions must give it an undoubted superiority over M. Houzeau's apparatus, which is provided with only one mirror.—On a problem relating to the theory of minima surfaces, by M. Gaston Darboux. To the different solutions of the problem given in vol. cii. of the *Comptes rendus* (1886), is here added another which rests on a new genesis of minima surfaces proposed in an important memoir by M. Ribaucour.—On the great movements of the atmosphere, and on M. Colladon's note of March 7, by M. H. Faye. The paper deals with M. Colladon's suggestion, based on M. Weyher's recent experiments, that rotatory movements with vertical axis may have both an ascending and a descending direction, thus presenting a middle term between the extreme views of M. Faye and his opponents.—On the artificial production of the ruby, by M. Fremy. Some remarks are presented on the two processes elaborated by MM. Fremy and Feil, in connexion with the recent death of M. Feil. A third method is referred to which has since been brought to great perfection with the co-operation of M. Verneuil. A paper followed, by MM. Fremy and Verneuil, on the action of the fluorides on alumina in connexion with the same subject.—The small *Ursus spelæus* of Gargas, by M. Albert Gaudry. A description is given of this species of cave-bear, a skeleton of which, made up with the bones of several individuals, has just been mounted in the new room for palæontological specimens in the Natural History Museum.—Details collected from various sources on the earthquake of February 23, by M. F. Fouqué. An account is given of the vibrations recorded at the Observatories of Lisbon, Wilhelmshafen, and Seville; the general conclusion being that the magnetic disturbances were not the cause, but rather the effect, of the shocks.—Report on MM. Guyou and Simart's memoir on the development of naval geometry as applied to the question of the stability of vessels, by the Commissioners, MM. Phillips, Lévy, Sarrau, and de Jonquières. The report speaks favourably of MM. Guyou and Simart's studies, which greatly reduce the elaborate calculations hitherto required to be worked out in determining questions of stability from the theoretical and practical stand-points.—Experiments on the effects of the transfusion of blood into the heads of decapitated animals (second note), by MM. G. Hayem and G. Barrier. The experiments show that the time is limited to about ten seconds, during which it is possible by transfusion of arterial blood to momentarily revive the action of the sensor and motor cortical centres.—On a correlation between earthquakes and the declinations of the moon, by M. H. de Parville. A systematic study of lunar and terrestial phenomena continued for a quarter of a century leads the author to infer a distinct relation between lunar declination and earthquakes, the general law being that the disturbances occur either at the equilune, the lunistice, or exactly when the sun and moon have the same declination.—On the variations in the absorption-spectra of didymium, by M. Henri Becquerel. Fresh experiments here described confirm the previous conclusion of the author regarding the presence of foreign substances in didymium, as revealed by its absorption-spectra. Some of these bodies may possibly be diverse combinations of the same with another substance or with itself, such combinations being so stable that it has hitherto been impossible to transform one into the other.—On the specific heat of a salt-solution, by M. P. Duhem. The method employed by the author to find the expression of the heat of solution is here shown to lead also to the expression of the specific heat of a salt-solution.—On a standard pile, by M. Gouy. The author describes a convenient standard of electromotor force, formed with zinc, sulphate of zinc, mercury, and dioxide of mercury.—Researches on the application of rotatory force to the study of certain compounds produced in the solutions of tartaric acid, by M. D. Gernez.—On a general method of forming the manganites from the permanganates, by M. G. Rousseau. The metallic permanganates are transformed to manganates at a temperature ranging from 100° to 150° C., and as the law of decomposition here formulated is applicable to the compounds of the whole series, it is proposed as a general method for obtaining most of the metallic manganates.—On the reticulated structure of the protoplasm of the Infusoria, by M. Fabre-Domergue.

BERLIN

Physiological Society, February 25.—Prof. Munk in the chair.—The President communicated two treatises sent, for publication in the Proceedings of the Society, by Prof. Kronecker, of Berne. In the first, Prof. Kronecker had, in conjunction with Fräulein Popoff, examined the formation of serous albumen in the intestinal canal. As reagents they made use of the hearts of frogs and tortoises, void of blood, which were stimulated to contraction only when blood or a solution of serous albumen was poured through them, but under every other albuminous or saline solution remained inactive. Stomachic peptone was incapable of nourishing the heart. When, however, the peptone was kept for some time in the stomach or in an intestinal coil connected with the mesentery, then it acted on the heart in the same way as did serous albumen. Pancreatic peptone was incapable, either of itself or after remaining in the stomach or the intestine, of stimulating the heart to contraction; by exposure for a considerable time to the air, the peptone likewise became nutritious to the heart.—In the second treatise, containing an investigation by Prof. Kronecker and Fräulein Rink, it was demonstrated that in peptone solution two kinds of Bacteria are developed in the presence of air: *Bacillus restituens*, which transformed the peptone into serous albumen, exactly in the same way as did the living mucous membrane of the stomach; and *Bacillus virescens*, which liquefied the alimentary gelatine and imparted a deep blue colouring to all sterilised substrata when exposed to the air. This latter Bacillus operated poisonously on the heart.—Dr. Benda spoke of the function of the cross-striped muscle substance. By anatomical investigation of the muscles of the river crayfish he had arrived at the conviction that it was only the cross-striped substance which generated the contraction, while it was in the highest degree probable that the protoplasm discharged the office of mediation between the ends of the motory nerves and the contractile substance.—Prof, Ewald described some comparative experiments performed on three patients to ascertain the amount of nourishment with different commercial peptones, with eggs, and with eggs to which were added pepsine and hydrate of chlorine. The nutritive fluids were supplied *per enema*, and the individually very changeable nitrogenous transpositions were determined by careful analyses of the ingesta and egesta.

Meteorological Society, March 1.—Prof. von Bezold in the chair.—Dr. Kremser communicated the results of an investigation into the variability of atmospheric temperature in Germany. Variability he understood, in accordance with Hann's definition, to be the difference between the mean temperature on two consecutive days. Such variability was found by Dr. Kremser to attain its greatest magnitude in the mountains and in the eastern provinces, and its least range along the coasts of the Baltic and North sea, and on the islands. The maximum was in the Riesengebirge, 4°·3 F., the minimum on the islands of the North Sea, 2°·3. If the monthly means were arranged in chronological sequence for the year, there was presented an annual march of temperature with a chief maximum in December and a secondary in June. The variability of temperature at each of the different hours, 6 a.m., 2 p.m., and 10 p.m., yielded values differing from those of the variability of the daily means of temperature. Yet the yearly march of variability of each of the different hours already specified was similar to the yearly march of variability of the daily means. The greatest change of temperature affecting an individual period of twenty-four hours was observed in Clausen, amounting to 68° F. In Berlin, the greatest change to which the same period was liable was 24°·7; in Munich it was 30°·6. A variability of 18°·0 affecting a period of twenty-four hours might be expected in the course of a year in the east and south, but along the North Sea coast only in a period of three years. As the basis for the above conclusions, Dr. Kremser had made use of the observations of ten years.

BOOKS, PAMPHLETS, and SERIALS RECEIVED

Gairloch: J. H. Dixon (Edinburgh).—Catalogue of Siwalik Vertebrata contained in the Geological Department of the Indian Museum, Calcutta; part 1, Mammalia; part 2, Aves, Reptilia, and Pisces: R. Lydekker (Calcutta).—Catalogue of Pleistocene and Prehistoric Vertebrata contained in the Geological Department of the Indian Museum, Calcutta: R. Lydekker (Calcutta).—Memoirs of the Geological Survey of India. Palæontologia Indica, ser. xiii. Salt Range Fossils: W. Waagen; ser. xii. The Fossil Flora of the Gondwana System, vol. iv. part 2, The Fossil Flora of some of the Coal-Fields in Western Bengal: O. Feistmantel (Trübner).—*Challenger* Reports, vol. xviii., 3 parts.—Science of Thought: F. Max Müller (Longmans).—Le Commozioni Telluriche il Terremoto del 23 Febbraio, 1887 (Roux, Torino).—On Over-work and Premature Mental Decay, 4th edition: C H. F. Routh (Baillière, Tindall, and Cox).—Geological History of Lake Lahontan: J. C. Russell (Washington).—Transactions of the Academy of Science of St. Louis, vol. iv. No. 4 (St. Louis).—Proceedings of the American Philosophical Society, vol. xxiii. No. 124 (Philadelphia).—Essentials of Histology, 2nd edition: E. A. Schäfer (Longmans).—Natural History Transactions of Northumberland, Durham, and Newcastle-upon-Tyne, vol. viii. part 2 (Williams and Norgate).—Verhandlungen des deutschen Wissenschaftlichen vereins zu Santiago, 3 Heft (Valparaiso).—A Plea for a Midland University: H. W. Crosskey (Cornish, Birmingham).—Proceedings of the Academy of Natural Sciences of Philadelphia, part 3, October to December 1886 (Philadelphia).—American Naturalist, January (Lippincott).—Annalen der Physik und Chemie, No. 4, 1887; Beiblätter der Physik und Chemie, No. 2, 1887 (Barth, Leipzig).

CONTENTS

THURSDAY, MARCH 31, 1887

A UNIVERSITY FOR LONDON

WE have from time to time informed our readers of the progress made in the attempt to organise the capacities for teaching and learning in London into a more complete and more efficient shape. The movement is most natural and admirable. What we have desired is to warn those interested in it not to lose sight of the full result obtainable while busied in their attempts to remove a particular grievance or further a particular interest. Each constituent of the future University—the Colleges and professional schools, the teachers and the students, the medical corporations, and the Senate and Convocation of the existing University of London—each is indispensable. Any one of these can block the way for the rest. Together they make up amply sufficient elements for the foundation desired, and this foundation would not be strengthened, but weakened, by attempts (which can never be realised) to bring in such heterogeneous elements as the British Museum or the Royal Society, the Government technical schools or the Corporation of the City and its Companies.

The present state of affairs is, we believe, pretty much as follows. The Convocation of the present University, in which the first efforts towards its reform began some six or seven years ago, rejected a scheme presented to it by a Committee of forty of its most distinguished members, of which Lord Justice Fry was the chairman. Among them were the present Home Secretary, the President of the Royal College of Surgeons, Mr. Justice Wills, Sir Joseph Lister, Dr. Wilks, Prof. Michael Foster, Dr. Bristowe, Mr. Power, Mr. Howse, Dr. Ord, Prof. Unwin, Mr. Thiselton Dyer, Mr. Anstie, Prof. Carey Foster, the Rev. Dr. Dale, and Mr. Cozens-Hardy. A second and much smaller Committee was then constructed by Mr. (now Sir Philip) Magnus, who had taken the lead in opposing some of the provisions of the previous scheme, and this Committee brought up, on report, a second and modified plan of reform, which passed Convocation last May, not without opposition, but by substantial majorities and with only minor alterations. This second Committee laid the amended scheme before the Senate and remain in charge of it. Meantime the Senate had appointed a Committee of its own members, who have for several months been elaborating a scheme of their own, who have already conferred both with the Committee of Convocation and with one appointed by the Teaching University Association, and who have now presented their Report to the Senate. Some opportune vacancies, which occurred in the latter body during the last two or three years, have led to the presence of Lord Justice Fry himself, and of Dr. Wilks, Dr. Pye Smith, and Prof. Carey Foster. It seems probable that a scheme of reform will be accepted both by Senate and Convocation, which will go as far as most who are sanguine could expect, and farther than most who are timid will approve. The Convocation of graduates will gain more direct representation, and the teachers of the Colleges which send up men for the University degrees will probably be also directly represented on the Senate. But a more important improvement, one that would be useful even if the Senate were to remain exactly as it is, will almost certainly be the institution of Boards of Studies, which will represent the teachers and probably the examiners in each Faculty, much like the standing Committees which sit under the same name at Oxford. The general body of teachers which would elect these Boards would include provincial as well as London Professors, and would more or less correspond to the Congregation of Oxford, but it would probably seldom meet, except for the purpose of election of the representative Boards of Studies.

The Association for Promoting a Teaching University held a general meeting several weeks ago, and admirable speeches were made, especially those of Mr. Marshall and Mr. Bryce, but it lacked the enthusiasm given by numbers. After communicating with the principal London Colleges and Medical Schools, the Council of the Association propose to apply either to the Crown or to Parliament, probably with the object of securing a Royal Commission on the whole question.

University College, after coquetting with the Victoria University (which has apparently not welcomed with great warmth the proposal of accepting so large and distant a Society as its daughter), is now engaged in direct negotiations with King's College, with a view to agreement upon a common plan of action. This is a prudent course, for if the reform of the University of London should prove unattainable or inadequate, the two chief Colleges, by acting together, would be far more likely to obtain the privileges which they then would rightly seek.

Meantime the great medical corporations have become tired of waiting. They represent the most urgent grievance, and are fully justified in pressing for its redress. They appear likely to ask for power to grant degrees to their own licentiates, though under what authority and on what terms, either of examination or of residence, they have not yet determined. They have the advantage of practically undivided counsels, of knowing what they want, and of having an indisputable cause of complaint. They are naturally supported by the whole influence of the medical schools of London, and it adds not a little to the complexity of the situation that those connected with University and King's Colleges prefer to throw in their lot with the other professional schools rather than to hold aloof and unite with the other Faculties of their own Colleges.

Of the several bodies concerned, it is possible that the Senate, or at least the Convocation, of the existing University may fear that the just value of its degrees, attained by fifty years' efforts, will be compromised by allowing teachers to have a voice upon the Senate. But they must see that if the University is forsaken by its two most important London Colleges after the secession of its only important provincial one (Owens College), and if the medical schools of London, which have supplied nine-tenths of its graduates in that Faculty, also forsake it, its position will be untenable. Even if it were suffered to exist as a degree-conferring machine for unattached and imperfectly-taught students all over the kingdom, it would become what its worst enemies have called it, a mere Government Board, and could scarcely keep the title of a University, still less of the University of London, when it had been stripped (or rather had stripped itself) of both characters. Moreover, Convocation would lose all importance, and could not possibly retain the only powers it at present possesses, of nominating certain members of the Senate and accepting new charters. The Senate would do its sole work, of choosing examiners and revising their lists, as a small body of salaried Government officials (probably in South Kensington), and no claim would remain for the unconnected waifs and strays who passed the examinations to take any part in the matter. No charters would be requisite, nor any apparatus of library or Senate House, laboratory or lectures. In fact all the efforts of the past twenty years would be thrown away.

Nevertheless, if the two original Colleges of the University secede, they will find the name, the prescription and the influence of the Senate too strong for them to, wrest its powers from the present holders.

The medical corporations have far more influence and far stronger grounds; for the three or four strongest of them are organised as complete Colleges in their own Faculty, and give a more academic training to their students in medicine than either University or King's College does to students in arts, science, or laws. They might, perhaps, succeed in gaining power to grant degrees where the others failed, but this could only be by showing that no reasonable concessions were made to their just demands by the existing University.

Hence it will be seen that the present University of London, its two original Colleges, and the principal medical schools, have each of them the power of checking, if not of checkmating, each other's plans. Even if they agreed to urge their several objects without opposition to each other, the result would be three Universities existing together in London. One would have become a mere examining Government Board; another would consist of two ill-endowed and ill-consorted Colleges, without residence, with slender endowments, and compelled to extend their proper functions by attempting the instruction of partial students; the third would be a combination of two large professional corporations with Colleges in one faculty only, two or three well equipped, several very poorly furnished, and all of necessity rivals, scattered over the country, none of them endowed, and only able by the terms of their existence to give a second-rate degree.

What hope would there be of any one of these three so-called Universities even approximating to what a University of London should be? Each would be strong enough to prevent the others succeeding; none would be strong enough to absorb its rivals. Meanwhile the higher education would deteriorate rather than improve, endowments would be indefinitely postponed, and the prospects of the University laboratories, museums, and libraries of London sending out worthy contributions to the progress of human knowledge would become poor indeed.

When the several separate movements now in progress are checked by the necessity of obtaining the sanction if not the support of Government, we may hope that broader views will be taken of what is best for the community, and more sober views of what is practically attainable. Believing in the public spirit and the good sense of our countrymen, we have little fear but that, with patience and mutual concessions, a combined result will be obtained which will benefit all the parties to the new confederation, and promote the only interests with which this journal is concerned—the national interests of learning and of science.

A JUNIOR COURSE OF PRACTICAL ZOOLOGY

A Junior Course of Practical Zoology. By A. Milnes Marshall, M.D., D.Sc., M.A., F.R.S., Professor in the Victoria University, assisted by C. Herbert Hurst. (London: Smith, Elder, and Co., 1887.)

NOTICE will be found in the columns of this journal (vol. xxxiii. p. 242) of the second edition of a small laboratory hand-book by the senior author of the above-named work, entitled "The Frog; an Introduction to Anatomy and Histology." In the preface to that we read: "The second instalment of the work, containing directions for the examination and dissection of a number of animals chosen as types of the principal zoological groups, is in active preparation, and will be published shortly." The author further acknowledges "valuable help from Mr. C. H. Hurst, Assistant Lecturer in Zoology in the College." Mr. Hurst now appears as junior author, and, although the work here under review differs in some important respects from its predecessor above referred to, we presume that it is the promised "second instalment."

The volume opens with an introduction, confined to the consideration of practical hints as to methods of working and manipulation; then follow fifteen chapters, each devoted to some one type of organisation, and the whole closes with an appendix, dealing with the uses and methods of preparation of reagents. We have, in all, a most successful and important book of 421 pages.

The work is largely akin, in its more salient features, to many of its predecessors; but it stands alone in respect of certain methods of treatment, to which we shall refer duly. Thick type has been employed throughout for the various headings, and the authors adopt the plan, introduced in the aforenamed smaller work, of printing the directions for dissection in italics. In dealing with the complications of the vertebrate skeleton, they have availed themselves of the printer's art, by way of restricting descriptions of homologous sets of elements to corresponding and distinct types.

The introduction is a model of perspicuity, and so well set as to render it impossible for the veriest tyro to obtain anything but full benefit therefrom. The advice given is sound in the extreme, and such as could only have embodied the results of a long and well-tried experience. The directions for injecting blood-vessels are, perhaps, a little too elaborate, being worthy of the *préparateur's* art, rather than of the ordinary beginner; this, however, is a small defect on the right side. We note that under the section on microscopical examination all reference to the micrometer has been omitted. Directions for measuring objects under observation should certainly be added to the next edition.

The several chapters into which the book is subdivided differ most conspicuously from those of certain earlier works in the fact that the more general statements made are diffused throughout the whole, except so far as they serve to define an animal under consideration, or to set forth the predominant characters of a given system of parts. The chapters on Protozoa and the Leech may be consulted as fair examples. In the latter, advantage is taken of this method to force upon the student, somewhat prematurely, the fact that (p. 36) "the segmental arrangement affects in a marked manner the nervous, excretory, and reproductive systems, and, to a less degree, the circulatory and digestive organs," and the deduction that "it appears to result from a definite arrangement of parts which, in the ancestors of the leeches, were scattered irregularly through the body, much as in *Fasciola*" (dealt with in the previous chapter).

By way of contrast with its predecessor on the Frog, this volume is shorn of much that is histological. In the earlier work a special feature was made of this branch, but here it by no means receives that amount of attention which its importance demands. A start in this direction might well be made with the lung-structure of the bird and mammal, especially in view of the statement made (p. 389) concerning the mechanism of respiration in the former.

The detailed descriptions of the various animals chosen are, for the most part, exceedingly well rendered. A slight ambiguity has crept in in one or two places, and the descriptions of the vascular systems of the mussel and snail might well be amplified.

No portions of the descriptive text stand more in need of revision than those relating to the digestive glands. These are, in Anodon, Helix, Astacus, and Amphioxus, designated under the old term "liver." A certain amount of justification is forthcoming in the last-named case, in view of its blood-supply; but in the three first-named the striking results of recent research, which call for no comment here, ought at least to be suggested in the term "digestive gland" or "hepato-pancreas." While we would see, thus, the substitution of a modern term for one well-nigh obsolete, we would desire the withdrawal of the terms "kidney" and "ureter" as applied to the excretory organs of the Invertebrata. In the case of the mussel, in which a portion of that which our authors term "ureter," is glandular and secretory, the terminology as restricted by them becomes misleading.

Conspicuous among the novelties offered us are certain words new to students' books. The volume is fully up to date, and its authors are to be congratulated on having produced the first book for students in the language, which describes the receptaculum ovorum of the worm. As regards pure nomenclature, it is worthy of note that they have embodied, in describing the pterylosis of the bird's wing (p. 386), that introduced by Prof. Flower so recently as February 1886, in a lecture delivered at the Royal Institution; and necessitated by the splendid work in which he is being assisted by Mr. R. S. Wray. (The description of the barbules on the same page is in error.)

In dealing with the appendages of the insect, the nomenclature customarily applied to the crustacean limb is utilised. To this extension we heartily assent. On turning to the crustacean itself, we meet with an innovation far less deserving of support. Our authors, faithful to precedent, reduce the body of the decapod crustacean to twenty segments; but in so doing they discard the ophthalmic somite of their seniors, and press the telson into the service. This introduces a serious difficulty when the nervous system is taken into consideration, and a still more formidable one as concerns the homology of the eye-stalk. That is passed over in comparative silence, and, although we are not told so in as many words, it is clear that they regard it as in no way serially homologous with the appendages. The condition of the visual organ in the lower Crustacea and other arthropods, taken in conjunction with the facts adduced by Brandt and others in the morphology of the insect's eye, render it probable that the above view may turn out to be correct. Nor must it be forgotten that Boas has challenged (*Morpholog. Jahrbuch*, vol. viii.) the accepted interpretations of the antennule. There are, however, two sides to this question, and it is important to observe that M. Alphonse Milne-Edwards has recently described a decapod (*Palinurus penicillatus*, *Comptes rendus*, vol. lix., 1864), in which one ophthalmite was for the most part multiarticulate and antenniform. This remarkable fact is the more striking in view of the reversion to the antenniform type of certain post-oral appendages, seen in *Mastigopus* and *Apseudes* among the Crustacea, and so well known in the scorpion-spiders; whatever may be its precise significance, it is clear that the question of general homology of the eye-stalk, with which we are here especially concerned, is far from settled. The introduction of so sweeping a change into a book for juniors without due comment is, under these circumstances, a false step, especially when it is considered that the precise converse is stated in all other books current.

Equally unjustifiable, in that it affects another debatable question, is the statement (p. 379) that the bird's pre-pubic process corresponds to the pubis of mammals. Clear proof of this is not forthcoming. The student's hand-book is not the place for such dogmatisms: if asserted, they should be well qualified, and put as alternatives.

The retention of the old nomenclature for the bird's air-sacs, with its atrocious "*thoracic*" element, is disappointing; the substitution (p. 220) of "pericardio-*cœlomic*" for the well-tried pericardio-peritoneal canal of the fish is as misleading as it is misjudged; while that of "*connective*" for the time-honoured commissure is, on the whole, inadvisable. We live in a word-mongering age. New terms which do not mark a turning-point in advance, or at least the era of a new discovery, are stumbling-blocks, unless introduced by way of replacing irrelevant or absolutely fantastic precursors. Such is not the case with those here under consideration. Our position is somewhat that of the port-bound crew, in dread of being stranded on their own beef-bones.

Attention has been already directed to the diffusion of the more general matter throughout the text. This has been effected very successfully, and in well-chosen language deserving of the greatest praise; but we dissent from the method adopted. It will be generally admitted that Huxley and Martin's "Elementary Biology" dissipated for students of the subject, once and for ever, the subtle "cram"; and subsequent writers working along similar lines have, as was to be expected, attempted to improve upon the plan therein created, each after his own lights. Messrs. Marshall and Hurst have aimed at producing a work which they hope "may meet the wants of those who desire to obtain a practical acquaintance with the elements of animal morphology, and who find the existing manuals insufficient for their purpose." It is to be assumed that they have been especially mindful of the needs of their own College, but the work also covers most of the requirements for the elementary examinations of other schools, and we presume the authors would wish it a general circulation among pure devotees. This said, we proceed to inquire into the method of treatment, and find with much regret that, at the outset, such deductions as are incorporated in the text almost invariably precede the description of those facts upon which they are based. For example: on p. 141, the alimentary canal of the crayfish—itself complicated—is ushered in with the words that it is "a tube running in a nearly straight line from mouth to anus. Of this tube, the middle portion, or mesenteron, which is very short, is alone formed from the primitive alimentary tract of the embryo, and the 'liver' is an outgrowth of it. The stomatodæum, or anterior portion of the canal and the proctodæum, or hind portion, which together form almost the whole length of the canal, are both formed by invagination of the external surface of the body; and both have a chitinous lining which is continuous, at the mouth and anus respectively, with the chitinous external covering of the body." Then follows the detailed description. Again, the podical plates of the insect are twice mentioned before the student is told how to find them. The tympano-Eustachian passage of the bird is (p. 414) similarly treated; and here the generalisation given should, if introduced at all, have been rather inserted when dealing with the mammal, on the supposition that, as can hardly be doubted, the authors would have the student work over the animals in the order of presentation. In such cases as the dogfish skeleton (p. 198), the limbs of the mammal and bird (pp. 287 and 376), and the enumeration of the differences between Amphioxus and the higher Vertebrata (p. 168), the system is tolerable, by way of clearing the ground and exciting interest. When, however, as in the first-cited instance, the crowning triumph of the student's labour is thus anticipated and his reward forestalled, deduction on reflection upon his work falls flat, and one of the chief aims of the whole system is lost. This, to our thinking, constitutes the gravest defect in this valuable work.

In describing the rabbit's liver (pp. 306–7), the lobes are rightly enumerated, but the student is not informed upon what grounds the customary nomenclature is adopted. In this, and one or two other instances, explanatory clauses are needed, but not given.

The illustrations are excellent, reflecting the greatest credit upon all concerned, and artistic merit such as that of Fig. 28 cannot fail to strike the reader. Fig. 27 is unnecessarily complicated, too much having been attempted. The beautiful new figures of Amphioxus are especially deserving of praise; but more of them are wanted, in order to do justice to the excellent description which they illustrate. Comparison of this chapter with that on the liver-fluke calls for this increase in number, in view of the relative chances of the student's procuring specimens.

Being mindful of the difficulties of preservation of Amphioxus, it is to be regretted that, while full directions are given for cutting sections, those for preservation, which have led up to the splendid results incorporated in this work, should have been omitted. This, the more so, as the animal is to be obtained in the Channel Islands, and is therefore within reach of the native student (a fact which should be mentioned in the text).

In dealing with the higher vertebrates, the authors follow one of their predecessors in first describing the skeleton. We doubt the advantages of this system, especially as in this work we have an "almost entire omission" of the muscular system, held to be "of subordinate educational value." The book, taken as a whole, is highly welcome and most admirable. It is provided with an exceedingly good index, and presented in a form demanding our sincere thanks alike to authors, printers, and publishers. Taking it, in conjunction with its predecessors, into account, we have to congratulate the student of zoology upon his accessions. This volume yields ample return for the immense labour which its authors have bestowed upon it; it is well worthy of the school which they represent, and of its prototype above named.

It is significant that the only typographical errors which we have detected should be the occasional absence of **i** and **r**. This fact might repay a careful research at the hands of the printer.

The authors state in their preface that "corrections or suggestions from those who use the book will be very gratefully received." Having dealt above with the more important matters which occur to us, we append comments on some of the more obvious among those of wholly minor importance, noted in perusing the volume.

Before proceeding to do this, we wish to call attention to two matters of exceptional note: the first, the respiratory folds of the lining membrane of the fish's mouth; the second, the attachment of the styloid element of the rabbit's hyoid-arch to the paramastoid process. It is indeed remarkable, seeing that these structures are of such common occurrence, and that they have been presented to every native student of recent years, that there is not yet a text-book in the language, or out of it for the matter of that, in which they are described. This is the more surprising in the case of the respiratory folds, in consideration of their general development among the gnathostomatous fishes.

The Hydra. We cannot accept the description of the supporting lamella as the "mesoderm"; it is misleading if not erroneous

The Leech. There is no mention of the intermediary nerve.

The Earthworm. The description of the histology of the nervous system needs amplification, especially as concerns the distribution of the nerve-cells, by way of bringing out the nature of comparison with the other types. The account given of the blood-vessels is incomplete; the sub-intestinal trunk (described by Horst, *Niederland. Tidschr.* vol. xxxvii., and others) is not mentioned, that term being applied, in error, to the supra-neural vessel.

We strongly dissent from the description given of the œsophageal glands. Further investigation is necessary before we can accept their subdivision into the two categories here proposed. By our contemporaries, as by ourselves, much variation has been observed in their number and relationships, and we have seen examples in which all contained calciferous concretions and opened into the gut.

The Edible Snail. In describing the liver, the terms left and right have been transposed. Mention should be made of the salient features, in structure and distribution, of the teeth of the radula.

The Lancelet. To the description of the supposed excretory canals of Lankester (p. 178) there should be added that of the much more likely one of Hatschek (*Zool. Anzeiger*, vol. vii.). We accept the senior author's views on oviposition, but Quatrefages' observation should have been mentioned unless finally disproved.

The Dogfish. The remarks on ossification (p. 194) are erroneous. The statement (p. 211) that the labial cartilages probably "belong to the same category as the extra-branchials" is unfortunate, in view of Dohrn's discovery that the latter are displaced rays of the gill-septum.

In describing the relative positions of the roots of the spinal nerves (p. 252) the terms dorsal and ventral have been transposed. The description is irreconcilable with Fig. 36.

The Rabbit. The description of the shoulder-girdle needs revision, with respect to the coracoid element and the relations of the clavicle. The statements concerning the morphological value of the pisiform would be better free of bias, in view of the tendency of current research. In describing the pelvic girdle, mention of the cotyloid bone has been omitted, and consequently we find the statement that the pubis forms a portion of the acetabulum (cf. Parker, P.Z.S., 1882; also Leche and Krause, *Internat. Journ. of Anat. and Hist.*, vols. i. and ii.). The Eustachian cartilage is deserving of note.

The structural differentiation of the lining membrane of the stomach and base of the rectum need description. The duct of the infra-orbital gland is insufficiently noted; the description of the cæcum needs revision. It is interesting to find that the authors have not discovered the ducts of the rectal glands.

The statement explanatory of the uterus masculinus must be withdrawn or considerably modified, in face of Kolliker's belief that it is a derivative of the Wolffian ducts ("Entwickelungsgesch.," 2nd edition, p. 981). Its structural features and relationships are much more intelligible on this view.

The description of the fifth ventricle needs modification, and that of the spiral valve of the portal vein might well be inserted (Hyrtl, *Sitzb. Akad. Wien.*, 1879).

The Fowl and Pigeon. Note of the more important muscles of the syrinx, as also of the larynx of the mammal, might advantageously be added.

The ventricle of the olfactory lobe is not mentioned, either in the bird or rabbit.

In conclusion, we would wish to draw attention to the satisfactory manner in which the authors have apportioned the several chapters of this successful volume in accordance with their respective value—no light task of its kind. The thoroughness of the book is one of its most striking features.

G. B. H.

EMBRYOGENY OF THE ANTHROPOID APES

Recherches Anatomiques et Embryologiques sur les Singes Anthropoides. By J. Deniker. (Paris, 1886.)

THIS work was presented to the Faculty of Science of Paris as a thesis for the degree of Doctor of Natural Science, and was approved of by it as sufficiently meritorious to warrant the bestowal of that degree on the author. It consists essentially of a comparison of the fœtus of the gorilla and of the gibbon with that of man, and also with young and adult anthropoids.

The embryogeny of the anthropoid apes, notwithstanding the great interest which it presents, is unfortunately little known, probably owing to the difficulties of obtaining embryo specimens. The author has therefore done well to utilise the opportunity which presented itself to further our knowledge of the subject, by publishing the descriptive anatomy of the fœtus of the gorilla and the gibbon which he has had the opportunity of studying. His account of the anatomy of these specimens is rendered more valuable by the comparison he has made between them and the human embryo, and between them and the adult animals of their respective species.

The work begins by a careful description of the external characters of the embryo gorilla and gibbon: the attitude, external form, coloration, and integumentary characters are respectively detailed with much care. The placenta and fœtal membranes were fortunately preserved with the fœtus of the gibbon, and their characters are described and figured, but unfortunately these parts were not obtained with the young gorilla, and so could not be described. A *résumé* is given of the observations of Owen, Huxley, Turner, and others on the placentation of apes and monkeys. The next section contains an account of the weight and dimensions of the various parts of the body of the respective fœtûs. Of the former little can be said on specimens preserved in alcohol, but the dimensions of the entire body, the head, trunk, and extremities, are carefully detailed in a tabular form, with the corresponding measurements in the human fœtus at the fourth and fifth month, and of the adolescent gorilla. A second table shows the relations which the dimensions of the several parts bear to the length of the body, and a third table those between the trunk and the extremities, and between the different segments of the latter. These tables show several interesting points in regard to the proportions which the various parts of the body bear to one another in the course of development. During the second half of intra-uterine life the upper extremity in the anthropoids is much shorter in relation to the length of the trunk than in the adult, and the same relation holds good with respect to the length of the fore-arm as compared with that of the upper arm. In the human fœtus of the same age, on the other hand, the upper extremity presents almost the same proportions that it does in the adult. The relative length of the superior extremity as compared with that of the inferior changes likewise considerably in the course of development. Thus in man during the earlier stages of embryonic life the lengths of both extremities are almost equal, but in the anthropoid apes, at an early period even, the length of the superior limb exceeds that of the inferior.

The skeleton of the fœtus is next compared with that of the adult anthropoids. In treating this part of the body the author naturally devotes considerable attention to the various parts of the skull, and has drawn up several valuable tables of its measurements in the fœtus and adult. The second chapter on the skeleton is devoted to a description of the vertebral column, and the limb bones; while the third treats of the dimensions of the individual bones. The points of ossification of the skull are found to be the same in man and the anthropoid monkeys, but the rate of their development in the monkeys in many important respects differs from what obtains in man. In general it may be stated that the frontal region ossifies more rapidly, whereas the occipital and petro-mastoid regions ossify more slowly than in man. The cranial sections unite probably in the same order as in man, but generally at an earlier age, nevertheless there are certain exceptions to this which are pointed out. The brachycephaly of the skull of young anthropoids diminishes as age advances. Elongation of the facial part of the skull occurs much more rapidly than that of the antero-posterior diameter of the cranial part, until the eruption of the teeth. Passing on to the osteological characters of the rest of the skeleton, we find that the points of ossification of the borders of the vertebræ in the fœtus of the anthropoids do not appear in the same order as in man, as they seem to form simultaneously in all the regions of the vertebral column. The points of ossification of the pleurapophyses of the cervical and sacral vertebræ appear later than in man. This is especially the case in the sacral region of the gibbon. The spinous processes of the cervical vertebræ are shorter in the fœtus and young gorilla than in the adult. In the former the sacrum is broader, the coccyx longer, and the sternum larger, than in the latter. The different segments of the upper and lower limbs, except the carpus, ossify more rapidly in the anthropoid monkeys than in man; the lower limb ossifies, however, more slowly than the upper.

The muscular anatomy of the young and adult anthropoids is fully described and compared, and presents many points of considerable interest. Contrary to the opinion of Bischoff, the muscles of the face are found by the author to be very distinct, not only in the adult but even in the fœtal state. The arrangement of the muscles of the neck, fore-arm, leg, hand, and foot are particularly noteworthy, especially when compared with those in man.

The encephalon of the fœtal gorilla was found to weigh 28 grammes, and equalled a sixteenth part of the entire weight of the body. In the fœtus of both the gorilla and the gibbon the cerebellum is very small, and is completely covered by the cerebrum. The relative and absolute dimensions of the brain of the fœtal gorilla correspond to those of the human fœtus at the fifth month, but in its convolutions it was equivalent to those of the human fœtus at the sixth month, while the frontal lobe corresponds to that of a seven-months child.

The heart of the fœtal gorilla, though absolutely smaller than that of the human, is much greater in proportion to the size of the animal; it is also more voluminous than that of the adult of the same species.

The form of the hyoid bone of the anthropoid apes resembles that of man more nearly in the fœtus than in the adult. Its ossification takes place earlier than in man. The ventricles of the larynx of the fœtal gorilla resemble those of man, and are not continued into the laryngeal sacs.

The development of the dentary follicles of the gorilla and gibbon takes place earlier than in man. The eruption of the milk-teeth occurs in the same order as in man, except that in the gorilla the teeth of the upper jaw appear before those of the lower, that is to say, the reverse of what generally obtains in man. The cæcal appendages increase relatively to age in the gorilla, while in man the contrary appears to be the rule. The spleen of the fœtal gorilla differs in form from that of other anthropoids and from that of man, and resembles more nearly the spleen of a carnivore. The liver of the gorilla has the four-lobed type-form common to the majority of mammals, and in this respect differs from that of man and the other anthropoids.

The work concludes with a chapter on the general result of the author's observations, in which he confirms the statement made several years ago by Huxley that the structural differences between man and the Primates which approach nearest to him are not greater than those which exist between the latter and the other members of the order of the Primates.

OUR BOOK SHELF

The Geographical and Geological Distribution of Animals. By Angelo Heilprin, Professor of Invertebrate Palæontology at, and Curator-in-charge of, the Academy of Natural Science of Philadelphia. (London: Kegan Paul, Trench, & Co., 1887.)

THE author of this book tells us that, while anxious to present to the student a work of general reference, wherein the more salient features of the geography and geology of animal forms could be sought after and readily found, he also wished to call attention to the more significant facts connected with the past and present distribution of animal life, so as to lead to a correct conception of the relations of existing faunas. The need of such a work will be generally acknowledged, and, without doubt, this little volume of some 400 pages does to a great extent supply the need; but it may be that the time has not quite arrived for the appearance of a perfectly satisfactory work on the subject. Though the record of both geographical and geological distribution is a vast one, still there is a vast deal more of the record yet to come, and the very pages of Prof. Heilprin's work show what immense additions to the facts and the deductions drawn from these are based on the as yet incomplete publication of the results of the *Challenger* Expedition. When the author has these results to rely on, we find a certainty of fact and a sureness of deduction which give confidence to a general reader or to a student.

The volume consists of three parts. In the first part the distribution of animals throughout space is treated of; in the second the succession of life, the faunas of the different geological periods, and the appearance and disappearance of species are dealt with; in the third the present and past distribution of individual animal groups is considered. On the many still debatable points the author is always judicious, giving when necessary the opinions both for and against; nor, as far as we have been able to judge, does he fail to call attention to difficulties that surround many of the problems he has to refer to. In reference to the subject of the appearance of species, we observe that he regards the once burning question of the animal nature of Eozoon as settled "through the negative researches of King, Rowney, Julien, and Möbius, the elaborate memoir of the last-named being conclusive."

For the class of readers for whom this work is meant, a glossary of the technical terms employed would have been very useful. Most of them can be learned on reference to original sources, but it would have been convenient to have them within the same cover.

Life-Histories of Plants. By Prof. McAlpine. (London: Swan, Sonnenschein, Lowrey, & Co., 1887.)

THIS book may be dealt with in a very few words. It professes to give the essential features in the life-histories of a considerable number of types. The descriptions are extremely scanty, but in spite of this, room has been found for many very doubtful statements. Thus we have Dodel-Port's speculations as to the fertilisation of red seaweeds by the agency of small animals quoted as if they were well-established facts (p. 184). Chara is spoken of as "a sort of transition stage" between the red and brown sea-weeds (p. 199). We fail to find any grounds for this extraordinary statement. We are informed that in Selaginella "the rain or dew will settle in the hollow of the leaf, and help to float the zoosperms; but in Pinus their dry and motionless representatives are more exposed to the wind on the outer surface of the leaf" (p. 279). It would be difficult to frame a sentence more hopelessly inaccurate than this.

The following passage from the introductory chapter is worth quoting: "Morphology by itself is thus seen to be a matter of mechanism, revealing nothing higher than a combination of mechanical movements, harmonious in action and beautiful in execution; but physiology, dependent on structure for the interpretation of the phenomena of life and the causes thereof, seeks to reveal the inner life as well as the outward expression of it" (p. 10). It will probably be new to most of us to learn that morphology reveals movements at all, mechanical or otherwise.

At p. 179 "apogamy" and "self-fertilisation" are used as equivalent terms; at p. 138 Spirogyra is said to produce gonidia, and at p. 25 reproduction in Selaginella is said to take place by means of a true seed.

We have only cited a few examples of positive errors, but throughout the book the terminology is strange and confusing, even where not absolutely incorrect.

The book is presumably intended for students "cramming" for examinations, but even for this purpose we fear that it will prove worse than useless. D. H. S.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Vitality, and its Definition

It is perhaps desirable that I should offer a few words of explanation, by way of reply to several of your correspondents, who have commented upon certain statements in my recent address to the Geological Society.

In the first place, I think that any candid reader of that address will acquit me of being guilty of such presumption as to make a statement, on my own authority, concerning the vitality of seeds. My object was to contrast the greater stability of mineral structures with the lesser stability of animal and vegetable structures. Consequently I selected what I thought would be regarded as the *extreme* examples of prolonged vitality in the animal and vegetable worlds respectively. It was quite sufficient for my purpose that competent botanists have cited the case of the germination of seeds taken from ancient Egyptian tombs as authentic, and that a botanist of such eminence as A. de Candolle should assure us that it is "not impossible." As a matter of fact, I have been informed, however, by a reliable authority that experiments on the germination of seeds taken from mummies have very recently been conducted to a successful issue.

With respect to Mr. Herbert Spencer's definition of life, my object was not to find fault with it but to show that the differences between "organic" and "inorganic" matter are of so shadowy a kind as to defy definition. Even straining the meaning of the word "correspondence" so as to give it the force implied in the passage cited from the "Principles of Biology" by your correspondent Mr. Collins, I maintain that in those changes undergone by minerals to which I apply the term "physiological" there is a complete "correspondence with external sequences." When the temperature of a crystal is altered through a certain range, expansion and contraction take place unequally in accordance with the molecular structure of the mass. In consequence of this unequal expansion and contraction, stresses are produced and the crystal undergoes an internal molecular rearrangement, which is determined by a latent "organisation," though it can only be detected, perhaps, by its action on the light-waves. But now let another set of forces come into play, namely, the chemical action of liquids containing gases in solution, and immediately the effects of the former change are seen in the manner in which the crystal yields to the new forces operating upon it. This *secondary* change is in fact only rendered possible by the primary one having taken place. But the changes produced by solvent action in turn weaken the stability of the whole mass, permitting other chemical affinities to assert themselves, in consequence of which the crystal enters upon a long series of metamorphoses which terminate in the complete "dissolution" of the ties that held together its molecules; it thus becomes a pseudomorph, a sort of mineral corpse, with the external form of the original crystal only, but without any of that capacity for undergoing a wonderful cycle of changes which was its original endowment. After this the materials of the "dead" crystal may be used up to form the substance of new ones.

It is scarcely necessary to add that I had no serious intention of asserting that minerals do actually live, in the sense in which "living" is popularly understood. All I care to insist upon is that minerals, like animals and plants, go through definite cycles of change, dependent on their environment, and that the distinction between "organic" or "living" matter and "inorganic" or "lifeless" matter is therefore not a fundamental one. Surely no better proof of this can be adduced than the fact that the more exact we try to make our definitions of the terms "life" and "organisation," the more shadowy and intangible become the distinctions upon which we are driven to depend. I am perfectly satisfied with Mr. Herbert Spencer's admission of "insensible modifications and gradual transitions which render definition impossible." But if this be the case, it is surely not wise to maintain that the science of "non-living" beings must differ totally in its aims and its methods from that of "living" beings. To bring out into clear relief the analogies between the science dealing with the mineral kingdom and those concerned with the animal and vegetable kingdoms was the main object of my address. John W. Judd

"The *Gecko* moves its Upper Jaw"

Thus by the substitution of one reptile for another—of the gecko for the crocodile—the well-remembered zoological statement in Arnold's Greek prose is at length put upon a satisfactory foundation. In the spring of 1886, I captured a small gecko (*Tarantola mauritanica*) at Rome, and I have hitherto succeeded in keeping it alive and in health. One of the first things I noticed about it was the extraordinary vigour with which so small an animal would bite one's finger. And the effect produced was certainly rather due to the lizard's expression of intense ferocity during the process than to the pinch which it was able to give. The expression chiefly depends upon two things—the fact that the anterior part of the head may be bent downwards, and that the eyes are retracted into the head. Examining the former movement more carefully, it was seen that in opening the mouth the upper jaw is distinctly although slightly raised above the normal, so that the profile of the upper surface of the head becomes almost straight (compare Figs. 1 and 2). In biting fiercely it is common for the upper jaw to be depressed below the normal, as is plainly seen in a profile view (compare Fig. 3), although in other positions the curvature of the head is

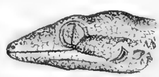

Fig. 1.—The Tarantola in the normal position of rest.

Fig. 2.—The Tarantola prepared to bite, with the upper jaw raised.

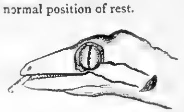

Fig. 3.—The Tarantola biting,—a common position, in which the upper jaw is depressed below the normal.

normal, and again in others the profile may remain straight in biting (as in Fig. 2). As far as I could observe in Tarantola, the upper jaw was always raised in opening the mouth, and the profile of the head straightened from its normal curve when at rest, but on closing the mouth in biting the movement of the upper jaw depended upon the relative position of the animal to the object which it was biting. This depression of the upper jaw may be also often witnessed when the mouth is closed, and it may be produced by applying slight pressure to the head. The animal seems to make the most of its powers of expression, for on provocation it opens its relatively huge mouth with the greatest readiness, and will keep it open for a considerable time, during which its appearance is sufficiently awe-inspiring. The fact that the anterior part of the skull is not co-ossified with the posterior part is well known. Thus in Huxley's "Anatomy of Vertebrata" (1871, p. 225) the following statement is made concerning the geckos: "Neither the upper nor the lower temporal arcades are ossified, the post-frontal being connected with the squamosal and the maxilla with the quadrate by ligament;" and Mr. Boulenger informs me that had he been asked whether the upper jaw of such lizards is moved in biting, he would have been inclined to answer in the affirmative, reasoning from the well-known condition of the skull. But I believe it has not been hitherto actually observed that such movable articulations possess a functional value in the living animal, and that the geckos must be added to the well-known instance of the parrots as Vertebrata which move the upper jaw in biting. It is extremely probable that the same observations will be found to hold for other families of lizards. EDWARD B. POULTON

Wykeham House, Oxford, March 1

Weight and Mass

TILL some quite new facts are discovered, such as shall force us to reconsider our convictions (which have not been lightly formed), I do not think it profitable to accept a quasi-metaphysical challenge from my friend Prof. Greenhill. He has at heart, as strongly as I have, the cause of *definiteness* and *accuracy*:—and if he, as is natural for one in his position, feels inclined to sympathise with the "vernacular" of Engineers rather than object to it as I do, there is nothing for it but to agree to differ. My remarks on this aspect of the subject were of the most cursory and general character; and I went so far as to say that, as the book in question was written by a practical man for practical men, "perhaps we ought not to complain."

I cannot, however, go *so much further* as to allow, with Prof. Greenhill, that it is "perfectly correct" to use the words pound or ton "side by side in two senses." As regards this practice I, in turn, must quote from an unpublished letter of Clerk-Maxwell's. [The passage purports to be part of a (reported) speech by a well-known Evolutionist.]

"He regretted that so many . . . . were in the habit of employing the word in a sense *too definite and limited* to be of any use in a complete theory. . . . . He had himself always been careful to preserve that largeness of meaning which was too often lost sight of in elementary works. This was best done *by using the word sometimes in one sense and sometimes in another*; and in this way he trusted he had made the word occupy a sufficiently large field of thought."

I have three other remarks to make upon Prof. Greenhill's letter:—

(1) He shows the absurdity of defining the weight of a body as "the force with which it is attracted by the earth." Of course such a definition must necessarily be absurd provided it comes *after* an explanation (given by Prof. Greenhill) that "weight" is to be understood in the sense of "mass." But from this explanation itself it would unfortunately follow that *a body has weight even when it is no longer heavy*; as, for instance, when it is in a (supposed) cavity at the centre of the earth! Prof. Greenhill says that "weight" is "used in ordinary language in most cases" in the same sense as "mass." Surely the great majority of men regard weight from the point of view of the sublime Porthos:—

"Ma vaisselle d'argent . . . . qui doit peser de mille à douze cents livres, CAR je pouvais à grande peine soulever le coffre qui la renferme, et ne faisais que six fois le tour de ma chambre en le portant."

(2) He also speaks of certain difficulties imposed by the "rules of language." I do not ascribe to them so lofty an origin. They are the offspring of the dogmatic ignorance which has peopled the realms of science with Centrifugal Force and its fellow monsters.

(3) He has commented solely on a passing remark in my article, and says nothing as to its main purpose. I hope, however, that he will eschew "statical" measures of force, and give his hearty aid as well as his good wishes in the war of extermination which must perpetually be waged against the too luxuriant undergrowth of the scientific garden:—the circle-squarers, the perpetual-motionists, and (in the case before us) *the measurers of potential energy in terms of horse-power*.

P. G. T.

An Error in Maxwell's "Electricity and Magnetism"

IT may be allowed to me to remark that the error mentioned on pp. 172 and 223 of NATURE has its origin really in Helmholtz's renowned paper ("Ueber die Erhaltung der Kraft," 1847, p. 67), and that it thence found its way into most of the text-books on electricity. It has sometimes been detected and hinted at; for the first time, I believe, in C. Neumann's paper published in the *Ber. d. k. sächs. Ges. d. Wiss*, at Leipzig (1871), "Elektrodynamische Untersuchungen mit besonderer Rücksicht auf das Princip der Energie." There we find (p. 436) the formula—

$$T\nabla + T_1\nabla_1 = T^2w + T_1^2w_1 - TT_1\frac{dV_{01}}{dt} + \frac{dF}{dt},$$

which is identical with the equation of energy given in NATURE, p. 223, if we put—

$$\nabla_1 = A_1,\ w_1 = R_1,\ -TT_1V_{01} = T_m,\ F = T_e,\ \text{\&c.}$$

The formula is followed by the remark that it agrees entirely with the formula given by Helmholtz, the only difference being the last term $\frac{dF}{dt}$, which in the latter is wanting; thus we may say that by Helmholtz the potential energy of the system invariably is expressed by zero.

Being formerly unaware of Neumann's researches, I, by another way, came to the same results, see the paper "Das Princip der Energie in seiner Anwendung auf die ponderomotorischen und elektromotorischen Wirkungen des elektrischen Stromes," published in the *Sitzber. d. k. böhm. Ges. d. Wiss*, (*vide* NATURE, vol. xxxii. p. 308). In this paper I have hinted at *one* probable cause of this and similar mistakes and their relatively difficult discovery, of which the repetition of the error in the *best text-books* is a decisive proof. This cause I believe to be the trivial circumstance that there is no consistent and generally accepted notation of the different forms of potential and energy. This renders the comparison of different writings on this subject sometimes quite perplexing. When, for example, two authors denote the *same thing*, the one by V, the other by $-V$, and when the first writes the expression $d(T_1T_2V)$ in the form—

$$T_1T_2dV + T_2VdT_1 + T_1VdT_2,$$

the other the *identical* expression $-d(T_1T_2V)$ in the form—

$$T_1T_2dV - T_2d(T_1V) - T_1d(T_2V),$$

it may happen that they themselves and also other readers overlook the difference of sign, and that they continue to reason as *if their* V *were identical*. Such mistakes occur oftener than is supposed. See the interesting note at the end of Sir William Thomson's paper on "Capillary Attraction," NATURE, vol. xxxiv. p. 369.

Could there not be found a means of avoiding the inconveniences caused by such mistakes and the loss of labour spent in detecting them? I dare not hint at the possibility of an international system of notations of the most important physical quantities; thoroughly consistent, and recommended by the highest scientific authorities; for the realisation of such a system would probably meet difficulties quite insurmountable.

Prague University, March 12 A. SEYDLER

Tabasheer

MR. DYER in his article on "Tabasheer" in NATURE of February 24 (p. 396), throws out the suggestion that the silica deposited in the joints of bamboo may have undergone a process of dialysis. It may be of some interest to him, and to your readers generally, to learn that plates of transparent compact silica, SiO_2, may be formed by dialysing the basic soda silicate. Four or five years ago I discovered this, and succeeded in producing plates a quarter of an inch in thickness and four inches in diameter, by placing the basic silicate of soda within a dialyser, which was floated on dilute sulphuric acid, 1 part to 20. The plate of silica was formed in the floated vessel. A similar result may be obtained by placing in a wide test-tube a portion of basic silicate. Taking care that the upper portion of the tube is quite free from adhering silicate, the dilute acid should be poured on to the surface of the silicate without disturbing it. After a few hours the silica is eliminated in a crystalloid form.

Possibly the first process may help us to understand how tabasheer may have been deposited, while the second may throw some light on the formation of raphides, carbonic or some other acid being the active agent.

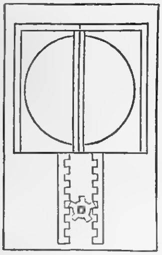
16 Savile Street, Hull, March 15 THOMAS ROWNEY

A Method of Illustrating Combinations of Colours

IN NATURE, vol. iv. p. 346, there is a description by Mr. Allen, of Sheffield, of some methods of showing the combination of various colours on a screen. He used a biunial or "dissolving view" apparatus to produce overlapping disks of colours, and also three lenses mounted close together in place of the ordinary single lantern objective, and giving images of three apertures in a lantern slide, close to which were placed cells of coloured liquids.

His experiments suggested to me the following method, which I have used for some years past, and for which only the ordinary single optical lantern is required.

A lens 10 cm. in diameter and 15 cm. focus is cut in half, and the two halves are mounted in frames so as to be capable of sliding past each other precisely in the same way as the divided object-glass of a heliometer. The motion is given by a pinion acting on racks in the same way as in the ordinary double-barrelled air-pump.



In the frames which carry the semi-lenses are cut grooves in which slips of coloured glass, or gelatine, or cells of coloured liquids may be placed; and the whole is fitted on the nose of the lantern in place of the usual objective, a diaphragm with round aperture about 3 cm. in diameter being put into the slide-holder.

Thus, when the two semi-lenses are so placed as to have their principal axes coincident, they act as a single lens and form one image of the aperture on the screen: but when they are moved past each other by turning the pinion, two disks of light are shown which can be separated entirely or made to overlap to any required extent. If, then, glasses or liquids of any given colours are placed in front of the semi-lenses, the compound colour produced by their union can be easily shown, either simultaneously with the component tints, or alone by accurately superposing the disks, thus avoiding any disturbing effect of the intrusion of other colours upon the eye.

It is in this way easy to show, taking four prominent colours, blue, green, yellow, and red, that blue + yellow = white; blue + red = purple; green + red = yellow, &c.

In place of coloured liquids, which are "messy" and liable to change, I almost always use coloured glasses, either singly or superposed (cobalt-blue, for instance, cemented to "signal-green" glass gives a good pure blue). Such glasses can by patient and careful selection be obtained of almost any required tint and intensity. H. G. MADAN

Eton College, March 26

Ice-Period on the Altai Range

IT is generally assumed that in the Altai Range there are no traces of so-called ice-ages. Hitherto, however, only ridges on the borders of the Altai Mountains have been examined. The geological phenomena of the mid-Altaic regions are still almost quite unknown. In the course of last summer it happened to me to visit some parts of the south Altaic regions—the Narim Range in the vicinity of Altaiskaia, Stornitza, or Koton Karagay, the neighbourhood of the Cossack settlement Oorool, then the so-called Katoon's Pales with their snowy giant Belooha. Subsequently I travelled in the valleys of the Belaia and Chernaia Berels, and visited the valley of the Arassan lakes and some other places. Everywhere I was struck by many and various traces and remnants of a large icy cover, which has left either strong glacier deposits, or abundant remains of moraines, or pieces of granite covered with lines. The valleys, too, bear on them the indubitable signs of glacial origin. In a word, there can be no doubt as to the existence of a large ancient icy cover here. Were these glaciers contemporaneous with the ice-age of Europe and North America, or do they present themselves as a quite independent system? My own observations convince me of their independence. The Altaic ice-period had, I think, its own causes. The Altaic system of mountains is of great antiquity; and its ridges were probably much higher at one time than they are now. Perhaps the whole system rose far above the line of eternal snow, although at present this line is reached only by some of the highest summits. It is probable, too, that in those very remote times the meteorological conditions of the country were far harsher than at present, because glaciers were more numerous and descended lower, digging the **V**-shaped valleys of the Katoon River, of the White and Black Berels Rivers, of Chindagatooy, &c.

The question of the periodicity of glacier-ages has again been raised lately, and perhaps it is from the Altai and from the Blue Alps that we may obtain the solid data for the complete solution of this very important question. A. BIALOVESKI

Oostkamenogorsk, November 1, 1886

A Claim of Priority

J'AI eu récemment l'occasion de lire dans le *Philosophical Magazine* (Août 1886) la description très-intéressante d'un "intégrateur sphérique," combiné par Mr. Frederick John Smith, et qui semble être une modification de celui du Prof. Hele-Shaw. Mais l'idée première de ces appareils, et c'est sur quoi je dois appeler votre attention, m'appartient sans doute, car dans le No. 630 du journal anglais NATURE (Novembre 24, 1881) j'ai donné la description d'un "Anémomètre Intégrateur," fondé sur le même principe, et qui a été plus tard cité dans le *Quarterly Journal of the Royal Meteorological Society* (No. 43, 1882), par Mr. Laughton ("Historical Sketch of Anemometry and Anemometers").

La modification imaginée par Mr. F. J. Smith, tendant à supprimer ou à amoindrir, autant que possible, le moment d'inertie de la sphère, me parait excellente, surtout s'il fallait transmettre des vitesses quelque peu considérables. Mais quand il s'agit simplement d'enrégistrer celle du vent sur une échelle moderée, je crois que la forme primitive suffit, et, d'après plusieurs essais que j'ai faits, une bille d'ivoire roulant sur des cylindres de bronze c'est ce qui donne les meilleurs résultats.

Je vous prie, Monsieur le Directeur, de vouloir bien faire constater dans votre estimable journal cette réclamation de priorité, ainsi que d'agréer mes plus sincères remercîments et l'assurance de ma considération très-distinguée.

Observatoire de Madrid, le 12 Mars V. VENTOSA

Oktibehite or Awaruite?

IN the notice of the proceedings of the Geological Society of London (NATURE, December 23, 1886, p. 190) the discovery in New Zealand of a nickel alloy allied to *oktibehite* appears to be claimed by Prof. Ulrich, of Dunedin. This requires explanation, as the mineral was first determined, and named *awaruite*, after the locality, by Mr. W. Skey, Analyst to the N.Z. Geological Survey Department on September 28, 1885, and described by him in a paper read on October 25, 1885, and published in the local papers at the time, as well as afterwards in the Transactions of the N.Z. Institute, vol. xviii., issued May 1886. A notice of it is also given in my twenty-first annual Museum and Laboratory Report, June 1886, of which I inclose a marked copy. It will be observed that while Ulrich accepts the identity of the New Zealand alloy with *oktibehite*, Skey's analysis shows that its formula is 2Ni + Fe, while that of the latter mineral is Ni + Fe. N.Z. Geological Survey Office, Wellington, N.Z., February 9

AËRIAL VORTICES AND REVOLVING SPHERES

A STRIKING series of experiments on aërial vortices and revolving spheres has lately been made by M. Ch. Weyher, one of the directors of the important establishment for mechanical constructions at Pantin. An account of these experiments, with illustrations, appeared in a recent number of *La Nature* (February 26). As the results obtained by M. Weyher are very interesting, we reproduce the more important figures, and translate the descriptions given by our French contemporary.

Fig. 1.—*Aërial Vortices.*—A glass cylinder of about 0·40m. in diameter by 0·70m. in height, has an upper cover, pierced by a hole through which passes the shaft of the drum, the latter being formed of one or two paddles of cardboard put cross-wise upon the vertical shaft.

The cylinder contains some sawdust, or, better still, some oatmeal. If the oatmeal is put at first so as to form

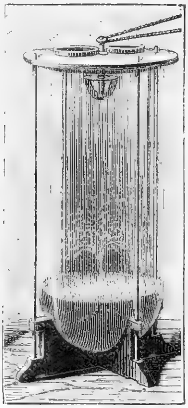

FIG. 1.

a cone or mound, and if the drum is turned round, a little waterspout can be seen forming at the top of the mound. Gradually the mass of oatmeal sinks into a hemisphere.

The matter runs without ceasing into spirals from the circumference to the centre; there it forms at first the lower cone, and then the upper reversed cone, in which the particles of oatmeal describe spirals, going from the centre to the circumference.

The whole system describes a primary general sphere, more or less distorted, the centre of which (where the two cones meet) is more or less deranged by the earth's gravity. If this is looked at from above, a hollow funnel is seen upon the axis: it is there that the air is most rarefied by rotation, and it is there that the finest particles come.

Substituting for oatmeal in the apparatus small light balloons inflated with air, the general movement can be followed. When the balloons are on the exterior circumferences, they fall in slow spirals; when they reach the circumferences nearer the axis of rotation, they rise rapidly upon a helix at a much more extended pace. In short, the experiment shows that, given a mass of air, if a

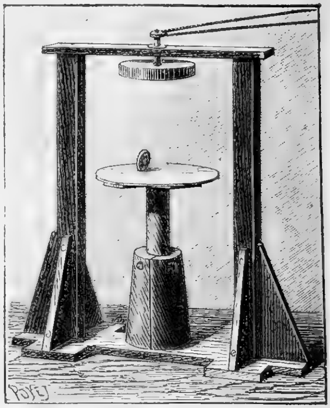

FIG. 2.

movement of rotation round a vertical axis is imparted to it this air falls constantly by the exterior circumferences, and rises by the interior circumferences, and the *whole* volume passes unceasingly through the centre of

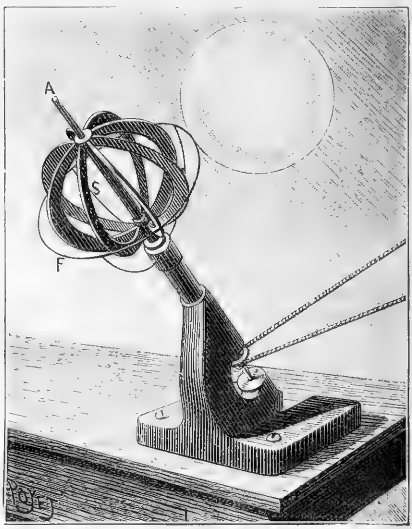

FIG. 3.

the vortex, drawing into its movement the substances or particles therein immersed.

Fig. 2.—A plate of glass or any other material is placed below a drum with paddles; when this drum is put in

motion, we immediately place upon the plate a disk or a coin, to which the fingers give a first movement of rotation round one of its diameters.

The hand being quickly drawn back, the aërial vortex continues to make the coin turn round like a top, and absolutely keeps it captive in its radius of action. The coin, while turning upon one of its diameters, makes a sphere, and a later experiment will show that a revolving sphere constitutes a centre of attraction.

Fig. 3.—*Equilibrium of Revolving Spheres.*—A free sphere keeps itself in equilibrium, and turns round another sphere, to which a rapid movement of rotation is imparted.

The apparatus consists of a pin, A, which is able to turn in a support, and has a pulley, made to receive a transmitted movement. Upon the pin A is placed a sphere, S, composed of from eight to ten flat circular pieces (these may be either flat disks, or disks cut into a crescent shape; it does not matter which). The pin may be at any angle whatever to the horizon; in this experiment it is inclined at 45°, but it may be horizontal

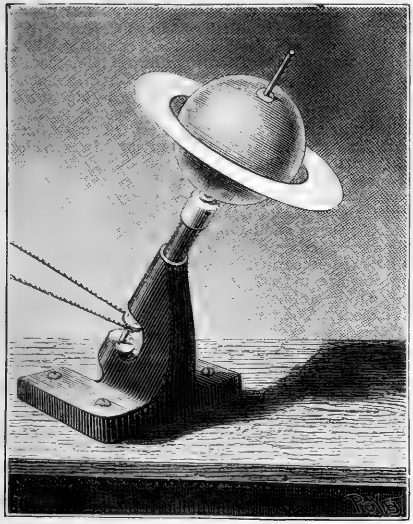

Fig. 4.

or vertical. The angle of 45° was chosen because it seemed to be most difficult for the experiment, which would therefore be the more conclusive. When the sphere S is turned round rapidly, you feel on the hand a strong blast which escapes all around from its equator. Bits of paper which are placed near it are thrown far away. Nevertheless, if a balloon is put near this blast, it is quickly attracted towards the revolving sphere, and describes orbits round it in the plane of the equator. As the experiment took place in a room, where there were obstacles producing eddies, and as also gravity has too much effect by reason of the proximity of the ground, it is very difficult to obtain a regular movement. The balloon comes easily in contact with the revolving sphere, and is then driven away by the collision too far to be caught again. A very simple contrivance consists in placing round the sphere S a wire guard or circle of iron, F, 1 millimetre in diameter, attached to the support by three similar wires.

The balloon will then keep on turning round the motive sphere, even ceasing to touch the guard in the lower part under the action of gravity. The experiment can be made in different ways, and the guard may even be suppressed, but these variations teach us nothing new.

In studying the vortex movements which the sphere imparts in the medium in which it is plunged, we easily calculate the ratio of the attraction which it exercises on the balloon.

Fig. 4.—The guard of the revolving sphere is taken away, and we place parallel to its equator a circle of paper with an interior diameter greater than the exterior diameter of the sphere; the circle is caught into the movement of rotation, and maintains itself strongly in the plane of the equator.

ON OLDHAMIA

THE organic origin of Oldhamia has often been disputed. Originally described by Edward Forbes from specimens found at Bray Head, near Dublin, in rocks of the Cambrian formation, it has been found in a few other localities in Ireland, in rocks of a similar formation. In the dispute the weight of the evidence has seemed to be in favour of the views of Forbes, Jukes, Harkness, and Kinahan, that this lowly form is a fossil probably belonging to the Polyzoa, or to the Sertularian Polyps. So the matter has stood for a long time. A recent paper by Prof. W. J. Sollas, published in the Proceedings of the Royal Dublin Society for January last, once again opens the discussion. In the hope of throwing light on this problematical structure, thin slices for microscopic examination were cut, both parallel and transverse to its planes of cleavage. When these were placed under the microscope, all trace of the Oldhamia structure appeared to have vanished. An examination with the unaided eye showed, however, that it was still there, presenting itself as narrow, undulating, and branching bands of a lighter colour than the surrounding matrix. Its appearance, moreover, varied in an extraordinary manner according to the direction in which it was viewed. Looked at obliquely in a strong light, the thread-like bands are brilliantly illuminated, and appear faintly coloured with spectral tints; looked at directly, the bands become fainter, and are less clearly distinguishable from the matrix. In certain positions the slice taken at right angles to the bedding has an appearance somewhat suggestive of shot-silk, and, from the planes of cleavage, markings which remotely resemble in form the dendritic markings of Sutton stones extend into the surrounding matrix.

These appearances suggest the presence of some mineral possessing high reflection or refraction arranged in more or less parallel planes. Mr. Teall, in the same paper, gives full details of the mineral characters of the rock. Aided by these, Dr. Sollas finds that the lighter-coloured bands, which correspond to the Oldhamia markings, owe their distinction from the surrounding matrix to the presence of an excess of sericite scales; and that the curious shot-silk appearances are produced by the local deflections of these scales from parallelism with the cleavage planes into directions tangential to curves, which are probably transverse sections of those long ridges which, when seen on the exposed surface of a cleavage plane, are recognised as the usual form of Oldhamia. It would appear possible that these ridges are wrinklings of the cleavage planes produced during the shearing which led to their formation. These observations were made on the form known as *O. radiata*, and in some supplementary remarks Dr. Sollas adds that when Oldhamia is present it shows itself on the surface of the laminæ as rounded discontinuous ridges, which are without definite boundaries, and have the appearance of fine wrinkles. When the phyllode is fractured obliquely to the cleavage laminæ, the Oldhamia markings are found to extend through the rock as fine ridges or wrinkles which mark the surface of oblique fracture in a similar manner to those of the cleavage face. In fact, the appearances are remarkably similar to those of *ausweichungs-clivage*, described by Heim in his "Gibergsbildung"; but the observations throw no light on the remarkable radiate form sometimes assumed by the structure. In a paper in the same journal Mr. Joly mentions that, in examining specimens of *O. antiqua* and *O. radiata*, he detected the following peculiarity: a sunken or depressed delineation of one form accompanied a raised or relieved delineation of the other form. Thus, if on any specimen *O. antiqua* appeared as a depression, on that same surface the *O. radiata* appeared in relief.

From this observation it appeared probable, if any meaning was to be attached to the relation, that a further

relation would be found to obtain between the mode of delineation and the position in the rock. This, a further examination revealed; in this order: on the upper surface, or what was most probably the surface of deposition (the cleavage of the Cambrian slate of Bray Head coincides generally with the plan of bedding), the *O. radiata* appeared invariably as a depression, the *O. antiqua* in relief.

When fragments were peeled off the slate, the marks were found to be transmitted, or extending to the layers beneath, so that lines on the upper are seen as continued on the adjacent lower layer, this, too, for thicknesses exceeding a millimetre. The accompanying woodcut recalls the appearance of a surface of rock in which this is fairly well shown.

ON THE DISTRIBUTION OF TEMPERATURE IN THE ANTARCTIC OCEAN[1]

IN the regions of the Antarctic Ocean where icebergs are numerous, and where in winter the sea-water freezes, the distribution of temperature in the deeper layers of water is peculiar. The facts are detailed in the "*Challenger* Narrative" (vol. i.). The general result of her observations went to show that, from the most southerly station, a wedge of cold water stretches northwards for more than 12° of latitude, underlying and overlying strata at a higher temperature than itself (p. 418).

Although the conditions and facts likely to throw light upon the cause of the existence of this cold intermediate or superficial stratum overlying water which at any rate in its upper layers has a temperature higher than that of freezing distilled water are discussed, no satisfactory explanation of the phenomenon is given. One important fact is noticed at page 421. "The fact that the cold wedge above referred to extended north just as far as the icebergs did in March 1874 points to there being some connexion between the temperature and the presence of melting icebergs." It is well known that icebergs consist of land-ice, which is as nearly as possible pure frozen water, and melts in the air at 32° F. It was thought that the effect of immmersion of such a substance in a medium having a temperature 3° F. lower than its melting-point would be to indefinitely preserve it, that in fact only the lower surfaces of the icebergs large enough to reach to a depth of 300 fathoms would suffer any melting at all. The existence of the cold stratum was ascribed wholly to the cold brine, separated from the ice on the freezing of the sea-water, sinking downwards with an initial temperature of from 28°·5 to 29° F. This cause, though existing and in operation, is quite inadequate to produce the effect observed. In Dr. Otto Pettersson's admirable work "On the Properties of Water and Ice," undertaken in connexion with the work of the *Vega* Expedition, there is a footnote at page 318 where he says: "As a thermometer immersed in a mixture of snow and sea-water *which is constantly stirred* indicates − 1°·8 C., we may regard this as the upper limit of the freezing and the nether limit of the melting temperatures of sea-water." In a review of Dr. Pettersson's work in NATURE (vol. xxviii. p. 417) I expressed doubt of the accuracy of this observation, but on repeating it I found it to be confirmed. It affords a complete explanation of the cold wedge of water in the Antarctic Ocean and the dependence of its thickness on the range of icebergs. These enormous islands of ice, a a very large proportion of which rise in tabular form to a height of 200 to 300 feet above the sea, float in many cases with their lower surfaces at a depth of from 250 to 300 fathoms. The warmer and denser water coming from lower latitudes (see "*Challenger* Narr." vol. i. p. 428) bathes these lower surfaces, the temperature of the mixture at the surface of contact falls, the heat abstracted from the sea-water melts a corresponding amount of the ice of the iceberg, and a saline solution is produced, less salt and therefore lighter than the water away from contact with the iceberg, and having a temperature which depends immediately on the strength of the resulting solution. Being lighter than the surrounding water, this resulting solution necessarily flows up along the sides of the berg to the surface, and its place is taken by fresh undiluted sea-water which in its turn is cooled, diluted, and transferred to the surface. The result is the production of a most energetic engine of circulation and means of cooling and equalising the temperature of the water within the reach of icebergs. As there is continual renewal of the ocean water brought into contact with the ice, and as its composition is constant, the temperature produced is practically constant, namely 28°·8 to 29°·0 F., or − 1°·7 to − 1°·8 C. The layer of lighter water from 50 to 80 fathoms thick at the surface is due principally to this melting of land-ice, though it is also due in very small proportion to the melting of sea-ice.

Table giving the temperature at which ice melts in sea-water containing different percentages of chlorine

Temp. C.	1°·0	1°·1	1°·2	1°·3	1°·4
Per cent. Cl... ...	1·040	1·131	1·222	1·313	1·404
Temp. C.	1°·5	1°·6	1°·7	1°·8	1°·9
Per cent. Cl... ...	1·495	1·586	1·678	1·769	1·880

This table is taken from a paper on ice and brines, communicated to the Royal Society of Edinburgh on March 21, 1887.

[1] Abstract of a paper read by Mr. J. Y. Buchanan before the Royal Society of Edinburgh, March 21, 1887.

The density (at 15°·56 C.) of the sea-water which comes in contact with the lower surfaces of the icebergs is 1·0255, which represents a chlorine percentage of 1·90. Ice actually *melting* in this water would produce a temperature of − 1°·92 C. When ice is *immersed* in this water it lowers its temperature, and a portion of the ice is melted, producing dilution. The concentration, therefore, or chlorine percentage, which will determine the melting temperature of the ice, will be a little lower than that of the original sea-water. From the *Challenger* observations we see that, on the confines of the pack-ice the cold stratum of water has a uniform temperature of 29° F. (− 1°·67 C.). Ice melts at this temperature in sea-water containing 1·65 per cent. of chlorine. In this process ice is melted, so that 100 grammes pure warm sea-water become 119 grammes of diluted cold sea-water. It will be observed that the ice which has been formed in the atmosphere at a temperature of 32° F. comes in this way to be melted at a temperature of 29° F.; and the pressure exerted by the 300 fathoms of sea-water, though it may assist in the lowering of the melting temperature, is insufficient to account for the amount.

TO FIND THE DAY OF THE WEEK FOR ANY GIVEN DATE

HAVING hit upon the following method of mentally computing the day of the week for any given date, I send it you in the hope that it may interest some of your readers. I am not a rapid computer myself, and as I find my average time for doing any such question is about 20 seconds, I have little doubt that a rapid computer would not need 15.

Take the given date in 4 portions, viz. the number of centuries, the number of years over, the month, the day of the month.

Compute the following 4 items, adding each, when found, to the total of the previous items. When an item or total exceeds 7, divide by 7, and keep the remainder only.

The Century-Item.—For Old Style (which ended September 2, 1752) subtract from 18. For New Style (which began September 14) divide by 4, take overplus from 3, multiply remainder by 2.

The Year-Item.—Add together the number of dozens, the overplus, and the number of 4's in the overplus.

The Month-Item.—If it begins or ends with a vowel, subtract the number, denoting its place in the year, from 10. This, plus its number of days, gives the item for the following month. The item for January is "0"; for February or March (the 3rd month), "3"; for December (the 12th month), "12."

The Day-Item is the day of the month.

The total, thus reached, must be corrected, by deducting "1" (first adding 7, if the total be "0"), if the date be January or February in a Leap Year: remembering that every year, divisible by 4, is a Leap Year, excepting only the century-years, in New Style, when the number of centuries is *not* so divisible (*e.g.* 1800).

The final result gives the day of the week, "0" meaning Sunday, "1" Monday, and so on.

EXAMPLES

1783, *September* 18

17, divided by 4, leaves "1" over; 1 from 3 gives "2"; twice 2 is "4."

83 is 6 dozen and 11, giving 17; plus 2 gives 19, *i.e.* (dividing by 7) "5." Total 9, *i.e.* "2."

The item for August is "8 from 10," *i.e.* "2"; so, for September, it is "2 plus 3," *i.e.* "5." Total 7, *i.e.* "0," which goes out.

18 gives "4." Answer, "*Thursday.*"

1676, *February* 23

16 from 18 gives "2."

76 is 6 dozen and 4, giving 10; plus 1 gives 11, *i.e.* "4." Total "6."

The item for February is "3." Total 9, *i.e.* "2."

23 gives "2." Total "4."

Correction for Leap Year gives "3." Answer, "*Wednesday.*"

LEWIS CARROLL

NOTES

IN the Report submitted yesterday at Edinburgh to the half-yearly general meeting of the Scottish Meteorological Society, the Council state that the work at the Ben Nevis Observatory continues to be carried on by Mr. Omond and the assistants in the same highly satisfactory manner as has been recorded in previous Reports. In addition to the laborious work of observing at all hours of the day and night, of reducing the observations, and forwarding copies for the Society and the Meteorological Council, the staff of the Observatory has given very effective assistance in the preparation of the tables of the meteorology of Ben Nevis now in the press. Several interesting researches are being conducted at the Observatory, the results of which will be communicated to a future meeting. The Directors took steps last autumn to raise subscriptions to clear off the debt on the institution, and to establish a low-level station at Fort William, at which hourly observations may be made for comparison with those at the Observatory. It is only by two sets of observations at the top and bottom of the mountain that the Ben Nevis Observatory can be utilised, with the desired success, in the furtherance of meteorological science, but particularly in that branch of it which concerns the improvement of the system of forecasting the weather of the British Islands.

ON Tuesday evening last the Lord Advocate stated in the House of Commons that the Scottish Universities Bill would shortly be introduced.

THE Paris Medical Faculty has decided to alter considerably the mode of competition for its Fellowships. The general object of the changes is to secure more original workers. The thesis (which has usually been the work, not of the candidate himself, but of his friends) is to be suppressed. Each candidate will henceforth have to deliver a lecture on his own scientific researches.

THE French Chamber of Deputies has decided that the buildings of the College of France shall be considerably enlarged. Fifty years ago, when this institution had only seventeen professors, its present buildings were sufficient; but now, when it has forty-one professors, they are very inadequate. It is to have four new lecture-rooms, a geological gallery, a set of rooms for other collections, a library, a meeting-room for professors, and eight laboratories. These additions will cost over 9,000,000 francs.

THE Anatomical Society, founded last September at Berlin, will hold its first general meeting at Leipzig on April 14. The Society has now over 170 members in England, Germany, Austria, Hungary, Switzerland, Holland, Belgium, Scandinavia, France, Russia, Italy, and North America.

DR. HANS REUCH, who has lately devoted much time to the study of earthquakes in Norway, has issued a tabulated circular, which has been reproduced in the entire Norwegian Press, requesting that reports of any phenomena observed in connexion with earthquakes may be sent to him. By Government permission all such reports may be transmitted through the post free of charge. Dr. Reuch asks especially for information on the following points: exact time of occurrence of the earthquake; the time compared with that of the nearest railway or telegraph station; locality of occurrence, and whether felt indoors or in the open; nature of soil; what the observer was occupied with; how many shocks were felt; nature of motion, undulating or oscillating; from what direction the shock came; whither it went; how long the motion lasted; what were its effects; did the shock resemble others experienced by the observer; was there any sound; was the sound heard before or after the earthquake; what was the interval between the shocks; were phenomena of restlessness in animals, or peculiarities of the weather, observed; if near sea or lake, were there any strange motions in the same; the names of any other persons who are known to have noticed the earthquake. Earthquake phenomena having been more than usually frequent in Norway during the past year, it is believed that Dr. Reuch's circular may be of considerable service to science.

AT a meeting of the Japanese members of the Seismological Society of Japan held at the Imperial University on January 20 (according to a report in the *Japan Weekly Mail*) two papers were read in Japanese. The first was by Mr. Kikuchi, on the geology of Corea. In it the writer described the geological map made by Prof. Gottsche, who visited that country after leaving Japan. The paper also gave a description of the geological formations and the minerals found in the different provinces of Corea, and showed that Corea differs from Japan in the fact that these formations in the former country are much older, and on that account more stable, than those in the latter. This, Mr. Kikuchi thought, might account for the comparative absence of seismological phenomena in Corea. The second paper, by Mr. S. Sekiya, was on recent destructive earthquakes. The writer described in succession the causes and effects of the earthquake which occurred in Japan on February 22, 1880; the earthquake at Ischia in 1883; the shock of October 15, 1884, in Japan; the earthquakes in Spain in 1884; those of the United States of last year; and the shock of January 15 in Japan. It was pointed out that the three earthquakes mentioned as occurring in Japan were very similar in their intensity, and that they extended over nearly the same area; but, with regard to their place of origin, the writer said the first two shocks originated in Tokio Bay, or in the ocean beyond the peninsula, while that of the present year originated in a spot to the south-west of the two previously mentioned. A third paper on the meteorology of Tokio was postponed. It appears from this and other reports which we have published from time to time that the Japanese Section of the Seismological Society, where the papers are read in the Japanese language, is, like the parent Society, in a very flourishing condition. It evidently supplies a demand for this department of science amongst Japanese who know no language well except their own.

AT the first meeting of the London Commission for the Melbourne Centennial International Exhibition, held on Thursday, the 24th inst., the chairman, Sir Graham Berry, said that the proposed buildings of the Exhibition would cover an area of more than 1,000,000 feet. It was decided that a deputation should ask Sir Henry Holland to take steps for the appointment, in connexion with the Exhibition, of a Royal Commission for the United Kingdom, and that the Foreign Office should be requested to communicate on the subject of the Exhibition with foreign Powers, India, and colonies other than Australasia.

ON Saturday evening last, a lecture on "The Habits of Ants" was delivered by Sir John Lubbock in the theatre of the Working Men's College, Great Ormond Street. The lecturer gave an interesting account of some of the results of his own observations, and brought forward much evidence to prove that ants possess "something more than mere instinct."

BY an Order in Council, dated March 7, Her Majesty has declared that the following antiquities shall be protected by the Ancient Monuments Act: (1) Little Kit's Coty House, or the countless stones of Tottington, at Aylesford, in Kent; (2) the chambered tumulus at Buckholt, in Gloucestershire; (3) the Druid's circle and tumulus on Eyam-moor, in Derbyshire; (4) the Pictish tower of Carloway, in Ross-shire; (5) the Ruthwell Runic cross in Dumfriesshire; and (6) St. Ninian's Cave, at Glasserton, in Wigtownshire. The Order will not come into force until it has lain for forty days before both Houses of Parliament.

IN the so-called Seelberg, where in 1816 the mammoth group which is the chief ornament of the Stuttgart Museum was found, further excavations are being made under the direction of Dr. Fraas. Many skeletons, weapons, and implements have been discovered, and Dr. Fraas is of opinion that the mammoth group found seventy years ago was artificially put together by prehistoric artists.

IN the *American Naturalist* there is an article by Mr. John Murdoch on what he calls "some popular errors in regard to the Eskimos." One of these "popular errors" is the notion that the Eskimos pass the winter "in a sort of hibernation, in underground dens, living in enforced idleness and supporting life by stores of meat laid up in less inclement seasons." Mr. Murdoch, who spent two winters at Point Barrow, says this is a wholly mistaken impression. In spite of the extreme inclemency of the climate, the winter, he asserts, is passed by the Eskimos "in one continued round of activity," and he gives a very interesting description of the manner in which they occupy themselves. Another "popular error" on this subject is the idea that the Eskimos always eat their food raw, and devour enormous quantities of blubber. At Point Barrow, Mr. Murdoch found that food was habitually cooked, although certain articles, like the "black skin" of the whale, were usually eaten raw. Taking into account the fact that the Eskimos have no butter, cream, fat, bacon, olive-oil, or lard, he doubts whether much more fat is consumed by them than by civilised peoples. At Point Barrow the fat of birds and the reindeer was freely partaken of, but comparatively little actual blubber either of the seal or whale was eaten. "Seal or whale blubber was too valuable,—for burning in the lamps, oiling leather, and many other purposes, especially for trade."

A BOOK on "Sensation and Movement," by M. Ch. Féré, of Paris, has just been published. The author tries to show how different sorts of sensations react upon the vasomotor and motor phenomena, as indicated by pletysphygmograph and dynamometer.

IN a work on "The Nationalities of Bohemia," lately published, Dr. L. Schlesinger shows that 37·11 per cent. of the population of that country are Germans, and 62·83 are Czechs The limits within which the languages of the two races are spoken are generally very sharply drawn. There are 13,184 inhabited places in Bohemia, and in 4304 of them German alone is spoken, in 8473 the Czech language alone. In only 407 places are both languages used.

THE death is announced of Prof. Simon Spitzer, Professor of Analytical Mechanics at the Technical High School of Vienna, the author of various well-known mathematical works. He died on March 16 at the age of sixty-one.

THE new University building at Upsala is approaching completion. It has been in course of erection since 1879, and will be one of the finest University buildings in Europe. It will be opened with great ceremony on May 18 next by the King of Sweden, in presence of delegates from the principal foreign Universities.

LAST week the American Government forwarded another consignment of whitefish ova to the National Fish-Culture Association. These have been taken from late spawners, and appear more healthy than the batch sent in January. The ova are well "eyed," and in some cases are on the point of incubation. A consignment of the Californian trout ova, viz. the Rainbow (*S. irideus*), has likewise been received by the Association from the American Government. This variety is likely to become highly popular in England on account of its unique colour and form and its capacity of gaining flesh rapidly.

WHEN the South Kensington Aquarium was closed, the sea-trout which had been maintained there were transferred to ponds in the Delaford Park Fishery; and in February last many ova were taken from them and crossed with the *S. fario*, as in previous years. There are now a large number of hybridised examples of *S. trutta* in the ponds produced from ova shed in the South Kensington Aquarium and crossed in a similar manner. The two-year-old specimens are now about 7 inches long, their size being much smaller than that of other trout of the same age. None of the fish have spawned.

THE meaning of the word "scientist" seems to be rather vague in the country in which it originated. In his annual address as President of the Philosophical Society of Washington, lately published, Mr. John S. Billings says the word was a coinage of the newspaper reporter, and, "as ordinarily used, is very comprehensive." Webster defines a scientist as "one learned in science, a *savant*." Mr. Billings, however, thinks that the suggestion conveyed by the word "is rather that of one whom the public suppose to be a wise man, whether he is so or not; of one who claims to be scientific." In his address, the subject of which is "Scientific Men and their Duties," he himself uses the term "in the broadest sense, as including scientific men, whether they claim to be such or not, and those who claim to be scientific men, whether they are so or not."

PROF. SARGENT, Director of the Arnold Arboretum of Harvard College, estimates that five foreign trees are planted in New England to one native. Yet, of all foreign trees introduced into America, the willow alone, he thinks, has qualities not possessed in a greater degree by some native. The European oak is perhaps the most unsatisfactory deciduous tree that has been experimented upon: it grows rapidly when young, but fails, when about twenty years old, from the cracking of the main stem, and then, after dragging out a wretched existence a few years longer, it miserably perishes. The Scotch pine dies long before reaching maturity, and the Austrian and the Corsican pine seem to be no better. The Norway spruce, which has been for many years the most widely cultivated foreign tree in Massachusetts, becomes decrepit and unsightly just at that period of life when trees should become really handsome in full development.

THE Sonnblick Observatory, in the province of Salzburg, Austria, is the highest in Europe, being 10,177 feet above the level of the sea. It was established chiefly through the exertions of M. Rojacher, proprietor of the mines in that district, in conjunction with the German and Austrian Alpine Club, and the Austrian Meteorological Society. Telephonic communication was established with Rauris, a distance of 15⅓ miles, and observations were commenced in September 1886. Observations at such elevated stations offer much that is of interest to science generally, and more especially as regards those problems of meteorology which relate to the variations of pressure, temperature, and humidity in the upper regions of the atmosphere. In the *Meteorologische Zeitschrift* for February last, Dr. Hann gives an interesting account of the first three months' observations. The mean temperature in October was 25°·9 F.; in November 15°·3, and in December 8°·1. In October, the decrease of temperature with height during the barometrical minima was, generally, rapid. But during the barometrical maxima it was very slow in the lower strata, up to about 5900 feet; then an increase of temperature with height frequently occurred. The periods of high pressure were generally warm intervals on the Sonnblick, and the periods of low pressure were cold intervals. It is noteworthy, however, that the change of temperature with height, in the strata between about 5900 feet and the summit, was almost independent of the conditions of weather, being nearly constant during the whole month, and amounting to about 1°·3 F. per 328 feet (100 metres); while in the lower regions, from about 1300 feet to 5900 feet, it varied between 0° and 1°·1. And, generally speaking, the same rates of decrease of temperature obtained in November and December. During the period of high pressure, on October 1 to 5, which was the warmest part of the month, the march of relative humidity showed a great contrast at the high stations and at the valley stations, humidity being greatest at noon at the high stations, and lowest in the valleys. As regards wind, it may be remarked that early in November the anemometer became a shapeless mass of hoar frost. It remains to be shown what use can be made of the observations on such elevated stations for the practical work of weather-forecasting. The observers of the Pic du Midi claim to have foretold, from the conditions at that Observatory, the disastrous floods that occurred in the South of France at the end of June 1875, and thereby to have rendered important services by their timely warning.

THE Norwegian Government has taken another step towards discovering the origin and nature of the terrible disease leprosy, which is so common on the west coast of Norway, by despatching Dr. G. A. Hansen, Director of the Leprosy Hospital at Bergen, to North America, for the purpose of inquiring into the heredity of the disease among Scandinavian emigrants to the United States.

SOME interesting statistics concerning the libraries of the United States have been printed in America from advance sheets of the forthcoming Report of the Bureau of Education. There are in the United States 5338 libraries, each with 300 volumes or over. Of these, 2981 have each 1000 volumes or over. Forty-seven have each over 50,000 volumes; and among the forty-seven are the public libraries of Boston, Chicago, and Cincinnati, and the libraries of Harvard, Columbia, Yale, Cornell, and Brown Universities. These forty-seven libraries aggregate 5,026,472 volumes; and the whole list of 5338 libraries aggregates 20,622,076 volumes, or one volume to every three persons in the country. In round numbers the United States has one library to every 10,000 of population, though in many States the proportion is far greater. New Hampshire, for example, has a library to every 2700 persons. Massachusetts and Connecticut furnish a library to every 3134 and 3479 persons respectively. California, Colorado, Wyoming, and Michigan, are well up on the list. Arkansas, which stands lowest, has one library to every 50,158 of population.

SOME time ago we reviewed a little book entitled "A Year with the Birds," by an Oxford Tutor. A second edition has now been issued. The author has added a chapter on the Alpine birds, and has also made a considerable number of additions and corrections in the original chapters.

THE annual general meeting of the Linnean Society of New South Wales took place on January 26. The usual address was delivered by the President, Prof. W. J. Stephens, who presented a general summary of all the scientific work included in the year's Transactions. He also drew attention to the labours of other scientific Societies of Australasia during the preceding year, and concluded with some observations on scientific teaching in general schools.

THE additions to the Zoological Society's Gardens during the past week include a Malayan Bear (*Ursus malayanus*) from Malacca, presented by Mrs. Bingham; a Common Squirrel (*Sciurus vulgaris*), British, presented by Mr. H. B. Meadows; two Tree Pipits (*Anthus arboreus*), British, presented by Mr. W. B. Tegetmeier; two Dwarf Chameleons (*Chamæleon pumilus*), two Robben Island Snakes (*Coronella phocarum*), a —— Toad (*Bufo augusticeps*) from South Africa, presented by the Rev. G. H. R. Fisk; two Pondicherry Vultures (*Vultur calvus*) from India, two Ocellated Sand Skinks (*Seps ocellatus*), South European, purchased; two Black Lemurs (*Lemur macao*), a White-fronted Lemur (*Lemur albifrons*), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *APRIL* 3-9

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on April 3

Sun rises, 5h. 33m.; souths, 12h. 3m. 22·6s.; sets, 18h. 34m.; decl. on meridian, 5° 18′ N.: Sidereal Time at Sunset, 7h. 21m.

Moon (Full on April 8) rises, 12h. 29m.; souths, 20h. 12m.; sets, 3h. 44m.*; decl. on meridian, 15° 47′ N.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′

GEOGRAPHICAL NOTES

THE new number of the *Mittheilungen* of the Vienna Geographical Society contains several letters written by Dr. O. Lenz during his journey from Kasonge, on the Upper Congo, and the Shiré River, to the south of Lake Nyassa (June to December 1886). These letters are, to a large extent, occupied with details of the troubles which Dr. Lenz had with his men. Kasonge is a most unhealthy town. Bohndorf, Lenz's companion, was struck down with fever, and had to be carried most of the way, while small-pox broke out among his men, seriously hampering the proper work of the Expedition. Lenz left Kasonge on June 30, and reached the Island of Kavala, off the west shore of Lake Tanganyika, the head-quarters of Capt. Hore, on August 7. On the route he passed many villages recently built by Zanzibaris, the native population having retired into the forests and mountains. The region is mainly an open table-land, sometimes of a beautiful park-like aspect, and with the river-valleys thickly wooded. As Tanganyika was approached, the plateau rose to a height of 3000 to 4000 feet, with mountains rising from its surface to an equal height. The chief rock was granite, with crystalline slates, and wooded spurs. After staying a few days with Mr. Hore, Dr. Lenz crossed to Ujiji, which he reached on August 15. Here he found himself compelled to give up his proposed journey to Emin Pasha, and in a large boat he and his men sailed down the lake to the south shore, which he reached on September 27. Mr. Hore informed him that the Lukuga River now flows with a strong current out of Lake Tanganyika to the Lualaba. Mr. Hore, who has known the lake for ten years, assured Dr. Lenz that during that time its level has fallen 15 feet, and as the latter sailed down the lake he saw clearly enough the marks of the old shore-lines. With difficulty Dr. Lenz obtained assistance on the inhospitable south shore to continue his journey onwards to Lake Nyassa. This route has been traversed several times, and Dr. Lenz does not in these letters add much to our knowledge. It is a plateau with mountains rising from it to a considerable height, and to the south-west of Lake Tanganyika he came upon the sources of the Chambeze, which, flowing into Lake Bangweolo, may be said to form the remotest sources of the Congo. On October 17 he reached Nkonde, on Lake Nyassa, a station of the African Lakes Company, and thence made his way down the lake and on to the River Shiré, whence his last letter is dated, in December 1886.

IN the same number will be found the conclusion of Herr Glaser's paper on his journeys in South Arabia, in which he gives some important information on the various classes of the population. He speaks in the worst possible terms of the climate of the region: highland and lowland are equally bad, and deadly for Europeans.

THE leading paper in the last number of the *Verhandlungen* of the Berlin Geographical Society is Dr. Wolf's account of his important exploring work on the Sankuru, the great southern tributary of the Congo. This he navigated upwards from the Kasai, exploring its three great sources, the Lomomi, the Lussambo, and the Lubi. It is on the whole a magnificent water-way, its banks in many parts thickly wooded and densely populated. He gives much information concerning the two leading peoples here, the Bakutu and the Baluba, both of them evidently intruders on the Batua, the pygmy people referred to in our last number, the former coming from the north-west and the latter from the south-east. Herr Stäudinger adds considerably to our knowledge of the Niger region in his narrative of his journey from Loko, on the Binué, to the kingdoms of Saria, Kano, Sanfarra, Sokoto, and Gando.

HERR FERDINAND SEELAND contributed to a recent meeting of the Austro-German Alpine Club some useful data on the rate of movement of the Pasterz Glacier. On October 3 last he found the glacier entirely free from snow, and he was lucky enough to find six pegs which he inserted in 1882 near the Hofmann Hut straight across the glacier to the base of the Glockner, and also two stones which he laid down in 1884. In the four years 1882-86 the first peg had moved downwards 121·5 m. (*i.e.* at the rate of 3·5 mm. per hour), the second 162 m. (4·6 mm.), the third 175·5 m. (5 mm.), the fourth 192·3 m. (5·5 mm.), the fifth 201·5 m. (5·8 mm.), and the sixth 198·6 m. (5·7 mm.). Of the stones, in the two years one had moved 104·2 m. (5·9 mm.), the other 100·7 m. (5·8 mm.). According to these results (in the direction from the north edge of the glacier towards the centre), the mean rate of movement on a slope of 4 to 5 degrees is 5·23 mm. per hour, or 125·1 mm. per day. Herr Seeland left the pegs and stones where they were, and laid down other marks for future measurements.

LIEUT. WISSMANN, who has already done so much good exploring work in the Congo region, started in November last on a fresh expedition, from Luluaburg, the station on the River Lulua, an affluent of the Kasai. Wissmann goes first to the junction of the Lubi with the Sankuru, the great southern tributary of the Congo. Thence he will endeavour to push northwards and explore the unknown country in which the Lulongo, the Chuapa, and the Lomami take their sources. He will then seek to reach Nyangwé, when he will make up his mind either to proceed northwards to the Muta Nzigé, or south to explore the Lanji, the Lukuga, and the Upper Lualaba.

THE paper at Monday's meeting of the Royal Geographical Society was by Mr. J. T. Wills, on the region between the Nile and the Congo. It was a summary of all that we know of the region, and places us in a position to appreciate the value of any exploring work which may be done by Mr. Stanley. It deals succinctly with all recent explorations of the Upper Nile region, and with the intervening country between that and the Middle Congo. The valuable work of Dr. Junker, as well as that of Emin Pasha, receives special prominence. Mr. Wills rightly dismisses the Shari hypothesis in connexion with the Wellé-Makua, and insists on the identity of the Makua and Mobangi. The Mobangi is known to be a waterway not inferior to the main Congo for practical purposes; deep, never less than 600 yards wide, even in February, when the Kuta Makua certainly (and it too apparently) is at its lowest level; and navigable at all times from Stanley Pool 650 miles thence straight north-north-east to lat. 4° 20′ N. beyond the limit which the Congo State, by private treaty with Germany, has placed to its future "sphere of operations," and beyond the limits which the French will probably occupy if they win in their dispute with the Congo State as to which of the two shall not operate in the Mobangi basin. It is then found to turn sharply to the east, flowing from the east through a gap it has cut in a line of quartz and red clay hills 1000 feet high, hills which may be continuation of the hilly watershed between the Makua at Ali Kobo and the sources of the Ngala. One would expects rapids at such a place, but there is only a good current and some awkward rocks; after reconnoitering in a boat, Mr. Grenfell got the *Peace* through easily, in February. Where we know the Kuta Makua next, they are placid and colossal; the Shinko at Marra is still 90 yards wide, 20 to 35 feet deep in October, and only 1980 feet above the sea. The average fall thence to Stanley Pool (1070 feet above the sea) is by this only some 9 inches to the mile, and the main Congo appears to nearly maintain this slope up to Bangala, beyond the Mobangi mouth.

BIOLOGICAL NOTES

INJURIOUS FUNGI IN CALIFORNIA.—The following facts recorded by Prof. W. G. Farlow are not without interest in Europe: *Nicotiana glauca*, abundant in Mexico, attracts attention by its pleasing foliage and graceful habit; it is a native of Buenos Ayres, but is acclimatised in Mexico. Within the last few years it has escaped from cultivation in California, and is now a common weed by the roadsides. At San Diego Prof. Farlow noticed that the leaves were badly attacked by a fungus which formed large, grayish-black spots on both sides of the leaves. Examination proved it to be *Peronospora hyoscyami*, De Bary, which was first found on *Hyoscyamus niger*, L., in Europe, where it does not appear to be at all common. Since it is well known that the species of Peronospora attack different species of flowering plants which belong to the same natural order, it is much to be feared that the disease which now attacks *N. glauca* may sooner or later extend to the cultivated tobacco, which belongs to the same genus. If this were to happen, the injury to the tobacco would be very great, since, by causing large spots on the leaves to rot, they would become worthless for manufacturing purposes. The question of the possible spread of the disease is one of importance, for it would be a very serious thing if it were to reach the great tobacco-growing regions of States like Virginia.

FERTILISATION OF CASSIA MARILANDICA.—The relation of insects to flowers continues to be a question of profound interest, but Mr. Meehan thinks that the dependence of a plant on insect aid is rather an indication that, instead of any material aid to its race being gained, its race is nearly run; he thinks that the opposite assumption has been an injury to the study of the main questions on fertilisation, and that the statements of Darwin and Asa Gray do not warrant the generalisations that have been drawn from them. In *C. marilandica* the phenomena attending pollen-formation are curious and apparently little known. The stamens are arranged in different sets. There are three beneath the pistil—the two lateral ones are very strong and equal the pistil in length, the central one immediately beneath the pistil is as long as those on each side, but more slender. Immediately above the pistil are four stamens, with short stout filaments, the anthers being perfectly formed and nearly as long as in the lower set. Above are three petaloid stamens. All the stamens have long black anthers, full of pollen, but which seems never to burst the anther cases. The only opening is at the apex, and this opening is covered by a membrane—never opening except by insect agency. As soon as the flower expands it is freely visited by humble-bees, and, as their loaded thighs evidence, for the pollen. To collect this they alight on the anthers of the long and lower stamens, as on a platform, make an opening in the apex of each of the four shorter ones, and then rifle them of their contents. A mass of plants containing eighty-eight flower-stems was watched on July 30, and the same lot for an hour on August 6, but no attempt was seen to be made by the bees to get the pollen from the longer anthers, or to use them in any way but as a platform. It would be very difficult for the bees to stand anywhere so as to have power to pierce the apical membranes of the longer stamens. When the flowers matured, and the anthers were ready to fall, they were examined, the four short ones were empty sacs, the three lower ones were full of pollen. These latter served no visible object to the flower or its insect visitors. While, however, no pollen could be detected on the stigmatic surfaces, still three out of every twelve flowers yielded a pod, and panicles of flowers covered so as to prevent egress of insects, neither produced fruit nor did a single anther open at its apex. In this case it would appear as if the fertilisation depended on the accident of the extracted pollen escaping from the insect to the stigma, and yet to an ordinary observer this plant would seem one specially arranged for cross-fertilisation. (Proc. Acad. Nat. Sci. Phil. 1886, p. 314.)

VARIATIONS IN THE NERVE-SUPPLY OF THE LUMBRICALES MUSCLES IN THE HAND AND FOOT, WITH SOME OBSERVATIONS ON THE PERFORATING FLEXORS.—Dr. H. St. John Brooks has lately investigated the subject of the varieties in the nerve-supply of the lumbricales. He finds—(1) Discrepancies in the statements of English and Continental anatomists. All these writers appear to be in error about the normal or commonest arrangement of the nerves to these muscles in the foot, and they appear never to have noticed a *double* supply to the third lumbrical in the hand. (2) Varieties of innervation that the author has observed in man, with an account of the nerve-supply in the orang, gibbon, and macaque monkey. He has discovered nerves entering the deep surface of the second (or indicial) lumbrical muscle in both hand and foot; these nerves, he believes, have never before been described: the latter, however, has been seen by Prof. D. J. Cunningham in the foot of a negro, and is recorded by him in his notes (as yet unpublished) of the anatomy of the negro foot. The following statistical table is compiled from the author's notes:—

Table of Variations in the Innervation of Lumbrical Muscles

HAND	Cases
First and second by median; third and fourth by deep ulnar	9
Third by median and deep ulnar (others as before) ...	6
Second and third by deep ulnar	1
First, second, and third by median (deep dissection not carried out)	2
Total	18
FOOT	
First by internal plantar; second, third, and fourth by deep external plantar	8

In the orang, gibbon, and macaque, the second lumbrical of the foot was supplied as in the above table. (3) Prof. Cunningham (*Challenger* Reports, vol. xvi.) has shown that, in Thylacinus and Cuscus, the lumbricals of the manus are all supplied on their superficial surface; a similar arrangement is found in the pes of the fox-bat; here, however, the deep external plantar also furnishes twigs to the two outer lumbricales. (4) It appears probable from these facts that the lumbricals were all originally supplied on their superficial surface: the deep nerve (ulnar in hand, external plantar in foot) is, on this hypothesis, gradually displacing the superficial (median; internal plantar). This invasion of the deep nerve has advanced further (in the case of the lumbricals) in the human foot than in the hand. The reverse is the case with the innervation of the short muscles of the pollex and hallux. (5) There is a general correspondence between the innervation of a particular lumbrical muscle and that belly of the long perforating flexor of which it is a part; this fact is best made out in the case of the first or indicial lumbrical of the band and the indicial belly of the flexor perforans, which are both supplied by the median; it is also seen in the fourth lumbrical and the belly of the long flexor ending in the tendon to the little finger (both by ulnar); also in the third lumbrical and annular belly (both of which have typically a double nerve-supply). In the foot and leg this part of the investigation presents special difficulties, which have, however, in a measure been overcome by minute dissections of the posterior tibial nerve and its branches, conducted under water. (*Dublin University Reports.*)

ON CERTAIN MODERN DEVELOPMENTS OF GRAHAM'S IDEAS CONCERNING THE CONSTITUTION OF MATTER[1]

I.

THERE is a certain fitness in our selecting this place to do honour to-night to the memory of Thomas Graham. For was in the chemical laboratory of this Institution that Graham carried out, upwards of half a century ago, the experimental investigations which culminated in his memorable discovery of the law connecting the rate of movement of a gas with its density. This law, combined with that of Boyle, which connects the volume of a gas with its pressure, and with the law of Charles, which expresses the relations of the volumes of gases to heat, has done more to give precision to our knowledge of the constitution of matter than all the speculations of twenty centuries of schoolmen.

Graham was made Professor of Chemistry in the Andersonian Institution in 1830, and it was from here that he gave to the world his classical paper "On the Law of the Diffusion of Gases," read before the Royal Society of Edinburgh, December 19, 1831. I am fully conscious that my only claim to be regarded as worthy to pronounce this eulogium of Graham arises from the circumstance that I also have had the good fortune to hold the Lectureship of Chemistry in this place; and with forerunners like Birkbeck, Gregory, and Graham, I may well be proud of an honourable and distinguished ancestry. This association with the Andersonian Institution naturally quickened my interest in Graham and his works, and my frequent opportunities of conversation with the late Dr. James Young, of Kelly, who for so many years was its President, and who was, as we all know, also one of Graham's discoveries, and for a long time, both here and in London, one of his most trusted assistants, enabled me to learn much of Graham's personal character and mode of work. On the occasion of the gift of Brodie's fine statue of Graham to the city by Dr. Young it fell to my lot to prepare the short biographical notice of my distinguished predecessor, which, with other papers relating to the matter, is, I understand, deposited in the archives of your Corporation. And I may be pardoned, perhaps, for recalling with what mingled feelings of pride and trepidation I set myself to the execution of that task.

In the preface to the admirable reprint of Graham's papers which we also owe to the filial piety of Dr. Young, the late Dr. Angus Smith has indicated in precise and even luminous language Graham's position in that chain of thinkers which includes Leucippus, Lucretius, Newton, and Dalton. Indeed, of all Angus Smith's papers with which I am acquainted there is none, to my thinking, more charming than this little introductory essay of a dozen octavo pages, in which, with unwonted perspicacity, he has defined Graham's place in the history of speculative philosophy. Angus Smith has here crystallised out, as it were, the thoughts of a life-time of literary research and meditation. Probably, no man—certainly no contemporary of Graham's—was better fitted by knowledge and by sympathy to form a sound critical estimate of such a position than the biographer of John Dalton. Angus Smith's mind was simply steeped in the old Hellenic philosophy. To him even Kapila was more than a name, and the atomic systems of India matters of more than conjecture or of passing interest. There was much in Smith's intellectual nature to make such inquiries congenial to him. With all his leaning towards objective science he had a Highlander's love of the mystical and a Lowlander's passion for metaphysics. And yet nothing is more admirable than the manner in which, in this essay, these qualities and this wealth of learning are subordinated and held in check, and nothing more striking than the way in which, in a few graphic strokes, done with a master hand, lightly yet firmly, with a consciousness of power and a sense of restraint, Graham's place in the evolution of the atomic philosophy is set forth.

It is here claimed for Graham that he was a true descendant of the early Greeks, and that to him belonged as of right the mantle of Leucippus. Atoms and eternal motion were as much fixed articles of his creed as they were of that of Heraclitus. But with no one of the older Greeks was Graham's thought more in harmony than with that of Leucippus. He, with his wider knowledge of the so-called "elemental" forms of matter, and of the persistency with which the specific properties which we associate with our "elements" are retained, could yet share with the old Greek his conceptions of the essential oneness of matter. It was with Graham, as Smith says of Leucippus, that "the action of the atom as one substance taking various forms by combinations unlimited, was enough to account for all the phenomena of the world. By separation and union, with constant motion, all things could be done."

In one respect Graham's position as an atomist is unique: no man before him had dedicated his life to the study of atoms and atomic motion. These fundamental ideas are intertwined to make up, so to say, the silver thread which runs through the work of forty years. They were the dominant conceptions of his life. Even in his earliest paper, published when he was just twenty-one, in which he treats of the absorption of gases by liquids, we are able to detect in the phraseology employed that his mind had been already permeated by the notion of atomic movement. That he should be familiar, even at this time, with the conception of atoms in the Daltonian sense is hardly surprising when we remember that he had already come under the influence of Thomas Thomson, whose place in the history of science is probably that of the first great exponent of Dalton's theory of chemical combination. But the idea of motion was never with Dalton an integral part of his theory, nor, in so far as it was necessary as serving to explain the phenomena of chemical union, was it held by Thomson. And this is the more remarkable when we remember that Dalton had discovered for himself the fact of the molecular mobility of a gas, and that his first glimpses of the truth of his great law were obtained by the study of chemical combination among gases. Graham was doubtless cognisant, in a general way, of the speculations of the early Greeks, but there is no evidence in any of his writings, nor has anything been preserved in the reminiscences of his friends and contemporaries, to indicate that he was knowingly influenced by them.

This continuity of idea is indeed the most striking characteristic of Graham's labours; all his work seemed to centralise round this fundamental conception of atomic motion. "In all his work," says Smith, "we find him steadily thinking on the ultimate composition of bodies; he searches after it in following the molecules of gases when diffusing; these he watches as they flow into a vacuum or into other gases, and observes carefully as they pass through tubes, noting the effect of weight and of composition upon them in transpiration. He follows them as they enter into liquids and pass out, and as they are absorbed or dissolved by colloid bodies, such as caoutchouc: he attentively inquires if they are absorbed by metals in a similar manner, and finds the remotest analogies, which, by their boldness, compel one to stop reading and to think if they be really possible. He follows gases at last into metallic combination, and the lightest of them all he makes into a compound with one of the heavier metals, chasing it finally through various lurking-places until he brings it into an alloy and the form of a medal, and puts upon it the stamp of the Mint. Indeed he is scarcely satisfied even with this, and he finds in bodies from stellar places—in meteoric iron—this same metallic hydrogenium which he draws out from its long prison in the form of a gas. . . If we examine his work on Salts and on Solutions we have a similar train of thought. One

[1] The Triennial "Graham Lecture," given in the Hall of the Andersonian Institution, Glasgow, on March 16, by Prof. T. E. Thorpe, F.R.S.

might have slighted the importance which he attached to the water of salts and the temperature at which it was reduced, but in his hands it was a revelation of some of the most mysterious internal phenomena of these bodies.

"A chemist must take great pleasure in following Graham when he seeks the laws of the diffusion of liquids and traces their connections, especially when they lead to such results as he expressed by dialysis, a process founded on a new classification of substances, and promising still the most valuable truths. We see in the inquiry how Graham thought on the internal constitution of bodies, by examining the motion of the parts, and from the most unpromising and hopeless masses under the chemist's hands—amorphous precipitates of alumina or of albumen—brought out analogies which connected them with the most interesting phenomena of organic life. Never has a less brilliant looking series of experiments been made by a chemist, whilst few have been so brilliant in their results or promise more to the inquirer who follows into the wide region opened."

In a short paper entitled "Speculative Ideas respecting the Constitution of Matter," originally published in the Proceedings of the Royal Society for 1863, Graham has left us his Confession of Faith upon the subjects to which he had devoted the whole of a thoughtful life. He conceives that the various kinds of matter now recognised as different elementary substances may possess one and the same ultimate or atomic molecule existing in different conditions of movement. Graham traces the harmony of this hypothesis of the essential unity of matter with the equal action of gravity upon all bodies. He recognises that the numerous and varying properties of the solid and liquid, no less than the few grand and simple features of the gas, may all be dependent upon atomic and molecular mobility. Let us imagine, he says, one kind of substance only to exist—ponderable matter; and further that matter is divisible into ultimate atoms, uniform in size and weight: we shall have one substance and a common atom. With the atom at rest the uniformity of matter would be perfect. But the atom possesses always more or less motion, due, it must be assumed, to a primordial impulse. This motion gives rise to volume. The more rapid the movement the greater the space occupied by the atom, somewhat as the orbit of a planet widens with the degree of projectile velocity. Matter is thus made to differ only in being lighter or denser matter. The specific motion of an atom being inalienable, light matter is no longer convertible into heavy matter. In short, matter of different density forms different substances—different inconvertible elements as they have been considered.

It should be said that Graham uses the terms "atom" and "molecule" in a wider sense than that which the limitations of modern chemistry have imposed upon them, and that he is referring to a lower order of molecules or atoms than those which more immediately relate to gaseous volume. The combining atoms of which he conceives the existence are not the molecules of which the movement is sensibly affected by heat with gaseous expansion as the result. According to Graham, the gaseous molecule must itself be viewed as composed of a group or system of the inferior atoms, following as a unit laws similar to those which regulate its constituent atoms. He is in fact applying to the lower order of atoms ideas suggested by the gaseous molecule, just as views derived from the solar system are extended to the subordinate system of a planet and its satellites.

We cannot as yet fix any limit to this process of molecular division. To Graham the gaseous molecule is a reproduction of the inferior atom on a higher scale. The diffusive molecules, the molecules or systems which are affected by heat, are to be supposed uniform in weight but to vary in velocity of movement in correspondence with their constituent atoms. Hence the molecular volumes of different elementary substances have the same relation to each other as the subordinate atomic volumes of the same substances.

On this basis Graham builds up a conception of chemical combination. He points out, in the first place, that these more and less mobile or light and heavy forms of matter have a singular relation connected with equality of volume. Equal volumes of two of them can coalesce together, unite their movement and form a new atomic group, retaining the whole, the half, or some simple proportion of the original movement and consequent volume.

Chemical combination thus becomes directly an affair of volume and is only indirectly connected with weight. Combining weights are different because the densities, atomic and molecular, are different. The volume of combination is uniform, but the fluids measured vary in density. This fixed combining measure—Graham's *metron* of simple substances—weighs 1 for hydrogen, 16 for oxygen, and so on with the other "elements."

Graham, however, points out that the hypothesis admits of another expression. Just as in the theory of light we have had the alternative hypotheses of emission and undulation, so in molecular mobility the motion may be assumed to reside either in separate atoms and molecules, or in a fluid medium caused to undulate. A special rate of vibration or pulsation originally imparted to a portion of the fluid medium enlivens that portion of matter with an individual existence, and constitutes it a distinct element or substance.

The idea of the essential unity of matter finds its analogy, to Graham's thinking, in the continuity of the so-called physical states of matter. He clearly perceived that there is no real incompatibility in the different states of gas, liquid, and solid. These physical conditions are, indeed, often found together in the same substance. The liquid and the solid conditions supervene, as Graham puts it, upon the gaseous condition rather than supersede it. They do not appear as the extinction or suppression of the gaseous condition, but as something superadded to that condition. Graham conceives that the three conditions (or constitutions) probably always co-exist in every liquid or solid substance, but one predominates over the others, just as the colloidal condition or constitution which intervenes between the liquid and crystalline states extends into both, and probably affects all kinds of solid and liquid matter in a greater or less degree. Hence, to Graham's thinking, the predominance of a certain physical state in a substance appears to be a distinction analogous to those distinctions in natural history which are produced by unequal development. Liquefaction or solidification does not involve the suppression of the atomic or molecular movement but only the restriction of its range.

Such then are Graham's ideas, formulated in 1863, respecting the probable constitution of matter. I have purposely stated them in great detail, and for the most part in Graham's own words. The paper is very short, but it has evidently been put together with great care. It is impossible not to be struck with the evidence it affords of Graham's insight, his grasp of principles and power of co-ordination. Consider, for example, what he says respecting the continuity of the so-called physical states of matter, and bear in mind upon what an extremely small experimental basis it rested at that time. The observations of Caignard Latour were almost forgotten, or, at all events their significance was not understood. The classical work of Andrews was not yet published. And yet this work and that of a dozen experimentalists in France, Russia, and Germany, has only served to confirm and expand Graham's fundamental conception. The whole paper shows Graham in a very different light from that in which the student of to-day might be apt to regard him. The greater number of his memoirs are mainly the records of measurements, but Graham was not a great measurer in the sense in which we apply that term to such men as Regnault, Magnus, or Bunsen. Very little of his work was done by his own hands, and it must be confessed that the earlier experimental portion was occasionally intrusted to apparently inexperienced assistants. Graham had, however, the *förscherblick* which characterises the true investigator, and he possessed a really marvellous faculty of sifting out the small grain of fact which often lay hidden beneath a mass of imperfect observation. And yet he was in no hurry to theorise. He patiently added fact to fact, repeating and verifying his observations long after he had got an inkling of the truth towards which they were tending. He laboured like Faraday, *ohne Hast*, *ohne Rast*, and his work is a monument of patient, concentrated thought, and of a singleness of purpose which never swerved.

"Experimentarian philosophers" of Graham's type (to use a phrase which Hobbes of Malmesbury once flung at the progenitors of the Royal Society) have very similar intellectual tendencies. One is insensibly led to compare Graham with the greatest of our English atomists—John Dalton. If you will turn to Dr. Henry's "Life of Dalton," and read the charming analysis of Dalton's mental characteristics, made by one who knew him well and who had studied him carefully, you will find that practically all that is there stated is equally applicable to Graham. Both men were pre-eminently endowed with the faculty of contemplating abstract relations of space and number, and each began his researches with the expectation that all empirical phenomena were to be brought under the control of mathematical laws. Thus Dalton strove to prove that the changes produced in the gaseous and liquid states of matter vary as the square, cube, or some other simple function of the temperature; Graham, in like manner, sought to show that the movement of his diffusive molecules, whether in liquids or in gases, was related to some equally simple function of their mass. Henry says of Dalton that "his inmost mental nature, and all its outward manifestations were in the language of the German metaphysicians, emphatically subjective. Thus in special or objective chemistry he has left absolutely no sign of his presence; no great monograph on an individual body and its compounds; no memorable analysis of a substance deemed simple into yet simpler elements; no new element—no Neptune—added to the domain of chemistry." Every word of these sentences could be applied with equal truth to Graham. The tendencies of both men were essentially introspective. Each was capable of the most patient concentrated thought and of steady prolonged attention, wholly abstracted from external objects and events. I have heard the late Dr. Young narrate the most extraordinary instances of Graham's power of mental abstraction. Dalton said of himself that, "If I have succeeded better than many who surround me, it has been chiefly, nay, I may say, almost solely, from unwearied assiduity. It is not so much from any superior genius that one man possesses over another, but more from attention to study and perseverance in the objects before them, that some men rise to greater eminence than others."

It seems like a contradiction in terms when we reflect for a moment upon the characteristic features and tendency of his work, to say that Graham, like Dalton, was utterly devoid of the quality we call imagination. Henry says of Dalton that imagination had absolutely no part in his discoveries; except, perhaps, as enabling him to gaze, in mental vision, upon the ultimate atoms of matter, and as shaping forth those pictorial representations of unseen things by which his earliest as well as his latest philosophical speculations were illustrated. Graham would not allow his fancy even that amount of play. Even in the speculative essay from which I have quoted so largely, it seems as if every word had been weighed and every sentence put together with slow laborious thought. This passionless aspect of his work seems to have greatly impressed Angus Smith, himself a man of lively sympathy and of quick susceptibility. "His works," says Smith, "are full of care, but not of joy."

(To be continued.)

SCIENTIFIC SERIALS

American Journal of Science, March.—On the absolute wave-length of light, by Louis Bell. The experiments here described were undertaken with a view to check the results obtained by C. S. Pierce for Prof. Rowland's great map of the solar spectrum, and to furnish a value of the absolute wave-length as nearly as possible commensurate in accuracy with the micrometrical observations. For the wave-length of D, at 20° C. and 720 mm. pressure, Mr. Bell obtains 5896·08, or *in vacuo* 5897·71, as compared with 5896·22, Rowland's micrometer measure from Pierce's preliminary result, and 5895·89, Thalén's correction of Ångström, both in air at ordinary temperature and 760 mm. pressure. But neither of these was corrected for errors in the gratings; hence, obviously, the cause of the discrepancy.—On the relative wave-length of the lines of the solar spectrum, by Prof. Henry A. Rowland. This measurement of the relative wave-lengths of the spectrum and its reduction to absolute wave-lengths by some modern determination has been undertaken in connexion with the photographic map of the solar spectrum on which the author has been engaged for several years, and which is now finished from the extreme ultra-violet wave-length 3200 down to wave-length 5790. Appended are tables of coincidences and of wave-lengths of standard lines.—The norites of the "Cortlandt series" on the Hudson River, near Peakskill, New York (continued), by G. H. Williams. Here are studied the mica norites, the augite norite (hyperite), pyroxenite, and the iron ore and emery in the Cortlandt norite. Owing to incipient alteration, easily visible under the microscope, the West-Chester County emery appears to be of less commercial value than that of Asia Minor.—Natural solutions of cinnabar, gold, and associated sulphides, by George F. Becker. In the course of investigations on the geology of the quicksilver deposits of the Pacific slope, the author has made some studies, here detailed, on the question of the state of combination in which quicksilver is dissolved in natural waters. The solubility of zincblende, pyrite (marcasite), copper sulphides, gold, and other associates of cinnabar, is incidentally examined, the quantitative analysis involved in the process being made by Dr. W. H. Melville.—Fluviatile swamps of New England, by N. S. Shaler. In examining the fresh-water swamps of this region, the author has carefully studied the geographical distribution of those formed along the banks of rivers. Although the inquiry is mainly limited to the post-glacial changes in the valleys trending northwards, much light is incidentally thrown on the pre-glacial altitude of the continent. It is made evident that these valleys could not have been excavated by streams of their present slope; hence the inference that the descent of the northward flowing rivers must have been more rapid in pre-glacial times than at present; in other words, this part of the continent was at that time relatively less elevated in its northern parts than it is at present.—On the Mazapil meteoric-iron which fell on November 27, 1885, by William Earl Hidden.—On observations of the eclipse of August 18, 1887, in connexion with the electric telegraph, by Prof. David P. Todd. Referring to his remarks in the Proceedings of the American Academy of Arts and Sciences for 1881, p. 359, the author points out how the proposed method of telegraphic transmission of important observations might be adopted during the eclipse of August 18 next.—On two new meteorites from Carroll County, Kentucky, and Catorze, Mexico, by George F. Kunz. The Kentucky iron has some ethnological interest in connexion with the ornaments of meteoric iron occurring in the mounds of the Little Miami Valley, Ohio, all apparently belonging to one and the same meteoric fall. The Catorze mass, weighing 92 pounds, was found near Catorze, San Luis, Potosi, in 1885. It is one of the caillite group of Stanislas Meunier, and shows the Widmanstätten lines very finely. Analysis: Fe 90·09; Ni and Co 9·07; P 0·24; with specific gravity 7·509.

Rivista Scientifico-Industriale, February.—On the cause of the electric discharge accompanying thunderstorms, by Prof. G. Guglielmo. The views of Ermann and Peltier are here subjected to close scrutiny, and shown to be inadequate to account for these electric phenomena.—On the variations in the electric resistance of antimony and cobalt in the magnetic field, by Dr. G. Faé. The author's researches show that, apart from the intensity of the observed effects, antimony behaves in the way determined by Righi for bismuth, and cobalt in the way determined by Thomson for iron and nickel.

Rendiconti del Reale Istituto Lombardo, February.—Summary of the meteorological observations recorded in the Brera Observatory, Milan, during the year 1886, by E. Pini. The daily, monthly, and annual means are tabulated for the atmospheric pressure, temperature, rainfall, velocity, and direction of the winds throughout the year.—Meteorological observations for the month of January, 1887, at the same Observatory.

SOCIETIES AND ACADEMIES

London

Royal Society, March 10.—"Note on Induction Coils or 'Transformers.'" By John Hopkinson, M.A., D.Sc., F.R.S.

"Note on the Theory of the Alternate Current Dynamo." By John Hopkinson, M.A., D.Sc., F.R.S.

March 17.—"The Embryology of Monotremata and Marsupialia." Part I. By W. H. Caldwell, M.A., Fellow of Gonville and Caius College, Cambridge. Communicated by Prof. M. Foster, Sec. R.S. (Abstract.[1])

(1) *The Egg-membranes.*—In Monotremata, in very young ova, a fine membrane exists between the single row of follicular cells and the substance of the ovum. This membrane, which I will call *the vitelline membrane*, at first increases in thickness with the growth of the ovum, and through it pass numerous fine protoplasmic processes connecting the protoplasm of the follicular cells with that of the ovum, and serving to conduct food granules, which, appearing in the neighbourhood of the nuclei of the cells, travel thence to the ovum; food granules also appear in the neighbourhood of the germinal vesicle, and travel away from it: hence the horseshoe-shape of the yolk-mass as seen in section.

[1] The author being at the present time in Australia and so unable to correct the proof of this abstract, I have undertaken this duty. In doing so I have ventured, for the sake of what appeared to be increased clearness, to introduce into § 1 some modifications of the author's manuscript, being guided therein by the author's more detailed account given in the fuller paper.—M. Foster, Sec. R.S.

The time during which food granules are thus passing from the follicular cells to the ovum may be called "the yolk forming period."

It is succeeded by a period during which the vitelline membrane again becomes thin, the follicular cells are reduced to a single layer, and the cells are very thin and flat. This period may be called the "absorption of fluid period," since during it the ovum absorbs large quantities of fluid through the thin vitelline membrane and single layer of thin follicular cells, and thereby increases largely in size.

This is in turn succeeded by a third period, during which the follicular cells again become active, multiply, increase greatly in size, and give rise between themselves and the vitelline membrane to a deeply standing homogeneous layer, which I will call *the chorion*. This period may hence be called "the chorion forming period." All these three periods are gone through while the ovum is still in the follicle.

Upon the bursting of the follicle and the reception of the ovum in the Fallopian tube, a few of the follicular cells remain attached to the chorion; the majority are left behind within the burst follicle.

During the passage along the Fallopian tube, the vitelline membrane again increases in thickness, and the chorion, also increasing in thickness, absorbs fluid and becomes *the albumen layer*. Outside this now appears a new structure, *the shell* or shell-membrane, of tough parchment-like consistency,[1] not staining with reagents. I have not yet traced the deposition of the shell to the activity of any special glands; but I can say that the shell-membrane does not increase at the expense of the chorion or albumen layer.

After reaching the uterus both vitelline membrane and shell-membrane increase in thickness, but the albumen layer diminishes and disappears, serving apparently for the nutrition of the ovum. Immediately beneath the vitelline membrane a new layer is now seen in hardened preparations; but it may be shown that this layer is really fluid, yielding a coagulum which stains deeply with reagents, the fluid being apparently derived, through the membranes, from the uterine glands.

In Marsupialia the history of the vitelline membrane, save that "the yolk forming period" is not marked off from the "absorption of fluid" period, is similar to that in Monotremata. I have not been able to trace the beginning of the "chorion" while the ovum is still in the ovary, in Marsupialia; but in an ovum of Phascolarctos from the uterus, I found a chorion like that of Monotremata, and surrounded moreover by a thin transparent membrane—a *shell-membrane*. Within the uterus the chorion, increasing in thickness, becomes transformed into an albumen layer, and is eventually absorbed, passing through the vitelline membrane to nourish the ovum, so that eventually the vitelline membrane comes to be close to the shell.

As in Monotremata, a coagulable, and, when coagulated, deeply staining fluid makes its appearance between the vitelline membrane and ovum (blastoderm).

The shell-membrane persists until the developing ovum becomes fixed to the walls of the uterus, after which it disappears.

The paper then compares the egg-membranes just described with those of Placentalia, and those of Vertebrata generally.

(2) *Segmentation.*—The telolecithal ova of Monotremata and Marsupialia go through a partial segmentation. The ova of Placentalia segment completely, but the resulting blastodermic vesicle is identical with that produced by partial segmentation in Monotremata and Marsupialia.

In Monotremata there is a posterior lip to the blastopore similar to that of Elasmobranchii. The epiblast grows in so rapidly from the sides, that a primitive streak region is formed in front of the posterior lip long before the epiblast has inclosed the yolk. This uninclosed area in front of the primitive streak probably includes a region where the hypoblast (yolk) has secondarily broken through the epiblast. The existence of such a region would hide the position of the anterior lip of the blastopore. The circumference of the circle made up by the larger arc of the edge of the blastoderm on the yolk, and the smaller arc of the posterior lip of the blastopore, is a measure of the quantity of yolk in a meroblastic ovum.

In Marsupialia the epiblastic growth incloses the hypoblast at a very early age, except over a narrow slit in front of the posterior lip of the blastopore. This slit corresponds to the area inclosed by the circle described above in a meroblastic egg. The primitive streak is not conspicuous at an early age because of the large size of the cells. No hypoblast projects through the epiblast in front of the primitive streak region. I would explain the segmentation and the gastrula of Placentalia in the same way. Balfour's objection ("Comp. Embryol." vol. ii. p. 187) to Van Beneden's original comparison of the blastopore of the rabbit with that of a frog, is explained away by the presence of a posterior lip to the blastopore in Marsupialia. My explanation postulates the existence of a similar structure in the rabbit. The blastopore of the rabbit corresponds therefore to the whole area marked out by the growing epiblast and the posterior lip of the blastopore, before the closing of the primitive streak region, or to this area minus the secondary extension, caused by the projecting yolk, in Monotremata.

[1] In the laid egg of Echidna I have not detected calcic salts, but that of Ornithorhynchus gives rise to gas when treated with dilute acid.

Linnean Society, March 17.—Mr. W. Carruthers, F.R.S., President, in the chair.—A recommendation of the Council to present to the British Museum, Kew, and the Oxford Botanical Gardens, the Society's carpological collection was submitted to the Fellows, but not approved by them.—Mr. C. B. Clarke, F.R.S., was elected into the Council in the place of Dr. H. Trimen, who resigned.—Mr. A. O. Walker read a paper on the Crustacea of Singapore. These were collected by Surg.-Major Archer during 1879–83. The species were chiefly dredged in 15–20 fathoms, or got on shallow banks. A full list is given of all the forms identified, and several new species are described. Among these are: *Doclea tetraptera*, *Xanthe scaberrimus*, *Maii miersii*, and *Caphyra archeri*.—A paper was read by Dr. Geo. King, on the genus *Ficus*, with special reference to the Indo-Chinese species. The genus *Ficus* was founded by Linnæus, and included seven species ("Species Plantarum," 1st ed.) Later editions contained 118 species. Blume described 93 Malayan figs, and Roxburgh 55 Indian species. In the "Hortus Cliffortianus" Linnæus clearly comprehended the difference of the sexes, *i.e.*, Caprifig = male, the so-called Fig = female, and *Erinosyce* = hermaphrodite. Vahl seems to have misunderstood the arrangement of the sexes, and Blume apparently followed him. Roxburgh is the first writer who examined minutely the florets of nearly the whole of the species, finding two androgynous and the majority monandrous. Later on Gasparini and Miquel each made a careful study of the flowers of the genus, and separately gave different classifications of the group. Miquel subsequently altered his arrangement, making divisions into six sub-genera, while enumerating 405 Old World, 128 American, and twenty-two species of doubtful nativity. In the "Genera Plantarum" of Bentham and Hooker four of Miquel's sub-genera are admitted, a fifth considered doubtful, and a sixth rejected. These authors regarded Miquel's divisions as too loosely defined, and recommended a re-working of the group. Dr. King goes into a lengthened description of the structural peculiarities of the flowers of the genus *Ficus*. He specifies (1) male, (2) pseudo-hermaphrodite, (3) neuter, and (4) female fertile flowers. Besides these, he states that there occurs in all the species of *Ficus* a set of flowers originally named by himself "*insect-attacked-females*," but for which he has adopted Count Solms-Laubach's term "*gall-flowers*" (*Bot. Zeit.* 1885); the latter botanist having anticipated him in publication, though King's researches had been commenced earlier. King enters into the question of these gall-flowers, stating that, in the majority, the pupa of an insect is present, and this pupa can usually be seen through the coats of the ovary. The pupa when perfected escapes into the cavity of the receptacle by cutting its way through or by bursting these coats; and fully-developed winged insects are often to be found in considerable numbers in the cavity of the fig. The opening through which each insect has escaped from the ovary in which it has been developed is afterwards clearly visible. The pupa of the insect must become encysted in the ovary of the gall-flower at a very early period, for about the time at which the imago is escaping from the ovary the pollen of the anthers of the male flower is only beginning to shed. Now, there is nothing in itself remarkable in the mere occurrence in the genus of numerous flowers having the general form of females, which yet by reason of certain peculiarities in their structure are incapable of fertilisation by pollen practically barren; while at the same time their structural defects fit them for becoming the nidus for the larvæ of special insects. But, when the manner in which these malformed female flowers are disposed in the receptacle is inquired into, it becomes clear that through the interposition of insects these malformed female flowers may play a most important part in the life-history of many species of the genus *Ficus*. Thus from the peculiarities in the structure and arrangement of the flowers, Dr. King is of opinion that the evolutionary history of the genus *Ficus* may be traced. On data derived therefrom he arranges the Indo-Malayan species into two great groups, the second of these being again divided into three subsidiary sub-groups as follows:—

Ficus, Linn.	Group I. Pseudo-hermaphrodite.			Palæomorphe
	Group II. Unisexual	Sect. 1		Urostigma
		Sect. 2		Synœcia
		Sect. 3	A	Sycidium
				Covellia
			B	Eusyce
				Neomorphe

Physical Society, March 12.—Prof. G. Carey Foster, Vice-President, in the chair.—Mr. Shelford Bidwell described some experiments which seem to show that the electrical resistance of suspended copper and iron wires, alters with the direction of the testing current. The apparatus used consisted of a metre bridge with coils of 100 ohms in the gaps adjoining the standard wire, the other two arms being two suspended wires united at the top, to which point one terminal of the galvanometer was joined. A commutator placed in the battery circuit served to reverse the testing current. When a wire is suspended vertically the stress increases from below upwards, and the author believes the observed effects to be due to the absorption of heat by the current as it passes from a stretched towards an unstretched part of a copper wire, and the evolution of heat when it passes from an unstretched towards a stretched part. As the apparatus was arranged the current passed up one side and down the other, heating the one and cooling the other, thus disturbing the position of balance. If iron wires were used the heating and cooling effects were reversed. Prof. S. P. Thompson suggested loading the wires at different points in order to vary the stress without using such long wires, and Mr. C. V. Boys thought still shorter wires could be used by joining the ends to a revolving spindle and stretching them by centrifugal force.—On a lecture experiment in self-induction, by Mr. Shelford Bidwell. A telephone is placed in series with the secondary coil of an induction coil and another coil whose self-induction can be raised by inserting a core of iron wires, or another coil, or both. The effect of introducing the iron core is very marked, reducing the sound enormously. If a coil of wire containing an iron core be inserted, the effect of short-circuiting the coil is to increase the sound in the telephone. The same author also described and showed an experiment due to Dr. Fleming, in which a disk of copper inclined at an angle of 45° to the axis of a coil of wire and suspended bifilarly, is deflected by passing an undulatory current round the coil. In explanation of the former experiment, Dr. Fleming wrote down the formulæ for the effective resistance and self-induction of a circuit near another closed circuit, which show that the former is greater and the latter less for undulatory than for steady currents. He had not arrived at any satisfactory explanation of the deflection of the copper disk. Prof. Ayrton exhibited a tuning-fork worked electrically, in which the pitch could be varied by altering the self-induction of the circuit, or by varying the position of the make-and-break screw. Mr. C. V. Boys referred to his experiments, published in 1884, on the impulse given to metal disks suspended in a magnetic field whose strength is suddenly changed, as being of a similar character to that described by Mr. Bidwell, and suggested the use of aluminium instead of copper in future experiments, owing to its conductivity for the same weight being greater. Prof. Thompson said he had recently used a similar apparatus to that described by Mr. Bidwell as an illustration of the effect of self-induction, and pointed out the uses of self- and mutual-induction in multiplex telegraphy and telephony. As an explanation of the deflection of the copper disk by alternating currents, Prof. Foster thought it possibly due to its initial position being that of maximum sensibility, and therefore each impulse had less effect than the preceding one. Mr. W. M. Mordey mentioned a simple arrangement for varying self-induction used by Mr. Ferranti to control the power of incandescent lamps worked by alternating currents, and Prof. Ayrton described a closed magnetic circuit of great self-induction, used to protect voltmeters on the telpher line at Glynde from disastrous inductive effects produced by breaking the locomotive circuit. Referring to tuning-forks, Mr. Bosanquet thought some self-induction was necessary in order that the current should act to the best advantage in attracting the prongs at the proper instant. Further remarks were made by Mr. Boys and Prof. Perry.—On a lecture experiment to show that capacity varies inversely as the thickness of the dielectric, by Profs. W. E. Ayrton and John Perry. The authors consider it easy for students to see that, other things remaining constant, capacity is proportional to area. Taking this as proved, a condenser is arranged such that the area A of the insulated inner coating varies as the thickness t of the dielectric, and the potential difference between the coatings is found by experiment to be constant. Then since $\text{capacity} = \frac{\text{quantity}}{\text{potential}}$, and both the latter being constant, therefore the capacity of the condenser is constant. But by the construction of the apparatus $\frac{A}{t}$ is constant, and it is assumed that capacity varies as A, therefore capacity must vary inversely as t.—Note on magnetic resistance, by the same authors. Two iron rings about 6 inches diameter, made from the same bar of best Swedish iron about half an inch in diameter, were wound with insulated wire in two halves, so that a current could be sent round either or both halves, and the resulting induction measured by the throw of a ballistic galvanometer placed in series with a few convolutions of wire wound round the outside of the main winding. One of the rings was continuous, and the other had a small air space of about 0·8 mm. in a plane perpendicular to that of the ring and passing through its axis, as if the ring had been cut by a saw. The primary object of the experiments, which were made by Messrs. Aldworth, Dykes, Lamb, Robertson, and Zingler, of the Central Institution, was to determine whether there was any appreciable "surface magnetic resistance." The results do not show any such resistance, and the relative resistance of air and iron as calculated from the unsaturated parts are about as 1200 to 1, a number agreeing fairly well with those obtained by other experimenters. From this the authors conclude that for small distances magnetic resistance of air is proportional to length. When the magnetising current was passed round the one half of the divided ring on which the test coil was wound, a greater induction could be obtained than by any other way of magnetising, and this the authors do not attempt to explain. Mr. Bosanquet said he had always found greater inductions obtainable in the middle of bar electro-magnets or open magnetic circuits, than could be produced in closed magnetic circuits, and thought the above observations confirmed his own results. A discussion followed in which Mr. C. V. Boys, Mr. W. M. Mordey, Mr. Bosanquet, and Prof. Perry took part.—On account of the late hour the reading of a note on dynamo machines and motors, by Profs. Ayrton and Perry, was postponed till the next meeting.

Zoological Society, March 15.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's menagerie during the month of February 1887.—Mr. Howard Saunders exhibited a young male Harlequin Duck (*Cosmonetta histrionica*), shot off the coast of Northumberland on December 2 last, and remarked that it was the second authentic British-killed specimen in existence.—Mr. Oldfield Thomas read a paper on the Bats collected by Mr. C. M. Woodford in the Solomon Islands.—A communication was read from Mr. W. R. Ogilvie Grant, containing an account of the birds collected by Mr. C. M. Woodford at Fauro and Shortland Islands, in the Solomon Archipelago, and in other localities of the group.—A communication was read from Mr. G. A. Boulenger, containing a second contribution to the herpetology of the Solomon Islands.—Mr. Oldfield Thomas read a paper describing the milk-dentition of the Koala (*Phascolarctos cinereus*), which was shown to be in the same state of reduction as had been described by Prof. Flower in the case of the Thylacine.—A second communication from Mr. Boulenger contained a description of a new Gecko of the genus *Chondrodactylus* from the Kalahari Desert, South Africa, based on a specimen which had been presented to the Natural History Museum by Mr. J. Jenner Weir. The author proposed to call it *C. weiri*.

Geological Society, March 9.—Prof. J. W. Judd, F.R.S. President, in the chair.—The following communications were read:—On *Chondrosteus acipenseroides*, Ag., by Mr. James W. Davis.—On *Aristosuchus pusillus*, Ow., being further notes on the fossils described by Sir R. Owen as *Poikilopleuron pusillus*, Ow.; on *Patricosaurus merocratus*, Seeley, a lizard from the Cambridge Greensand, preserved in the Woodwardian Museum of the University of Cambridge; on *Heterosuchus valdensis*, Seeley, a procœlian crocodile from the Hastings Sands of

Hastings; on a sacrum, apparently indicating a new type of bird (*Ornithodesmus cluniculus*, Seeley), from the Wealden of Brook, by Prof. H. G. Seeley, F.R.S. In the last paper, after some remarks on the characters of the sacrum in birds, Ornithosauria, and Dinosauria, the author proceeded to describe a sacrum composed of six vertebræ in the Fox Collection, now at the British Museum, and then to compare the fossil with the corresponding bones of the three groups named. The resemblance to the Dinosaurian and Ornithosaurian sacral vertebræ was less than those which connected the fossil with birds. From the latter it was distinguished by the smaller number of vertebræ in the sacrum, the absence of sacral recesses for the lobes of the kidneys, and the form of the articular face of the first sacral vertebra. But the small number of sacral vertebræ in *Archæopteryx*, the want of renal recesses in *Ichthyornis*, and the characters of the articulation in the Solan goose showed that these differences were not essential; and the author concluded that the fossil belonged to a true bird, but that it formed a link with lower forms, and approximated more to Dinosaurs than did any other Avian type hitherto described.

Chemical Society, March 17.—Dr. Hugo Müller, F.R.S., President, in the chair.—The following papers were read:—The action of heat on nitrogen peroxide, by Dr. A. Richardson.—Supersaturation of salt solutions, by Dr. W. W. J. Nicol. This paper contains an account of experiments on the physical constants of supersaturated and dilute salt solutions. The solutions were examined in two ways: (1) concentration constant and temperature varying; (2) temperature constant and concentration varying; in this way it was possible to pass from dilute to supersaturated solutions, and to examine the change in the various physical constants. The electric conductivity, specific viscosity and rate of expansion were examined by the first method. The specific viscosity and density by the second. In every case it was found that the curve corresponding to the non-saturated solutions was perfectly continuous with that for the supersaturated solutions. From this the author concludes that the constitution of dilute, saturated, and supersaturated solutions is the same. Supersaturation is explained by the hypothesis that the substance in solution is not the same as that which crystallises out. A supersaturated solution of sodium thiosulphate deposited crystals of the composition $Na_2S_2O_3,H_2O$ when evaporated *in vacuo*, showing that the solution does not contain the pentahydrate. The author believes that the salt in solution is combined with the whole of the water, an opinion based on his experiments on vapour-pressures and molecular volumes. Colour changes in solution are not, he believes, due to hydration, but to rearrangements of the salt molecule similar to that which occurs in the case of chromium sulphate. Dr. Nicol's views were criticised by Mr. Pickering and Dr. Armstrong.—The formation of γ-naphthalenesulphonic acid by means of sulphuric anhydride and on γ-dihydroxynaphthalene, by Dr. Henry E. Armstrong and Mr. W. P. Wynne.—α-Cyanonapthalenesulphonic acid, by Dr. Henry E. Armstrong and Mr. S. Williamson.—Addendum to paper entitled an explanation of the laws which govern substitution in the case of benzenoid compounds, by Dr. Henry E. Armstrong.—The transformation of citric acid into pyridine-derivatives, and on the constitution of pyridine, by Dr. S. Ruhemann.—Silver containing bismuth, by Mr. William Gowland.

Royal Meteorological Society, March 16.—Mr. W. Ellis, President, in the chair.—The following papers were read:—Notes on taking meteorological observations on board ship, by Capt. D. W. Barker. The author makes various suggestions as to the placing of meteorological instruments on board ship with the view of securing uniformity.—Marine temperature observations, by Dr. H. R. Mill. After briefly sketching the principal historical methods of observing temperature beneath the surface of the water, Dr. Mill discussed in some detail the relative merits and defects of the two instruments now in common use for this purpose. The self-registering maximum and minimum thermometer on Six's principle, even with the addition of an outer bulb to protect it from pressure, has certain inherent defects. It merely shows the highest and lowest temperatures passed through, the indices are liable to be shaken from their proper position, and it requires long immersion in order to attain the temperature of its surroundings. Mr. J. Y. Buchanan has shown how, by the use of mercury and water piezometers, the actual temperature at a given point may be obtained, no matter how the temperature between that point and the surface may vary. Such instruments have not been much used, and now a modification of the mercurial outflow thermometer, patented by Messrs. Negretti and Zambra as the "standard deep-sea thermometer," is largely used. When fitted in a frame which admits of the thermometer registering at a precisely known depth, admirable results are obtained by it. The manner of using these thermometers in the Scottish frame and of conducting temperature trips in comparatively shallow water was described; and the best ways of recording the observations and elaborating the results were alluded to; the work of the Scottish Marine Station on the Clyde sea area being taken as an illustration. The importance of marine temperature observations as bearing on submarine geography, on navigation, on the distribution of animal life, and consequently on fisheries, was alluded to. The paper was illustrated by diagrams, and by the exhibition of the apparatus which was described.—After the reading of these papers the meeting was adjourned in order to afford the Fellows an opportunity of inspecting the Exhibition of Marine Meteorological Instruments and Apparatus which has been organised under the auspices of the Society.

Victoria Institute, March 7.—The Rev. Dr. Walker read a paper on insect life in the East, in which he gave a full report of his entomological researches in Egypt and the East, and drew special attention to the very great number of British varieties that he had captured in various parts of the world. During the discussion, Dr. Sydney Klein remarked on the value to science of Dr. Walker's labours, and, in regard to insect life in the East at night, said that when passing a night among the ruins of Ephesus he found its superabundance manifested by the actual roar of chirps, scrapings, rattles, hummings, and cries from the country round, quite equalling his experience in the woods of Central America. Mr. Hastings C. Dent gave an account of his observations in South America and elsewhere.

MANCHESTER

Literary and Philosophical Society, January 17.—Prof. W. C. Williamson, F.R.S., in the chair.—Mr. Henry Hyde exhibited a leaf of *Bryophyllum calycinum*, with young plants growing out of the margin.—Dr. Alex. Hodgkinson read a paper on cavities in minerals containing fluid, with vacuoles in motion, and other inclosures.—Prof. W. C. Williamson, F.R.S., gave a practical demonstration by means of sections, shown by the oxy-hydrogen camera, of the structure and development of young roots. Beginning with those of the maize as they appear within the seed, Prof. Williamson exhibited and explained those of the vine, of the bean, of the crown imperial, and of the several species of cycads, illustrating the changes which roots undergo between the uniform structure seen near the root or tip, to their more advanced condition, as seen first in the roots of endogenous plants, and afterwards in the more complicated ones of exogens.

PARIS

Academy of Sciences, March 21.—M. Janssen, President, in the chair.—On the movement of a solid in a liquid, by M. Halphen. A theoretical demonstration is given of the general proposition that this movement consists of (1) a uniform helicoidal motion round a fixed axis in space; (2) a uniform rotation round a fixed axis in the solid; (3) a periodical movement.—On the great atmospheric movements in connexion with MM. Schwedoff, Colladon, and Lasne's cyclonic theories, by M. Faye. The paper is devoted to a refutation of these various theories, which are stated to be mainly due to the confusion caused by failing to distinguish between movements produced artificially in the air or water by a simple rotatory action, and the natural cyclones, tornadoes, waterspouts, &c.; the two orders of phenomena having only an apparent relation to each other.—Some observations and reflections on the earthquake of February 23 at Antibes, by M. Ch. Naudin. At this point of the coast the sea suddenly retired about 3 feet, soon returning with considerable velocity to its normal level. This and the associated phenomena are attributed, not to any volcanic action or to the gases confined in vast subterranean cavities, but to the resistance offered by certain parts of the terrestrial crust to the electricity generated in the globe itself. It is pointed out that these disturbances occur always in districts destitute of forest growths which might serve to discharge the atmospheric electricity, and on this is founded a fresh argument for replanting lands that have become disafforested.—On the red fluorescence of alumina, by M. Lecoq de Boisbaudran. Some experiments are described leading to the inference that this fluorescence is due to the presence of traces of chromium in ordinary alumina, and cannot be produced by the pure earth itself.—Earthquakes in connexion with fire-damp, by

M. F. A. Forel. It is suggested that the series of slight vibrations almost invariably following the first great shocks may tend to cause the escape of fire-damp in mines, and that the precautions against this danger should consequently be redoubled in mining districts within the range of the general disturbance.—On a possible cause of the earthquakes of 1755, 1884, and 1887, by M. A. Blavier. An attempt is made to associate these occurrences with an abnormal accumulation of ice in the Polar waters, causing a deflection of the Rennel branch of the Gulf Stream, attended by great climatic changes and a slight disturbance of equilibrium in the submarine bed, followed by a possible local fracture along the line of least resistance. The in-rush of cold oceanic waters would appear to be indicated by the disappearance of the sardines from the West Coast of Europe in the years in question.—On the employment of gas as a constant source in experiments on radiation, by M. Edouard Branly. In this communication a comparative study is made of the moderator lamp and gas jet, as two sources of mean temperature in these experiments.—On the tartrate of antimony, by M. Guntz. A process is described for preparing in the pure state the acid tartrate of antimony, which Peligot obtains by alcoholic precipitation of a concentrated solution of the oxide of antimony in tartaric acid.—On the presence and quantitative analysis of alumina in wine and the grape, by M. L. L'Hote. The results are given of experiments made to determine the presence in appreciable quantities of antimony in Burgundy, Roussillon, and some other red wines.—Note on some new syntheses in the fatty series by means of the chloride of aluminium, by M. Alphonse Combes.—On the microbe of yellow fever and its attenuation, second note, by MM. Domingos Freire, Paul Gibier, and C. Rebourgeon. In continuation of their studies on this microbe, discovered by them in 1884, the authors describe a process by means of which the virus may be attenuated and converted into a prophylactic vaccine.—Calorimetric studies on sick children, by M. P. Langlois. The experiments here described show that in chronic disorders with hypothermy there is a diminution of caloric, which increases in maladies with hyperthermy.—On certain characteristics of the pulse in morphiomaniacs, by Messrs. B. Ball and O. Jennings. The observations here illustrated by sygmographic tracings serve both to detect the practice in patients secretly addicted to the taking of morphia and to remove the craving for intermittent doses.—Mineralogical study of the Fort Duncan meteoric iron recently presented to the Paris Natural History Museum, by M. Stanislas Meunier. The analysis of this specimen, found in 1882 near Fort Duncan, Maverick County, Texas, shows a remarkable resemblance to the mass which fell at Braunau, Bohemia, on July 14, 1847. It yielded: iron, 92·02; nickel, with traces of cobalt, 6·10; residuum, 1·80; density 7·699.

STOCKHOLM

Royal Academy of Sciences, February 9.—The following papers were accepted for insertion in the Proceedings of the Academy:—On the so-called anomalous dispersion, by the late Colonel C. E. af Klercker. On benzol and toluol monosulcombinations, by Dr. Mats Weibull.—The Lettersted Prize for 1887 for the best original scientific work was awarded to Prof. F. A. Smitt for his "Critical Index of the *Salmonidæ* in the National Museum," whilst the amount of the same legacy for special scientific work was awarded to Prof. A. G. Nathorst for his researches on the Tertiary flora of Japan.—The Secretary announced that the Proceedings of the Academy for 1886 were completed, and that the first part ("Aurores boréales") of Series II. of the work "Observations faites au Cap Thordsen, Spitzberg, par l'Expédition Suédoise," published at the expense of the Academy, was issued.—The following two papers were also presented by Prof. Berlin:—On six isomeric acids of toluol disulphone, by Dr. P. Klason. On the substitution of the amido group in aromatic combinations for hydrothion as well as oxysulphuryl by means of diazo combinations, by the same.—Prof. Edlund advanced a strictly mathematical demonstration showing the correctness of his theory regarding unipolar induction.—Prof. Gyldén presented the following papers:—Untersuchungen über einen speciellen Fall des Problems der drei Körper, founded on studies at the Stockholm Observatory, by Dr. P. Harzer, of St. Petersburg. On the absolute correctness of terms of expression employed by Prof. Gyldén in order to solve the problems of three bodies, by himself, which paper will shortly appear in the *Acta Mathematica*.—Prof. Smitt announced the appearance of a new edition of the illustrated work "Skandinaviens Fiskar" ("The Fishes of Scandinavia"), in which are a number of original drawings by Herr W. von Wright, belonging to the Academy, which have never been published before. He also presented the first report of the Ornithological Committee appointed by the Academy.—Prof. Mittag-Leffler presented the following papers:—On convergents to definite integrals, by Herr C. B. S. Cavallin. On a treatise by Ascoli relating to the integration of the differential equation $D^2u = 0$ for a given Riemann surface, by Dr. G. Eneström. Integration der differential Gleichung $D^2u = 0$ in einen beliebigen Riemannischen Fläche, by Prof. Giulio Ascoli, of Milan.—The Secretary presented the following papers for insertion in the Proceedings:—On the influence of chlorium on α-acetic naphthalid, by Prof. Cleve. On naphthalid acids, by Dr. A. G. Ekstrand. On α- and β-naphthamidoxim, by the same. On the resin acids in galipot, by Dr. A. Westerberg. On pteropods in the Zoological Museum of the Upsala University, collected by Capt. G. von Scheele, classified by Dr. H. Munthe. Notes on Permian fossils from Spitzbergen, by Prof B. Lundgren. Einfluss der Neutralsalze auf die Reactionsgeschwindikeit der Verseifung von Actylacetat, by Dr. S. Arrhenius.

BOOKS, PAMPHLETS, and SERIALS RECEIVED

Ligaments, their Nature and Morphology: J. B. Sutton (H. K. Lewis.)—School Hygiene: Dr. A. Newsholme (Sonnenschein).—Atlantic Weather Charts, part 1, from August 1 to November 7, 1882 (Stationery Office).—Electrical and Anatomical Demonstrations: Dr. H. Tibbits, (Churchill).—Memoirs of the Literature College, Imperial University of Japan, No. 1; The Language, Mythology, and Geological Nomenclature of Japan, viewed in the light of Aino Studies: B. H. Chamberlain and J. Batchelor (Tōkyō)—Verhandlungen des Naturhistorischen Vereines, Zweite Hälfte (Max Cohen, Bonn).—Colonial and Indian Exhibition; Reports on the Colonial Sections: Edited by H. T. Wood (Clowes).—Monthly Results of Observations made at the Stations of the Royal Meteorological Society for the Quarter ending September 30, 1886 (Stanford).—Instantaneous Photography for Amateurs (Seers, Bath).—General Guide to the British Museum, Natural History.—Quarterly Journal of the Royal Meteorological Society, January 1887 (Stanford).—Studies from the Biological Laboratory, Johns Hopkins University, vol. iii. No. 9.

A NATURALIST IN SOUTH AMERICA

Notes of a Naturalist in South America. By John Ball, F.R.S., M.R.I.A., &c. (London: Kegan Paul, Trench, and Co., 1887.)

I.

BY this unpretending little volume its author has opened up to view a new avenue to knowledge—a royal road, in short, to anyone as competent as he has shown himself to be to take advantage of all that it offers to an intelligent traveller with his eyes and ears open. Its contents are a rich collection of facts and thoughts, chiefly botanical, meteorological, and geographical, acquired during a five months' voyage over 18,400 miles of ocean, and embracing 100° of latitude, during which the author passed only seventy days on dry land; and they are laid before the reader in a style which is as attractive as instructive.

In the preface Mr. Ball says of his voyage:—"A tour round the South American continent, which was completed in so short a time as five months, may not appear to deserve any special record; yet I am led to hope that this little book may induce others to visit a region so abounding in sources of enjoyment and interest. There is no part of the world where a traveller can view so many varied and impressive aspects of Nature, whilst he whose attention is mainly given to the progress and development of the social condition of mankind will find in the condition of the numerous States of the continent, and the manners and habits of the many different races that inhabit it, abundant material to engage his attention and excite his interest." Mr. Ball adds that, though the aim of his journey was mainly to see Nature in aspects new to him, he, as an unprejudiced visitor, gives also his impressions as to the social and political condition of the different regions which he visited. With these impressions we need not concern ourselves, though we may say that they seem to us to be both just and liberal.

Leaving England in March 1882 as a passenger on board a West Indian mail-steamer, Mr. Ball found that the passage across the Atlantic offered nothing of unusual interest, but even this well-beaten track suggests some good ideas as to rate of flow of the upper and lower strata of the aërial currents forming the trade-winds. Barbados was made in thirteen days, where, amongst other vegetable treasures, he obtained the fruits of the sandbox-tree (*Hura crepitans*), the explosive nature of which is well known, though not the violence of its character, which would suggest an alternative name of the dynamite-tree. Mr. Ball carried away a specimen packed in a wooden box, which he subsequently placed in his herbarium room in London, where, nine months after it had been obtained, it burst with such violence that the box was broken to pieces, and the valves and seeds of the fruit were scattered all about the room.

A single day at Jamaica afforded him his first glimpse of a thoroughly tropical vegetation *in situ*, and it would be difficult to find a terser or better description of its appearance to a Londoner than his simple statement that "it seemed to me as if the inmates of the Palm House at Kew had broken loose and run scrambling up the rocky hills."

The Isthmus of Panama crossed and the Pacific reached, the real interest of the voyage begins. The first impression Mr. Ball gains—suggested by the breadth of the Bay of Panama (120 sea[1] miles across)—is of the vastness of the geographical features of America as compared with the ideas formed of them from experience of "our diminutive European continent," and from maps, and especially from those on Mercator's projection. In respect of this last he not inaptly complains that it profits nothing to explain, even to the most intelligent youth, the nature and amount of the errors involved in that mode of representing a spherical surface on a plane; and he goes on to say: "I verily believe that all the mischief done by the stupidity, ignorance, and perversity of the writers of bad school-books, is trifling compared to the amount of false ideas spread through the world by the production of that respectable Fleming."

A few hours botanising in the coast forests of Buenaventura, a port on the coast of Columbia, yielded a harvest of plants which forged the first link in a chain of reasoning that has led Mr. Ball to the conclusion (opposed to the view of all other writers on the same subject) that the most marked division of the flora of tropical South America is not that between the regions east and west of the Andes; for on his arrival in Brazil he found that, though he was nearly 3000 miles from Buenaventura, and separated from it by the great barrier of the Andes, the plants of the forests of that country were almost all nearly allied to Brazilian forms. This is followed by a bold speculation, dwelt on at greater length towards the conclusion of the work, that "the ancestors of the Brazilian flora, and to a large extent also those of the Andean flora, came into existence in the ancient high mountain ranges of Brazil, where we now see, in the vast extent of arenaceous rocks, and in the surviving pinnacles of granite, the ruins of one of the greatest mountain regions of the earth."

Crossing the equator, our naturalist was disappointed in not seeing Chimborazo, still in popular estimation the "hub" of the South American continent, though geographers have long known that it has to bow its head to Aconcagua, upwards of 2500 miles further south. Chimborazo is only seventy miles from Guayaquil, whence it is easily seen on clear days, but we are told these occur only about half a dozen times in the year!

Cape Blanco, the westernmost cape of South America, rounded, the so-called rainless zone of South America, which extends for nearly 2000 miles to the southward, is reached. This is a feature of the highest interest to the biologist and meteorologist. Its access was signalled by the sudden fall of temperature from an average of 80°, with a relaxing atmosphere "heavily charged with vapour,"[2] to 74°, with an elasticity in the air that dispelled a previous lassitude, which had rendered burdensome even the first taste of the charms of tropical scenery.

In no part of the world is a change in vegetation more suddenly effected than in the short distance, amounting to little over 100 miles, between the Gulf of Guayaquil and

[1] Surely an oversight for English miles.
[2] When shall we have accurate conceptions embodied in our colloquial phraseology? The vapour of water is lighter than atmospheric air, yet the latter is conventionally described as "heavily laden" with it.

Payta. Nowhere in the world are the forests more luxuriant than in the former place, whereas, on arriving at Payta, Mr. Ball was informed by the officers of the ship that it was no use his taking his botanical box ashore with him, because the country was absolutely without vegetation. As, however, the forewarned expected, this was not quite the case: stunted bushes grew in the cliffs, nor were plants absent on the plateau above, where, however, the vegetation was more scarce than he had anywhere seen it, except in the tract west of the Nile above Cairo. He remarks that the gullies furrowing the seaward face of the plateau show that heavy rains must visit this part of the coast, and on inquiry he was informed that abundant rain, lasting for several days, recurs at intervals of three or four years. This, he subsequently found, is a normal feature of the rainless zone, added to which he was informed that slight showers occur at intervals a few times in the year, which suffice to maintain the vitality of the few species of plants that hold the ground persistently; whilst the heavier rains are followed by an outburst of herbaceous vegetation covering the surfaces that have long been bare.

For the existence of this rainless zone Mr. Ball considers that the hitherto assigned causes are insufficient. These are: the influence of the Andes in condensing the Atlantic vapours brought by the westward atmospheric flow; the warming in its passage north of the vapour-bearing aërial currents that accompany the Antarctic or Humboldt oceanic current; and the effect of this warming of the air in enabling it to hold in suspense all the vapour it absorbs in its passage north. Mr. Ball's principal objections to the sufficiency of these causes are that the Andes of Ecuador and Columbia do not condense the western vapour-bringing winds, whilst those of Peru, Bolivia, and North Chili do; and that the littoral zone of the former regions is, for a distance of 800 miles, even moister than parts of the coast of Brazil and Guiana. His supplemental explanation is based chiefly on the physical features of the Andes. In Peru the Andes present four parallel longitudinal chains, increasing in mean elevation in going westward, though the highest peaks are not on the westernmost range. In Ecuador only two such ranges, the two westernmost, exist, and these do not suffice to drain the vapour-bringing winds, a portion of whose moisture is precipitated on the Pacific coast. In Columbia, again, there are three of these parallel ranges, enough perhaps to drain the easterly winds; and its sources of moisture may be supposed to be derived from the diversion southwards of easterly currents from the Caribbean Sea which have crossed the Isthmus of Panama. On the whole, however, Mr. Ball considers that the influence of the Humboldt currents, oceanic and aërial, is of far greater moment than is that of the Andes, since the influence of these currents is felt even to the north of the Gulf of Guayaquil, as at Cape St. Elena, where the rains are less frequent than at Guayaquil. For the further description of this interesting subject we must refer to the work itself.

On April 15, Callao, the port of Lima, was reached, and a ten days' expedition to the higher Andes was effected. For this there were two railroad facilities. One line starts from the coast at Mollendo, south of Callao, and, running by Arequipa, crosses the crest of the Andes, and terminates at Lake Titicaca, 12,800 feet above the sea. The other starts from Lima itself. It was projected with the intention of piercing the crest of the Cordilleras at an elevation of 15,645 feet above the sea, thence descending to Oroya, a plateau between the main ranges. Its ultimate object was to afford a route to the fertile districts on the eastern slopes of the Andes. As yet it has only reached a village called Chicla, 12,200 feet above the sea, its progress having been stopped by the war between Peru and Chili. The first of these routes was obviously the most desirable for a naturalist, but want of time and the fact of Arequipa being in possession of a Peruvian force drove Mr. Ball to take the Chicla route. To the professed naturalist Mr. Ball's observations on this little expedition offer much of interest, but the season was unfavourable for botanising, the weather at the culminating point wretched, and the natural features of the country, under such conditions at any rate, anything but inviting. There is a brief discussion on mountain sickness, of which Mr. Ball has already detailed his symptoms in this journal (vol. xxvi. p. 477). They are anomalous; but as his elevation was only 12,200 feet, at which many mountaineers who suffer acutely at 16,000 feet and above it feel no inconvenience at all, his experience is insufficient. That the symptoms should disappear during bodily exercise is opposed to what is described in the cases not of man only, but of cattle, sheep, and horses, in crossing high passes. The observations on the temperature of the upper Andean regions as compared with that of the coast are very valuable, as are the notes on the zones of vegetation, the ranges of species, the distribution of endemic forms, &c.

On his return to Lima, Mr. Ball obtained some further information regarding the well-known hollowed cliffs of volcanic rock which occur along the coast, and reach to 700 feet above it, and which have been written of by Lyell and others as indications of a rise of the land. According to a very intelligent local observer, Mr. William Nation, of Lima, the excavations are due chiefly to a cryptogamic plant which grows on the surface of the cliffs, and is in active vegetation as a disintegrating agent during the dense fogs that prevail for many months of the year. Mr. Nation thinks that alternations of dry and damp air, by causing the cells of this burrowing plant to expand and contract, effect the removal of scales of mineral matter from the surface of the rock, and hence eventually excavate the latter. Fancying that the plants might (as do some lichens) chemically affect the rock, Mr. Ball submitted specimens to an eminent cryptogamist, who found it to be an Alga, and harmless in this respect. Mr. Ball himself is disposed to think that vicissitudes of temperature aided by alternations of moisture and dryness, dry fog and sun, may play the greatest part in effecting the hollows. It is to be hoped that Mr. Nation will follow up the problem, which wants only careful observation to solve it.

Between Callao and Coquimbo, along a monotonous coast, several places were visited, but these seem to be far from being oases; some of them, indeed, are dependent on transport by sea for a supply of fresh water. The track between Arica and Copiapo, a distance of 600 miles, "further than from Liverpool to Oporto," is that in which the rainless zone is most pronounced. With the possible exception of Pisagua, there is no inhabited place where drinkable water is to be had, and yet the wants (or greed) of men have established many industrial settlements along the coast for the purpose of working mines of silver, copper, and lead, and digging deposits of alkaline nitrates. Drinking-water is, in most of these towns, provided by the distillation of sea-water; in others it is imported. Nine such places were touched at by the steamer; their features were uniform, and, we may add, uniformly repulsive: chemical works with tall chimneys, sheds of reeds for workmen, a few clean-looking houses for managers, and grog-shops. At one of these, Tocopilla, Mr. Ball observes:—"At last I found, what I had often heard of, but in whose existence I had almost ceased to believe, a land absolutely without a trace of vegetable life. Not only was there no green thing; not even a speck of lichen that I could detect, though I looked at the rocks through a lens. Even more than by the absence of life I was impressed by the appearance of the surface, which showed no token that water had ever flowed over it. Every edge of rock was sharp, as if freshly broken, and on the steep slope no trace of a channel furrowed its face. The aspect is absolutely that of the scenery of the moon—of a world without water, and without an atmosphere." Curiously enough, small birds, which live on stable manure, were the only trace of indigenous animal life; what they were Mr. Ball could not approach them near enough to see. Seaweeds, however, though scarce, occurred in pools left by the tide, and relieved the barren coast from the curse of being without vegetation. At Caldera, the port of Copiapo, vegetation begins, and, though the environs are sandy, bushes and inclosed gardens are to be seen, and at Coquimbo green is, in the spring at any rate, a dominant colour. On May 9, Mr. Ball disembarked at Valparaiso, and made that town and Santiago his headquarters for twenty days. During this period he made numberless observations on the scenery, climate, vegetation, and geographical features, many of which though referring to matters that are familiar to every scientific reader, abound in thought and shrewdness, and are exceedingly instructive. Leaving Valparaiso, the voyager entered a totally different region of America, physically and biologically, and into it we shall follow him in a future number.

(To be continued.)

COLEOPTERA OF THE BRITISH ISLANDS

The Coleoptera of the British Islands. A Descriptive Account of the Families, Genera, and Species indigenous to Great Britain and Ireland; with Notes as to Localites, Habitats, &c. By the Rev. W. W. Fowler, M.A. Vol. I. Adephaga—Hydrophilidæ. Pp. xxii. and 269. Two Plates. (London: Lovell Reeve, 1887.)

DURING the last thirty years, seven or eight distinct catalogues of British Coleoptera have been published, and have met with an encouraging sale; hence there can be no doubt that there exists a considerable number of collectors of British Coleoptera. But no really satisfactory systematic work on this department of the aunæ of our islands exists, and Mr. Fowler has done well in attempting to supply such an one. The earlier works of Curtis and Stephens are, for obvious reasons, of little practical use in the present day, and though, twelve years ago, Mr. H. E. Cox published a hand-book of British Coleoptera in two volumes, it cannot be said to have been the work required, owing to the facts that it contained no reference to localities, and that it consisted entirely of systematic tables, without the addition of any matter that could make it a pleasant book to use.

In the work now before us, the author has been very successful as regards these points; he adopts the system of tables, but gives, in addition, brief diagnostic descriptions of all the species, and satisfactory details of localities and the distribution in our islands. In his prefatory remarks he very properly calls attention to the necessity of access to collections of an elementary nature, so that the student shall have some elementary notions about, at any rate, a few beetles before attempting to use the work. There can be no doubt that he is quite correct as to this point, and it may be hoped that the local museums and school collections that are now becoming numerous throughout the country will be of great use in this respect; and for this object such institutions should possess a small but well-selected general collection in addition to that of their local fauna.

There are now about 3200 species of Coleoptera on the British list, and the present volume deals with only about one-sixth of these, so that the work when completed will be of considerable extent. The author promises to give, when it is concluded, an introduction to the system of classification employed in it. This is, indeed, indispensable, as at present the student is not supplied with any definitions of the "series" which form the basis of the arrangement used. He already finds, however, under the various subdivisions, remarks on classification and affinities; these are usually well considered, and will, no doubt, increase greatly the interest of the work, and, it may be hoped, will induce the student to extend his studies to questions of greater interest and importance than the determination of the names of species.

The Coleoptera are an enormous order of insects, comprising already fully 100,000 species, and as their organisation is such that the details of their external structure can be readily observed, much has already been done towards establishing a natural classification of the order. The author has made himself well acquainted with the various recent improvements in this department, and acknowledges in the frankest manner his obligations to authorities in various parts of the world. There are some points of general interest as to the British Coleopterous fauna, such as the number of species peculiar to the islands, but the work before us has not yet sufficiently advanced to enable such points to be discussed with advantage, and we may perhaps find occasion at a future time to consider them.

It would be a very great advantage if zoologists could agree on a system of names for the various aggregates larger than genera. Mr. Fowler's work only gives the individual names of these larger aggregates, and distinguishes them merely by rather slight typographical distinctions; as a consequence, the student finds himself introduced to a large number of these names in rapid succession, and they must be rather a source of bewilderment to him than a key to the classification adopted; it would probably be an improvement if, in future volumes, the author would prefix to these names the terms "Family," "Sub-Family," "Group," &c., so as to allow the systematic value of the names themselves to be more readily appreciated. The two plates accompanying the volume are intended to give an idea of those structural characters on which the classification used in the work is based, and they also give three figures of larvæ borrowed from Schiodte; it may be hoped that these latter extraordinary forms may incite some student to continue the work of investigating the earlier stages of beetles, so ably pursued by the talented Dane whose recent decease is still a matter of general regret amongst entomologists. The structural diagrams II. and III. on Plate A are, as given, far from being successful. They are described as representing the under-skeleton, but, actually, one-half of each of the diagrams represents the upper surface, and the manner in which the two halves are connected will inevitably suggest to a beginner that the structures displayed are those that would be seen on removing the parts covering the upper surface.

Mr. Fowler, as we have already stated, has taken great pains to make himself acquainted with the modern authorities, and to render his work as interesting as the nature of the subject and its great extent will permit; his efforts in these directions will no doubt be duly appreciated, and his work will, it may be hoped, find a place in the libraries of all our local museums, as well as on the book-shelves of the amateur. D. S.

BRITISH STALK-EYED CRUSTACEA AND SPIDERS

British Stalk-eyed Crustacea and Spiders. By F. A. A. Skuse. (London: Swan Sonnenschein, Lowrey, and Co., 1886.)

THIS is a modest little volume of 126 pages, professedly written for the "tyro." We are informed, on p. 14, that the "pages do not profess to be either scientific or in the least anything beyond the production of a humble admirer of Nature, and only intended to put the reader on the road to the investigation of the creatures written about." This being so, it would be unfair to judge the work from the stand-point of more special treatises, and we need do no more than comment upon the introduction of a somewhat antiquated system of classification and of minor errors which would be unpardonable in a work of greater pretensions.

The book is a clearly stated compilation, and is, so far as it goes, fairly accurate and up to date. There is, manifestly, little room for originality, and the reader must be prepared to find that most of the more pleasing passages—those dealing with the habits of the animals described—are, of necessity, quotations from earlier authors, references to whose works are in all cases given as footnotes.

The subject-matter is apportioned into nine chapters and an introduction, and it deals with methods and accessories as fully as with the animals themselves. Under the head of Development (Chapter III.) are to be found the facts of morphology and physiology which fall within the scope of the work. It is in this that the author is at his worst, and there is much here which stands in need of revision. We are told, in the introduction, that "the earliest known insects have been found in the Devonian, so probably there also existed spiders." Taking the context into consideration, it is surprising that the author should thus presuppose the discovery of Palæozoic spiders, and overlook that of Silurian scorpions and cockroaches, the former so well to his purpose.

"Big-tails," "Queer-tails," and "Little-tails" are renderings of *Macrura*, *Anomoura*, and *Brachyura* as unfortunate as they are unconventional.

The illustrations are good as a whole; some are excellent, being faithful copies of standard figures. More spiders might be advantageously delineated, and exception must be taken to the wretchedly wooden drawings of crustacean larvæ, especially of the young lobsters (p. 27). For the latter the author would do well to substitute, should a second edition be demanded, the strikingly truthful drawings of Sars ("Om Hummerens postembryonale udvikling," Christiania, 1874), or, failing those, Kent's figures ("International Fisheries Exhibition Literature," vol. vi. "Conferences").

There is much truth in the author's assertion (p. 10) that "everybody knows a crab. Everybody knows a spider. But it is just these every-day things that people know really least about; while, on the contrary, things that must be sought for in order to be seen are often most commonly known." The writer is true to this tenet, and his book ought, in the hands of an intelligent "tyro," to be productive of good results; while passages such as that in which he describes (p. 73) the construction of the spider's web are well calculated to arouse that enthusiasm which he is sanguine enough to presuppose. The appreciation of the beautiful in Nature must precede the devotion to that which is more useful, and the little handbook before us, invested, as it is throughout, with a true dignity of purpose, will serve as a means to this desired end.

OUR BOOK SHELF

Catalogue of the Fossil Mammalia in the British Museum, (Natural History) Cromwell Road, S.W. Part IV. Containing the Order Ungulata, Sub-order Proboscidea. By Richard Lydekker, B.A., F.G.S. (London: Printed by Order of the Trustees, 1886.)

THE collection of Proboscidean remains preserved in the British Museum is by far the largest in any Museum in the world; containing as it does the splendid collections made in the Siwaliks of India by Sir Proby T. Cautley, the unrivalled British series of mammoth remains, the unique collection of pygmy-elephant remains from Malta, the series of remains of dinotherium and mastodon, from Eppelsheim, &c., and a fine collection of American mastodons from the United States and from South America.

An immense collection like this, containing remains belonging to nearly all the described forms, was admirably adapted for the study of transition forms, and Mr. Lydekker has not been content in this Catalogue with giving merely a detailed enumeration of the contents of the cases, but has written a full account of the families, genera, and most of the species of the known extinct Proboscidea. In a short introduction he gives some most interesting notes on the geographical and geological distribution of the species. In reference to the subject of the structure of the cheek-teeth Mr. Lydekker thinks that this can be traced from the most generalised to the most specialised member of the Elephantidæ. So complete indeed is this transition that not only is there no real line of demarcation between Mastodon and Elephas, but several of the species of the two genera seem to pass so imperceptibly into one another that it is not unfrequently a matter of extreme difficulty (if indeed it be not an absolute impossibility) to determine to which species individual teeth really belong.

In regard to geographical distribution, there appears to be considerable evidence in favour of an easterly migration of the mastodons having taken place from Europe to India; while the restriction of the stegodont group of elephants to the latter country and the regions to the eastward, points to the conclusion that the transition from the mastodons to the higher elephants took place in those regions. From this we may also infer that there subsequently ensued a westerly migration of these higher forms to Europe, and finally on to North America, where the true elephants did not make their appearance till the Pleistocene, and then appear to have been represented only by two species, one of which ranged over the greater part of the higher latitudes of the northern hemisphere. The descriptive details are very usefully illustrated by a number of woodcuts of the teeth and cranial bones. The work, despite its name of Catalogue, is a most important contribution to our knowledge of the subject.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Iridescent Clouds

THIS phenomenon is very common here in the winter, occurring, with few exceptions, whenever there are scattered clouds near the sun. The colours are often brilliant enough to catch the attention of the most casual observer, but at other times they can only be made out with the aid of dark neutral-tint spectacles. These reduce the intensity of the glare near the sun to a point favourable to the discrimination of colour.

I have lately been watching the somewhat complicated phenomena, and taking rough measures of the angular distances of the various colours from the sun, and I have little doubt that the colours are due to diffraction of light by fine particles of ice.

Within a circle, radius about 2°, the clouds are white, perhaps faintly tinged with blue; but it is difficult to observe a delicate shade of colour so near the sun. This circular space is surrounded by a ring of yellow or orange. The region of most vivid hues is comprised between 3° and 7°, the most striking being purple, blue, orange, green, and red. These are not arranged in rings, but are distributed over the thinner parts of a cloud in irregular patches. Beyond this region the only colours visible are green and red, becoming fainter as the distance from the sun is increased. I have detected them in three or four cases at a distance of 21°. At some distance from the sun the greens and reds are frequently arranged in bands parallel to the edge of the cloud, sometimes as many as three bands of each being visible. I have often seen a cloud completely encircled by bands, the impression given to the observer being that the colour depends on the thickness of the cloud. No doubt the real explanation is that the ice particles are larger in the interior of a cloud. We have thus two independent factors to determine the colour of a particular portion of cloud: the distance from the sun, and the average size of the particles. Near the sun slight variations of the former are more important, so we get a tolerably regular yellow ring. Far from the sun the variations of the latter have overwhelming influence, and we have bands along the edge of a cloud. At a medium distance, in the region of vivid colour, we have the two factors nearly equally powerful, and indescribable confusion as the general result.

On one occasion, when the edge of a large cloud passed almost through the sun, I noted down the colours in order along the edge, where the size of the particles would be tolerably uniform: white, yellow, red; blue, green, yellow, pink; green, faint red. This list consists evidently of three successive diffraction spectra, and it is in satisfactory agreement with a number of less complete series that I have obtained. The blue, however, is often replaced by a brilliant purple, due to the first and second spectra overlapping. Another method of discovering the true order of the colours is by watching the changing hues of a cloud approaching or leaving the sun. This tended to corroborate the list just given, but I could seldom trace more than two or three changes, so rapidly did the clouds grow or dwindle away. I noticed, indeed, that the more rapid the growth the more brilliant were the colours displayed. One interesting observation deserves special mention. A cloud showed faint colour at a great distance from the sun. It was edged with green, with red inside. As it approached the sun, the bands moved inwards, and red appeared on the edge, then green, then red, then green. The last tint was very undecided, and afterwards the whole cloud remained white. The inward motion of the bands showed that the inner particles were larger.

We now come to the question of the form of the diffracting particles. The form most favourable to diffraction is the sphere, as with a sphere the angle of diffraction for any given spectrum depends only on its diameter. Thus if a cloud be composed of spheres of uniform size, and be at the angular distance from the sun corresponding to the first spectrum for that size, each sphere will send its quota of light to the observer. Next to the sphere comes the circular cylinder. In order that a cylinder may send diffracted light to the observer, its axis must lie in or near the reflecting plane. By the reflecting plane I mean the plane of a mirror which would reflect sunlight to the observer. But, when this condition is satisfied, the angle of diffraction, corresponding to any particular spectrum, depends only on the diameter of the cylinder. Any other form, a circular disk for instance, gives different diffracting angles according to the orientation of the particle. The spectra corresponding to different orientations would be superimposed and white light be the result.

Now, among the manifold forms of snow-crystals there is, I believe, nothing approximating to a sphere. But thin hexagonal prisms are common, either separate, or attached as rays to hexagonal disks. These would produce much the same effect as circular cylinders; for the extreme variation of the apparent diameter of an hexagonal prism from its mean value is only 7 per cent.

Granted that the diffracting particles are hexagonal filaments, my measurements of the angular distances of the colours from the sun supply data for determining the average diameter of the filaments. For this purpose purple is a useful colour, as it always arises from the overlapping of the first two spectra. I took some five-and-twenty measures at various times, which varied from $3\frac{1}{2}°$ to $6\frac{3}{4}°$. These give diameters from ·017 mm. to ·009 mm. Orange of the first spectrum ranged from $2\frac{1}{2}°$ to $5\frac{1}{2}°$, six measures. These give diameters from ·021 mm. to ·010 mm. Blues of the second spectrum, four measures, $4\frac{1}{2}°$ to $6\frac{3}{4}°$; diameters ·014 mm. to ·009 mm. If the colours I observed at 21° from the sun were produced by filaments ·013 mm. in diameter, they must have belonged to the ninth spectrum. But the ninth spectrum, in addition to being only one-fortieth as bright as the first, is overlapped by four spectra of higher order and three of lower, so it can hardly be distinguishable. At such a distance from the sun the finer particles would have a great advantage in colour-producing power, so I think it probable the spectrum was of the fifth order, produced by particles of diameter ·009 mm.

The next difficulty is to explain why colours are not seen in clouds composed of minute spheres of water. As explained before, the spherical form has a great advantage. I find by calculation that if the spheres were of uniform size, diameter ·013 mm., the colours of the first spectrum would be about twenty times as brilliant as if the cloud were composed of filaments of the same diameter, arranged at random, but occupying the same fraction of the field of view. So we might *a priori* expect that water clouds would be more brightly iridescent than ice clouds. But it is not so. During the summer here I looked frequently and vainly for iridescence. This want of colour must arise from the minute drops not attaining sufficient uniformity of size. So we have to find some cause of uniformity which acts more powerfully on particles of ice than on drops of water. I venture to offer the following suggestions.

Let us consider what happens when an ice cloud is forming. Dust particles, no doubt, act as nuclei to ice crystals as well as to water drops; so that a number of crystals will start into existence about the same time. Soon there will be no more dust particles of sufficient size to form nuclei. The rate of deposition on a crystal will be proportional to its surface, so all the crystals will grow in diameter at the same rate. The ratio of the largest diameter to the smallest will become less. In fact the crystals will become more uniform in size. No doubt, too, the supply of aqueous vapour near a large crystal will be consumed more rapidly than it can be refunded by diffusion. So the larger crystals will grow somewhat more slowly. These are causes tending towards uniformity. They account for the observed fact that they are newly formed clouds, which show the brightest colours, though when they first come into view they are white. It is easy to give reasons why some clouds should lose their colour so soon. Varying conditions may affect the growth of different layers of particles in a different manner, or a slight increase in the rate of deposition may call new dust particles into action.

In the case of water clouds there are two special causes brought into action against uniformity. Sir William Thomson has shown that the maximum vapour-tension at the surface of water is largely increased when the surface is highly convex. So the large drops will grow more rapidly than the small ones, and the range of size will be more and more extended. Secondly, whenever two drops of water come into collision, they will combine into one larger one.

In conclusion I may remark that St. Moritz is 6000 feet above sea-level, and the iridescent clouds were generally above the surrounding mountains, *i.e.* at least 11,500 feet above sea-level. On some days the sky was overspread at a great height, with a thin haze gathered here and there into denser streaks (cirro-stratus?). The haze sometimes formed coronæ close around the sun. I have not made out more than two spectra. From rough measures of the diameters of the rings, I find for the diameters of these filaments values varying from ·04 mm. to ·07 mm.

JAMES C. MCCONNEL

St. Moritz, Switzerland, March 14

Aino Hairiness and the Urvolk of Japan

IN Mr. B. H. Chamberlain's remarkable and instructive monograph on the Ainos, contained in the first number of the Memoirs of the Literature College of the Imperial University of Japan, just published, will be found an explanation of the different conclusions that have been arrived at by different observers as to the *hairiness* of that singular people, equally isolated, so far as our present knowledge extends, by language and by physical characteristics from all surrounding races. When I spent some days among these so-called savages in 1865 or 1866, I had the opportunity of examining some four or five score of them, chiefly men, and in every individual I found the phenomenon of hairiness more or less marked. The sternal, inter-scapular, and gluteal regions were, in particular, thus provided with a natural covering, the very regions where such a protection from the drip of rain would be most serviceable. I remember well that in some individuals the gluteal fur was so abundantly developed that thick tufts of hair, several inches long, could be grasped in the hand. But recent travellers have been struck by the number of natives they met with deficient in hairiness—whether they were proportionately lacking in face-hair is not stated—and it has been doubted whether hairiness is really an Aino characteristic. Dr. Baelz's investigations have, however, amply vindicated the claim of the Ainos to be the hairiest people in the world, and now Mr. Chamberlain shows that the smooth-bodied natives are in fact half-breeds, the progeny of native mothers by Japanese fathers. Unions of this kind have probably increased in frequency during the last two decades. Between the two races, however, some incompatibility seems to exist, for their progeny exhibit a diminished fertility. "The second generation," says Mr. Chamberlain, on the authority of the Rev. Mr. Batchelor, who has lived for years among the Ainos, and contributes an exhaustive grammar of their language to the volume of Memoirs before me, "is almost barren; and such children as are born—whether it be from two half-breed parents, or from one half-breed parent and a member of either pure race—are generally weakly. In the third or fourth generation the family dies out."

The injury to the reproductive system caused by this "miscegenation"—a phenomenon not unparalleled in the history of man, and proving the existence in man, as in other organisms, of a tendency to specific variation—has an important bearing upon the much-debated question of the proportion of Aino blood that runs in the veins of the Japanese of to-day. Mr. Chamberlain, chiefly from philological considerations based upon an examination of place-names, arrives at the conclusion that the *Urvolk* of the Japanese group, from the extreme south to the furthest north, was an Aino race, and we know from history that up to the time of Yoritomo (twelfth century A.D.), and probably later, the northern half of the main island was still, to some extent, peopled by Ainos. Yet even the northern Japanese are smooth-bodied, although it is extremely unlikely that "miscegenation" did not obtain between their Japanese ancestors and the aborigines. In the light of Mr. Batchelor's observations the explanation of this apparent anomaly is easy. The half-breeds died out, and the prepotency of the Japanese in numbers and civilisation gradually expelled the Aino element from the population, which has thus become an almost purely Japanese one.

It must not, nevertheless, be forgotten that at least two distinct races may still be traced in the existing population of the Japanese group. One is slim, high-headed, and often aquiline-nosed; the other stouter and broader, more brachycephalic, and flat-nosed. Excellent types of both, especially of the first, will be found in Siebold's "Nippon Archiepf." The former constituted the military class of Old Japan, the latter the peasantry; and of the latter some degree of hairiness of the limbs is a not uncommon characteristic. The drawings of Hokusai sufficiently prove this assertion, which the experience of every resident in Japan will confirm. It may therefore be safely assumed that the elimination of the Aino element has not been complete. For my own part I believe that the earliest inhabitants of Japan were tribes of Malayo-Polynesian blood coming from the south, and of Aino blood coming from the north. Altaic immigrants followed, and, partly perhaps through some degree of reproductive prepotency, gave a characteristic and predominant stamp to the population without total elimination of its aboriginal elements.

Units of Weight, Mass, and Force

HAVING read with much interest Prof. Greenhill's letter in NATURE of March 24, p. 486, I am inclined to think that much of the perplexity felt by some who begin the study of dynamics arises from the want of names for the units of the various magnitudes with which the science deals. We have names for units of time, space, mass, force, work; but no names for units of velocity, acceleration, impulse, momentum, &c. I venture to suggest the following:—Let the unit velocity be that with which a point describes uniformly one foot per second. Let this unit be called a vel. Let the unit acceleration be that whereby the velocity is uniformly changed by one vel per second. Let this unit be called a cel. Then everything becomes clear. *E.g.* the meaning of the equation $W = mg$ is seen to be this: The weight of a mass of m pounds at a place where the acceleration arising from the mutual stress between it and the mass of the earth is g cels being W poundals, the *numbers* $W m g$ are connected by the equation $W = mg$. Then, for the sake of the beginner, let the names of the units be given thus: $W = mg$ poundals, $m = \frac{W}{g}$ pounds, $g = \frac{W}{m}$ cels. It is too common to see acceleration expressed in feet per second, instead of in vels per second. If the weight of a mass of m pounds be defined to be the mutual stress between it and the mass e pounds of the earth, it is evident that the weight of e attracted by m is the same as the weight of m attracted by e; and, in the absence of either, the other would have no weight.

Bardsea, March 29 EDWARD GEOGHEGAN

The Earthquake in the Riviera

THOUGH there can be no question as to the amount of damage done by the late earthquake—I am writing in a shed, the hote being destroyed—I think that the violence of the shock has perhaps been very greatly exaggerated. I have only been able to make a flying visit to this place and to Diano Marina, but I cannot help being struck by the fact that the peculiar architecture is the main cause of the large amount of destruction.

Indeed, judging from the small amount of damage done to buildings in which flat or square stones and flat floors have been used, I should doubt whether the shock was much more severe than that which not long ago damaged the brick buildings in East Anglia.

At both Oneglia and Diano Marina the building material is usually rounded stones from the beach, or rubble with stones of all shapes and sizes. The stucco is apparently expected to make good any deficiencies. Besides this the floors are nearly always brick arches abutting against the vertical walls, without any reference to other lateral support. Most of these houses are three or four stories high. Of course any vibration affecting buildings of this construction will split the walls in all directions, for besides the lateral thrust of the arches, the walls are full of wedge-shaped stones ready to slip into any fissures which may form.

The complication caused by these arched floors makes it very difficult to trace the direction or angle of emergence of the shock. CLEMENT REID

Oneglia, March 13

Scorpion Virus

ALLOW me to state that the results of my experiments on Cape scorpions are in full accord with Prof. Bourne's conclusion that the poison of the scorpion has no fatal effect on the same individual or another individual of the same or even of another species. Speaking before the South African Philosophical Society in February 1883, I said :—"Members of the Society will see on the table a scorpion of the larger (Cape) species. That scorpion I caught at 11 o'clock this morning. I at once pierced him in three places with his own sting, on which in each case there was a drop of poison. In the last inoculation I held the sting in the wound, and squeezing the 'bulb of the sting' with the pincers forcibly injected poison. The creature is alive and active" (Proceedings for 1883). These and subsequent experiments, however, led me to believe that the poison has *some* effect, causing sluggishness and torpor for a while. I quite agree with Prof. Bourne that it is physically possible for a scorpion to sting itself in a vulnerable place; and though I never was able to observe the infliction of a wound on itself by any scorpion, I can well believe that this is possible, but, I am convinced, wholly accidental.

I found also that the poison of the ring-hals snake (*Naja hæmachates*) was not fatal when inoculated in the same individual or another individual of the same species.

The Supposed Myzostoma-cysts in *Antedon rosacea*

SOME eighteen months ago I called attention in these columns (vol. xxxii. p. 391, and vol. xxxiii. p. 8) to certain malformations which I had discovered on the pinnules of *Antedon rosacea* from various British localities. They often take the form of small cysts which are very like those produced by encysting Myzostomida on the arms and pinnules of various Crinoids from the Pacific; and as no other cyst-builders but *Myzostoma* were then known to infest the Crinoids, the inference seemed a natural one that the cysts on the pinnules of *Antedon rosacea* had been produced by a small member of this genus. I subsequently found several more cysts on some examples of *Antedon rosacea* which were dredged at Gibraltar by the Italian corvette *Vettor Pisani*, and the whole collection was sent to my friend Prof. L. von Graff for examination.

To our great surprise, however, he has not found a single *Myzostoma* in any one of the fourteen malformations of the pinnules, whether cysts or otherwise, which he has opened; and "the new British Myzostoma" must therefore be disestablished.

But what, then, has been the cause of these malformations? Prof. von Graff has found them to be always associated with the presence of a minute globular body, which has the appearance of an egg that has undergone superficial cleavage, but yet exhibits no trace of nuclei when stained. It is impossible to decide at present what this structure may be. Prof. von Graff has described it more fully in a "Supplementary Report on the Myzostomida of the *Challenger* Expedition" which he has just completed. But its nature seems to be as problematical as that of the sacculi; and fresh material, not spirit specimens, must be examined before we can expect to learn much more about it. In any case, however, it would seem that we have to deal with a hitherto unknown parasite of the Crinoids, which is capable of producing modifications in the calcareous tissues of the arms and pinnules, of essentially the same character as those caused by *Myzostoma*, though of smaller size.

I would commend the question to the attention of those naturalists who may meet with *Antedon rosacea* in the dredgings of the ensuing season; and in order that they may know how to catch their hare, I shall be most happy to forward specimens of the cysts to anyone who desires to become acquainted with their external appearance. I may add that the largest cysts I have seen are on Comatulæ from the Cumbrae, Milford Haven, and Gibraltar; while I have no knowledge of their occurrence either at Naples or anywhere else in the Mediterranean.

Eton College P. HERBERT CARPENTER

On some Observations on Palæobotany in Goebel's "Outlines of Classification and Special Morphology of Plants"

THE few modern authors of botanical text-books who have ventured to summarise recent palæobotanical researches have achieved but moderate success. These authors have too little knowledge of the rapid progress of the study of fossil plants during the last few years to make success possible; hence, their summaries, if not absolutely inaccurate, are usually misleading. So long as these errors are confined to works published in Continental languages, British palæobotanists need not take the trouble to correct them. But the case is altered when English translations of these books appear amongst us. Palæobotany has nowhere made greater progress during the last few years than with ourselves. Many errors have been corrected, and new truths, results of careful and prolonged investigations, have taken their place. With the more important of these new discoveries many of our younger students of geology are now familiar. It is desirable that what they have been taught should not be contradicted by the utterances of authors ignorant of the subjects upon which they venture to express an opinion.

Some little time ago Dr. Goebel, of Rostock, published a volume which was virtually a new edition of Book II. of Sachs's "Lehrbuch der Botanik," and an English translation of this volume, made by Mr. H. E. F. Garnsey, and revised by Prof. I. B. Balfour, has just appeared. Dr. Goebel's volume contains some references to the Palæozoic flora which are seriously behind the times. To allow these statements to reach our students uncorrected will do harm, because they must suggest to those students that certain questions are still open and debatable which cannot now be regarded as such.

Had I not unfortunately misunderstood a wish expressed by my friend Prof. Balfour, some explanatory footnotes would have been introduced into the above volume, which would have rendered this communication unnecessary.

On p. 193 of the translation we find the following statement :—"Other groups are the Sphenophylleæ, Lepidodendreæ, and Sigillarieæ, the first of which are only heterosporous Lycopodiaceæ." We have no reasons for concluding that Sphenophyllum is Lycopodiaceous, still less that it is heterosporous. This latter statement rests upon M. Renault's interpretation of a minute *multicellular* fragment which he observed in a sporangium, and which he believed to be a macrospore; it could not be this, since the exosporium of a macrospore is a *unicellular* organism. On the other hand, the Lepidodendra were both homosporous and heterosporous. As to the Sigillariæ, even M. Renault now admits that all the vertically-fluted forms are Lycopodiaceous. The assertion that the Lepidodendra were all heterosporous is repeated on p. 196. On p. 272 we have a brief paragraph of eight lines remarkable for the number of the inaccurate statements which it contains. I have indicated these inaccuracies by reproducing them in italics.

"The Calamites are Equisetaceæ which appear in the older geological formations, *beginning in the Carboniferous Limestone* (1), culminating in the Coal-measures, and disappearing in the Permian formation. The spikes of sporangia are either not known, or so badly preserved (*Calamostachys*) (2), *that their structure cannot be determined; it remains doubtful, therefore, whether they were homosporous or heterosporous forms* (3). The stems *had neither leaves* nor leaf-sheaths, *or else these were transitory formations and soon fell off* (4). In other respects *the structure of the stems resembles that of the Equisetaceæ* (5).

Their surface was marked with ridges (6), and they had a central hollow divided by diaphragms."

I will examine these statements *seriatim.*

(1) The author appears to have been strangely ignorant of Sir William Dawson's magnificent discoveries of Calamites and other Carboniferous plants in the Devonian strata of North America, announced in his Report on the subject in 1871.

(2) In 1874 I published in the Philosophical Transactions the detailed structure of extremely beautiful examples of *Calamostachys Binneyana*, and, since then, Prof. Weiss, of Berlin, has figured equally fine examples of *Calamostachys Ludwigi.* In the Philosophical Transactions for 1881 I further showed that this genus comprehended both homosporous and heterosporous forms. At the same time Calamostachys is not the fruit of Calamites.

(4) Both Sir William Dawson and Prof. Weiss have shown that the slender twigs of Calamites were abundantly supplied with verticils of linear leaves.

(5) This statement is true with an important limitation, which Dr. Goebel ignores; or, as a follower of M. Renault, he more probably rejects. Whilst the type of Calamitean organisation is unquestionably Equisetiform, their arborescent stems and branches contained an enormous xylem or woody cylinder, developed exogenously, which made them differ very widely from their degenerate living representatives.

(6) This is a repetition of the old fallacy, which regarded the vertical groovings of the surfaces of the inorganic casts of the fistular medullary cavity as belonging to the cortical surface. We have now numerous sections of the Calamitean cortex, no one of which exhibits the slightest trace of vertical flutings; they are all smooth.

On p. 281, speaking of heterosporous Lycopodiaceæ, the author accepts M. Renault's old conclusions that in Lepidodendron "there is no certain indication of secondary growth in thickness." "The connection of fossil stems capable of great increase in thickness, such as the Sigillarieæ and Calamodendron is at present questioned." These facts are no longer capable of being justly questioned. The structure of *Lepidodendron Selaginoides* alone suffices to settle the matter so far as that genus is concerned; to say nothing of the many other species that demonstrate the same fact. M. Grand'Eury himself, long one of the most influential questioners, has now recognised that the genus Arthropitus only represents the thick woody zone of a true Calamite. Prof. Stur, of Vienna, long ago demonstrated in an unanswerable manner the almost absolute identity of Calamites and Calamodendron; and M. Renault himself, as I have already observed, has still more recently been compelled by the discovery of a Sigillarian fructification by M. Zeiller to alter his view respecting the Sigillariæ. He no longer insists that these cannot be Cryptogams because their stems grow exogenously, but now hands over to his opponents, who have so long contended for the Lycopodiaceous affinities of this Sigillarian genus, all the vertically fluted examples of it.

Whilst deeming it desirable that his readers should be put in possession of the other side of the question to which he refers, it is only fair to Dr. Goebel to say he is himself aware that those questions are dealt with in a one-sided manner. In a footnote on p. 272 of the English translation the author says:—"The short description given in the text from Renault may serve at least to draw attention to these interesting types, in which there is much that is yet uncertain. We cannot enter here into disputed or doubtful points." At the same time it is to be lamented that the leading botanists of the world cannot give us palæontologists more of that valuable aid which their special studies would so well enable them to do. I do not yet despair of enlisting some of the Strasburgers, de Barys, Goebels, and Van Tieghems in this honourable service. W. C. WILLIAMSON

Owens College

A Sparrow chasing Two Pigeons

ON Sunday, I asked three men what they were observing, when they pointed out a sparrow chasing two pigeons.

The pigeons were evidently greatly alarmed at their pugnacious attendant, who took occasional pecks at them when flying underneath, and whenever possible. The sparrow lost ground when the others made their more rapid doubling, but soon came up with them again, and renewed its attack.

What was the original quarrel of course we do not know, but the persistency of the sparrow's attack greatly amused us. Have any of your readers observed anything like this? or is there any record of the like? E. A. C.

Luton, Chatham, March 14

Top-shaped Hailstones

I DREW attention to hailstones possessing the above form in *Science Gossip* of December 1884. These pellets, which fell in my garden at Polmont, Stirlingshire, on the morning of May 6, 1884, were about one-fourth of an inch in length, and nearly three-sixteenths of an inch across. I did not see any horizontal stratification as observed by your correspondent Mr. Middlemiss, but found that each transverse section, when examined by a good lens, exhibited a fairly well-marked internal radiated fibrous structure, somewhat similar to that shown in sections of the mineral wavellite. Below are two (transverse

FIG. 1.—Transverse section (near base of cone) × 2.

FIG. 2.—Longitudinal section × 1½.

and longitudinal) diagrammatic sections of the Polmont hailstones.

Since then, however, I have found top-shaped hailstones com-

FIG. 3.—Longitudinal section.

A Peculiar Radiation of Light

AT 10.30 p.m. this evening, my attention was called to a peculiar radiation of light in the eastern sky. The centre of radiation was due east, and the bars on the *right-hand side* were increased in brilliancy by light evidently arising from the moon, which was not visible, but concealed by cloud. The extent of these rays was from horizon to zenith; the rays being of unequal size, but of a pale gray colour, slightly iridescent.

The east wind was blowing smartly at the time, and I should like to be informed whether this strangely beautiful appearance in the sky was caused by the radiation of light from a rising moon on thin clouds, or was it the effect of a strong current of wind from a given point?

By 11 p.m. the moonlight was full; the moon still to the right of the axis of the rays, and the rays nearly dispersed.

Falmouth, March 12 ROBERT D. GIBNEY

THE CHEMICAL SOCIETY'S ANNIVERSARY MEETING

THE anniversary meeting of the Chemical Society was held on Wednesday, March 30. We give some extracts from the address of the President, Dr. Hugo Müller, on the recent progress of chemical science:—

As we contemplate this ceaseless activity in chemical research now manifested all over the world, and which from year to year is continually on the increase, we are nevertheless bound to recognise the fact that vast as the work thus accumulated may appear, there remains still much to be accomplished. The more the field is worked the richer will be the harvest.

Overwhelmed by the quantity of material, especially in the direction of the production of new compounds, hasty critics were wont to denounce such work as superfluous, but it is now generally recognised that we must still continue with the patient and careful elaboration of the substructure of facts before we can with advantage proceed with the longed-for rearing of the edifice of a comprehensive scientific generalisation, that is to say, of ideal chemistry.

The infinite complexity which inquiry reveals in every direction bids us more than ever to be cautious in taking flight on the wings of speculation.

In the meantime we must content ourselves with the use of working hypotheses in the various fields of inquiry; these we develop and modify as we go on, or, it may be, discard in favour of others which for the time being seem more in accordance with the facts before us.

The triumphs of modern chemistry bear testimony that faulty and incomplete as our present theories undoubtedly are, our science is ever advancing.

It is now well understood that the most important data for the future extension of chemical theory will be derived from the interpretation of the results of investigations into the physical side of chemical phenomena.

The examination of the optical properties of chemical elements and compounds, the determination of thermo-chemical constants, and the verification of physical constants generally, are now pursued by a great number of investigators. Of late also the experimental inquiry into the connexion between electrical and chemical force is becoming a fruitful field of research; and we may hope that further determinations of the coefficients of conductivity of electrolytes will before long lead to a clearer perception of the intimate nature of chemical change.

To pass in review the chemical work published during the year, as some of my predecessors have done on similar occasions, has now become an impossible task, even supposing that the time at my disposal permitted me to do so. I am, however, tempted to refer briefly to a few results which strike me as particularly noteworthy.

The work accomplished in thermo-chemistry is, as I have already observed, very considerable, and thanks to the patient labour of many workers the results thus achieved are comprehensive enough to admit of a consideration of their general bearings. In this respect I wish to direct attention to the publication of Julius Thomsen's fourth and concluding volume of "Thermochemische Untersuchungen." This remarkable work is entitled to the highest appreciation of all who realise the manifold difficulties which beset the execution of thermo-chemical investigation. But while referring to the many highly important and remarkable deductions which the author draws from his experiments, we cannot at the same time help being struck by the many anomalous results and startling conclusions which he arrives at. It would seem that further determinations of the fundamental values, if possible by different and varied experimental methods, must be obtained before the full importance of this work can be entirely realised.

An important addition to our still very limited knowledge of the density of metallic elements in the gaseous state has been made by V. Meyer and Mensching, who have now succeeded in overcoming the great experimental difficulties formerly encountered in the determination of the vapour-density of zinc. The molecule of zinc has been found to be monatomic, like that of cadmium and of mercury, the only two other metals the vapour-densities of which are thus far known.

The remarkable results recently published by Crookes in his papers on the spectra of the so-called rare earths are still fresh in our memory, and the ingenious application he has made of the doctrine of evolution in this speculation on the genesis of the elements has not failed to attract the attention it deserves.

The further investigations of the chemical and physical properties of the new element germanium by Winkler, Nilson, and Petterson have established its chemical position, and the supposition that its proper place in the periodic system is that of ekasilicon has been confirmed.

Ladenburg's long-continued researches on conine have been crowned by success. He has effected its synthesis and has shown that it is identical with α-propylpiperidine. This must indeed be considered one of the most noteworthy achievements in organic chemistry of the past year, inasmuch as it is the first instance of the artificial formation of an optically active natural alkaloid.

Wallach found that the diazo-amido-compounds formed from diazo-salts and piperidine are for the most part well-characterised substances, and that when heated with concentrated hydrofluoric acid they yield the fluor-derivative in almost theoretical proportions. He has prepared in this way fluorbenzene, parafluortoluene, parafluornitrobenzene, parafluoraniline, and fluorphenyl, &c.

Studying the action of sodium on mixtures of ethers such as oxalic and acetic ethers, W. Wislicenus has discovered a new and ready method of effecting the synthesis of compound acids, and this reaction cannot fail to become of great value.

Brieger has succeeded in isolating a well-characterised alkaloid from the liquid used for cultivating a certain Bacillus which causes tetanus traumaticus in animals. This substance, which the author calls tetanine, seems to be the immediate cause of the toxic action of this Bacillus, and thus for the first time a specific pathological effect of a microbe has been traced to a well-defined chemical compound produced or secreted in its life-process.

Finally, I must also allude to the very remarkable observation recently published by Liebreich which demonstrates the fact that under certain conditions chemical reaction is retarded, and even altogether suspended. He noticed that in a mixture of aqueous solutions of chloral hydrate and sodium carbonate the formation of chloroform does not take place uniformly throughout the liquid. For instance, on performing the experiment in a test-tube there appears immediately below the meniscus a sharply defined space of 1–3 mm. thickness in which no reaction takes place. Similar results were obtained when an aqueous solution of iodic acid was mixed with sulphurous acid and soluble starch. The inert space manifests itself on the surface of the liquid which is in contact with the air or separated from it by a thin membrane. In narrow tubes the reaction is much more retarded, and it is altogether suspended in capillary tubes.

In my opinion this preliminary communication contains the germs of a discovery in a new direction, and the further study of the nature of these subtle influences which bring about the phenomenon in question must lead to important results.

In bringing this report to a conclusion I must briefly allude to a subject only indirectly connected with our Society, viz. the progress made in the organisation of technical education in this country, which, more particularly under the guidance and fostering care of the City and Guilds of London Institute, is gradually making its way.

Most of you are aware that the President of this Society is one of the *ex officio* members of the governing and organising body of this Institute, and it may be mentioned in passing that the regular attendance at the frequent meetings of the various Committees and Sub-Committees involves the necessity of devoting a by no means inconsiderable amount of time to this honorary office.

The chief event to be recorded in this connexion is the inauguration of the Central Institution which is to fulfil the function of a Technical University or Polytechnicum, and to afford higher scientific education to the future owners, directors, managers, engineers of manufacturing works, and the teachers in the various branches of technology. This magnificent Institution has now started on its career, and we have every reason to think that before long its value will be fully recognised by those who ought to take advantage of its existence. It is, however, unfortunate that the organisation of this Institution has stopped short of the plans originally laid down, and has been not at once carried to completion. Strange as it may appear, this is due to the want of funds. The City and Guilds, in taking so prominently charge of the initiation and diffusion of technical education in this country, have thus far most liberally furnished the means required, and have thus earned the gratitude of the country; but as the development of the scheme progresses an even and commensurate flow of further contributions is required, which, being voted in many cases but annually, at once demonstrates the somewhat precarious conditions on which this important enterprise is dependent.

It is to be hoped that a more general recognition of the absolute need of an education of a higher scientific character both for masters and men will before long have its proper effect; and that the ways and means will be forthcoming to carry out a work which promises so well, and that the Central Institution may then stand a fair comparison with numerous institutions of a similar kind in other countries which have already helped in so marked a degree to advance the industries of those countries.

The mistaken notion is still too prevalent that technical education has to confine itself to the theoretical considerations of known technical processes, and that a more extended acquisition of scientific knowledge is not required. It is obvious that a pupil educated on these lines may find by the time he is able to enter on his practical career that the processes with which he has been made acquainted have in the meanwhile become obsolete, and unless his education has been sufficiently comprehensive to enable him to strike out new lines for himself he will be ill fitted to compete with those who have been educated on a wider basis.

Essential as it is to impart to the future manager scientific knowledge, it is above all necessary to train him by practical work and research in the laboratory how to investigate a subject which may present itself in his daily occupation, whether it be some unexpected development in a new direction, or whether it be some new difficulty which confronts him in carrying out the processes under his direction.

It is self-evident that such knowledge and such practical experience in carrying out investigations is not to be attained by merely attending one or two courses in the lecture-room or in the laboratory. Those who mean to effectually qualify themselves for such functions can only accomplish this object by devoting years of patient and intelligent work under the guidance of the professor in properly appointed laboratories.

THE INSTITUTION OF NAVAL ARCHITECTS

THE spring meetings of the Institution of Naval Architects this year were, to a considerable extent, adversely affected by the recent death of Mr. William Denny, of Dumbarton, the eminent shipbuilder, who was for many years one of the most active members of the Council, and who was foremost amongst the mercantile shipbuilders of this country in the application of scientific methods to naval architecture. Mr. Denny, as is well known, set up at Dumbarton a large experimental tank similar to that contrived by the Admiralty at Torquay for the late Mr. W. Froude, F.R.S., and in which most of his famous experiments on the resistances of the hulls of ships were carried out. It is not often that manufacturers can be induced to spare time and money for the purposes of scientific investigation, even when such investigation is directly conducive to the success of their business. But Mr. Denny was an exceptional man. He firmly believed in the mercantile value of exact scientific knowledge, and he possessed the courage and the ability to act up to his beliefs. It is satisfactory to know that he considered himself fully repaid for the risks he ran, in the results which he attained.

The opening address of the President dealt, as might have been expected in this Jubilee year, with the remarkable progress in steam navigation achieved during the fifty years of Her Majesty's reign; a progress which must certainly be acknowledged to be extraordinary when we remember that, at the commencement of the reign, the late Dr. Lardner publicly offered to eat the first steamship which should cross the Atlantic, whereas nowadays we have vessels which make the passage in a few hours over six days, and a fuel consumption at sea of $1\frac{1}{2}$ pounds of coal per indicated horse-power per hour is not uncommon. The speaker alluded to the various improvements, such as the use of steel in the construction of both hulls, engines, and boilers, the adoption of high-pressure steam and triple compounding, &c., which have principally contributed to the remarkable results attained.

The first paper read was by the late Director of Naval Construction at the Admiralty, Sir Nathaniel Barnaby, and dealt with the important subject of the connexion between the Royal Navy and the merchant service. This paper was rather political than technical in its character. The author's main object was to support the Admiralty in their recently announced policy of so organising the mercantile marine as to increase the power of national defence. He pointed out that a fast and properly constructed mail steamer may be as efficient a factor in naval war as an ordinary cruiser costing a quarter of a million sterling; and that there are even certain services which the mail-steamer, by reason of her greater size and travelling power, can perform better than the cruiser. On the other hand, the great mass of our mercantile marine is now relatively weaker than it has ever been before against the attacks of an enemy; for in the wars of the last century such ships as the armed East Indiamen possessed a well-recognised fighting value, but nowadays warships are so specialised that the majority of merchant vessels possess no powers of resistance whatever. Sir Nathaniel Barnaby also called attention to the fact that the State makes provision annually for a reserve of seamen, who are drilled periodically and paid by it, and who are liable to be called out to serve in case of war; and he then proceeded to show how, by good organisation, the superior merchant-ships, if manned mainly by naval reserve men, could in case of war be immediately available for service in whatever part of the world they might chance to find themselves. At the present moment the Royal and mercantile navies are under the control of two different Departments of State, and by some strange perversity the First Lord of the Admiralty is almost the only great political officer of State whose name is not to be found on the long list of members of the Board of Trade. As a natural consequence there is no community of action between the two Departments, and no organisation at present exists by which the services of the better class of fast merchant steamers could be rendered instantly available in case of war. The author's cure for this condition of affairs is the creation of a Secretaryship of State for the Navy, so that the interests of the merchant shipping and the Royal Navy might be united, and a truly national marine formed. There is no doubt but that Sir Nathaniel Barnaby in reading this paper has called attention to a very serious set of evils, which may all be remedied by a little organisation and by co-operation between two of the Departments of State. Even if the Board of Trade did not see its way to help in the work, what is to prevent the Post Office authorities from backing up the Admiralty by declaring that they would in future give the preference for mail-carrying purposes to steamers which fulfilled the Admiralty requirements of speed, subdivision, and structural strength, and what is to prevent the Admiralty from assisting the Post Office to obtain a cheap and efficient mail service by granting moderate retaining fees or subsidies to such steamers, provided they were always manned with a due proportion of naval reserve men and trained officers, and provided also that in consideration of the yearly subsidy their services were to be always at the disposal of the State in case of war at a fixed rental to be arranged beforehand. A beginning has undoubtedly been accomplished in the arrangements recently concluded between the Cunard and the White Star Lines on the one hand, and the Admiralty and the Post Office on the other, but much yet remains to be done, and we earnestly trust that Sir Nathaniel Barnaby's paper may be brought under the serious notice of those upon whom will devolve in time of war the care of our mercantile navy and the protection of our food supplies.

M. L. de Bussy, the Inspecteur-Général du Génie Maritime in the French Ministry of Marine, read a short paper on the results of a series of trials carried out on a torpedo boat at progressive speeds, in which he called attention to the fact that there is a diminution in the resistance of the hull after a certain speed has been passed. This fact was, however, already well known to members of the Institution, the peculiar sinuosities, or humps, as they are called, on the speed and power curves of vessels tried at progressive speeds having been often discussed at previous meetings. When all the causes of resistance to propulsion are separately analysed and expressed by correct formulæ, the causes of these successive maxima and minima of resistance will no doubt be clearly intelligible.

Mr. J. H. Biles, the scientific adviser of the firm of Messrs. J. and G. Thomson, of Glasgow, read an interesting paper on the twin-screw torpedo boats, *Wiborg* and *El Destructor*, constructed by his firm for two foreign Governments. The author first gave full particulars of the dimensions of the boats and engines, and their performances. These vessels were considerably larger than the generality of first-class torpedo boats, the *Wiborg* being 142 feet 6 inches, and the *Destructor* 192 feet 6 inches in length. They are both minutely subdivided, the former being provided with 23 and the latter with 39 water-tight compartments, the object being, of course, to enable them to keep afloat as long as possible when exposed to the fire of machine guns. The paper is interesting as showing the most recent tendency in torpedo-boat design. Recent experience in this country and in France undoubtedly points to the conclusion that the older type of first-class boats, though useful enough for harbour defence, are of little or no avail for service at sea. Whether the latest types described by Mr. Biles will fulfil reasonable expectations in this direction is a question which can only be solved *ambulando*. It may be noticed as a curious instance of the skill of modern marine engineers in evolving enormous powers out of engines of limited size, that the *Destructor*, whose load displacement is only 480 tons, has developed over 3800 horse-power, and has made the run of 495 knots from Falmouth to Muros in twenty-four hours, which corresponds to a mean speed of 20·625 knots.

Mr. Dixon Kemp, a well-known authority on yachting matters, read an interesting historical paper entitled "Fifty Years of Yacht-Building," in which he traced out the gradual evolution of the English and American types of racing yachts from the commencement of the present reign down to the most recent times. The author brings out very clearly the causes which have led to the adoption of the relatively narrow and heavily lead-ballasted boats which have hitherto found favour on this side of the Atlantic, and the broad, shallow, centre-board yachts peculiar to the Americans. In view of the recent triumphs of the American type, as represented by the *Puritan* and *Mayflower*, an alteration has been considered desirable in the old tonnage rule which taxed the beam so severely. The Committee of the Yacht-Racing Association appointed to report on the subject have recommended the following rule:—

$$\text{Rating} = \frac{\text{Length of loadline} \times \text{sail area}}{6000}.$$

The first outcome of the new rule is the Clyde-built yacht *Thistle*, the principal proportions of which contrast strongly with those of the now famous *Galatea*, as will be readily seen from the following figures:—

	Galatea.	*Thistle.*
Length of loadline	87·0 feet	85·0 feet
Beam extreme	15·0 ,,	20·3 ,,
Draught of water	13·5 ,,	14·1 ,,

It should be mentioned that in the case of the *Thistle* the depth of the hold is measured to the bottom of the keel, which is a hollow box intended to hold the lead ballast. The contests, which will doubless take place during the coming season, between the *Thistle* and some of the powerful American centre-board yachts, will be watched with great interest by yachtsmen. Whether a contest between a keel-yacht and one fitted with the centre-board is a satisfactory trial of merit is at least open to question. In this connexion it may be mentioned that a yacht like the *Mayflower* when sailing off the wind can effect a reduction of 10 per cent. in her immersed surface by housing the centre-board, an advantage which is manifest, especially in the case of light winds and slow speeds.

A subject of great importance with regard to iron and steel ships is the protection of their bottoms from corrosion. Mr. V. B. Lewes contributed a valuable paper on the nature and genesis of rust, and on the protection of plates from its effects. It seems now to be generally admitted that the corrosion which distinguished some of the earlier steel-built ships was due to the presence on the plates of mill-scale or black magnetic oxide of iron, which forms, with the metal of the plate, a powerful galvanic couple, and gives rise, in the presence of sea-water, to very rapid pitting or local corrosion. The action is, in fact, similar at the outset to that which takes place between metallic lead and its peroxide in the well-known Planté secondary batteries. At the present time, steel plates are always carefully freed from this magnetic oxide before being worked into the hulls of ships—a practice which has been attended with the best results. Mr. Lewes believes that the protective compositions of the future will be made by dissolving a good sound gum, not easily perished by sea-water, in a volatile solvent, care being taken that neither gum nor solvent give rise to any organic acids. Body will be given to this varnish by finely-divided metallic zinc, which can now be obtained in so fine a powder that it can be used as a pigment. When, in time, the varnish perishes, as it must do from the action of sea-water under pressure, the zinc will set up galvanic action with the hull-plates; but, being the more electro-positive of the two metals, it will corrode, and will thus protect the iron or steel plates. This paper does not deal with the much-vexed subject of anti-fouling compositions—a much larger subject, which the author reserves for a separate memoir.

Sir Nathaniel Barnaby read a second paper on the subject of fuel-supply in ships of war, which, together with a paper by Mr. Biles, on the comparative effects of belted and internal protection upon the other elements of design of a cruiser, apparently provoked more interest and discussion than any other communication made to the Institution this year. The ships to which Sir Nathaniel Barnaby alluded were the *Impérieuse* and *Warspite*, belted cruisers, for the design of which he was himself chiefly responsible. These vessels have lately been the subject of much adverse comment both in and out of Parliament. As originally designed, the armoured belt was intended to reach from a height of 3 feet 3 inches above the water-line to a depth of 4 feet 9 inches below it. The supply of coal on which this calculation was based was 400 tons, but bunker space was allowed for an additional supply of 500 tons. During construction various additions were made to the weights of the boilers and the armament, which in their turn involved an increase in the weight of hull, and the net result was that the total weight of each ship was increased by 415 tons. Moreover, the present Board of Admiralty have decided that war-ships are in future to coal up to their full stowage capacity; that is to say, in the case of the *Impérieuse* and *Warspite* 500 tons more fuel are to be carried than the designer allowed for. As a natural consequence, the addition of 915 tons to the total weight of each vessel has immersed these ships so deeply that the height of the armoured belt above water has been reduced from 3 feet 3 inches to a little under 1 foot, and there are not wanting those who declare that this circumstance greatly injures, if it does not totally destroy, their fighting efficacy. Sir Nathaniel Barnaby very successfully proved that the responsibility for the additions to the weights of the hull and machinery belongs to the then Board of Admiralty, and not to himself. He also demonstrated that the addition of the extra 500 tons of coal was a case of deliberate reversal of the policy of one Board by its successor, but, judging from the tone of the discussion, he failed to convince his audience that the original policy of calculating the immersion of the belt on a fuel-supply of 400 tons was a wise one.

Mr. Biles's paper, above referred to, on the armour question, was an interesting and useful attempt to solve a difficult problem. He commenced by taking, as the basis of a definite comparison, the latest type of British belted cruiser, viz. the *Aurora*, of 5000 tons displacement. This vessel has a belt 5 feet 6 inches wide, of which 1 foot 6 inches is above the load-line; the thickness of the belt is 10 inches, and its top edges are united by an armoured deck 2 inches thick, under which are placed all the vitals of the vessel. With this he compares a type of cruiser without any side armour, but protected by means of a plated deck, the sides of which curve down so as to join the bottom some feet below the water-line, the curved or sloping portions of the deck being covered with armour of the same horizontal thickness as the *Aurora's* belt. In making the comparison he assumes—

(1) That the length and draft of the proposed vessel are to be the same as in the case of the *Aurora*.

(2) That the displacements are to be the same in each case.

(3) That the costs are to be the same.

Mr. Biles claims that in design No. 1 the internally protected vessel would weigh less than the belted cruiser by about 210 tons; that it would cost nearly 40,000*l*. less; and that the designer would have the option, on the smaller displacement, of either increasing the thickness of the flat portion of the armoured deck by 40 per cent. amidships, or of adding about six-tenths of a knot to the speed, or finally of adding one 9·2-inch gun and two 6-inch guns to the armament.

In the case of design No. 2, where the displacements of the two types are equal, it is estimated that either a knot and a half might be added to the speed, or else that the thickness of the whole of the deck-plating might be increased by 44 per cent.

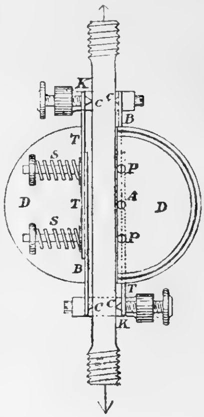
Lastly, on the assumption that the cost of the vessels is the same, Mr. Biles claims for the internally protected vessel the following important advantages: viz. 20 per cent. greater thickness of protection on the slope of the deck, 50 per cent. more on the flat, two more guns of the heaviest calibre, 20 per cent. more coal, and one knot additional speed. Mr. Biles very pertinently asks the question, Is the adoption of the belt worth the extra money paid for it with its accompanying sacrifices? or, If the money is to be spent, is the belt worth the sacrifice of speed, protection, and armament, which is entailed in its adoption?

The papers on marine engineering were not quite so interesting as some which have been read at recent meetings of the Institution. There were three on the subject of screw propellers, by Prof. Cotterill, F.R.S., Mr. Calvert, and Mr. Linnington of the Admiralty, and one on the machinery of small boats, by Mr. Spyer, also of the Admiralty. In addition to the foregoing there were two papers on stability, a subject which has been perhaps lately somewhat overdone; and an important contribution by Mr. Archibald Denny on the practical application of stability calculations in relation to the stowage of steamships. Mr. Jenkins, the newly-appointed Professor of Naval Architecture at Glasgow University, prepared a paper on the subject of the shifting of cargoes.

STROMEYER'S STRAIN-INDICATOR

THIS is a very useful and ingenious apparatus for measuring the extension or compression produced on any material by tensile or compressive forces. Such deformations having been observed, the corresponding variation in the stresses to which the material has been subjected may at once be inferred by the ordinary law of elasticity connecting strains and stresses in solid bodies. The instrument affords one of the many examples of the valuable results obtainable by the simplest possible mechanical means—results which before the construction of the strain-indicator were considered altogether unattainable.

The instrument is shown in the woodcut, and consists of two flat plates, T, B, about 1½ inch wide and of any convenient length, pressed together by means of two springs, S, S, in such a manner that one plate projects at one end and the other at the other end. The plates are



free to slide over each other at their ends opposite A. Fixed centre-points, C, C, are screwed one into each end of each plate, and a graduated dial, D, is attached to the upper one of the two plates T. Two of these instruments are held together by a pair of clamps, K, K, fixed just over the centre-points, which, when screwed tight, press the centres against both sides of the test-pieces; for safety against slipping, a few taps of a hammer embed them more firmly. The figure shows a round bolt about to be operated upon by tensile force, the screwed ends forming attachments to the grips of the testing-machine. Then, when everything is ready, a pair of very fine hardened steel wire rolling pins, P, P, to which light pointers have been attached, are inserted between the plates. These rolling pins, when in position, should be in the centres of the dials. On applying the load to the test-piece, elongation takes place; the centre-points move slightly away from each other, carrying the plates with them, which, as they move in opposite directions, and as they are held apart only by the interposed rolling pin, cause it to revolve, and the angle through which it has moved can then be read off with the help of the pointer and dial. The best results have been obtained with a wire which was drawn, and which measures exactly ·015 inch in circumference. The dial is divided into fifteen equal parts, and their decimals, so that one division represents one-thousandth of an inch, and variations as small as a twenty-thousandth of an inch can be detected.

The above instrument is the outcome of another instrument invented by Mr. Stromeyer, of still greater sensitiveness, and which is based on the production of Newton's rings. Its extreme sensitiveness and certain practical difficulties, however, make it unsuitable for the use of the engineer or naval architect, to whom the present instrument is of great value, and by whom it can be very conveniently used.

The strains of a ship in a sea-way have always been very difficult to deal with. Agur and Solomon of old frankly admitted they were "too wonderful" for them, and although the same ingenuousness has not always been practised by naval architects since, the fact remains that the present state of knowledge in this subject is extremely meagre. Methods of calculation have, it is true, been in use by naval architects which have given results most useful for comparative purposes, but which in absolute units frequently indicated forces that ships could not bear. These methods therefore, except for the comparative purposes they were primarily designed to serve, threw no light whatever on the actual conditions of stress on the various parts of the structure in a sea-way. One able investigator showed that the dynamic constitution of sea-waves was such as to make the effective variation of buoyancy enormously less than the apparent variation, and that this difference meant a reduced variation of stress in large ships from, in some cases, 170 to 100. This investigation cleared up many pre-existing difficulties. Mr. Stromeyer, however, by means of his beautiful and simple apparatus, enables the variation of stress on any part of any structure, ship, or anything else under the action of any forces to be arrived at with certainty by direct experiment.

The invention of this little apparatus constitutes an era in the science of the strength of complicated structures such as ships, boilers, &c.

WILLIAM BABCOCK HAZEN

THE sudden death of Brigadier-General William B. Hazen, Chief Signal Officer of the United States Army, which occurred on Sunday, January 16, 1887, deprived the country of one of its most distinguished officers, and the Signal Corps of a chief who took a broad view of its duties and relations to the world of business and science.

General William B. Hazen was the great-grandson of Thomas Hazen, who was born 1719. Thomas Hazen was himself great-grandson of Edward Hazen, who emigrated from England before 1649, and settled at Rowley, Mass., where he died in 1683.

The descendants of Edward Hazen include many names eminent in business, theology, and war: energy, industry, and strong convictions characterise the members of the family on all sides.

General Hazen was born at West Hartford, Vermont, September 27, 1830. While he was a child his parents removed to Hiram, Portage County, Ohio. In 1851 he was appointed from Ohio as a cadet to the United States Military Academy, at West Point, from which he graduated on July 1, 1885. He was assigned to the 8th U.S. Infantry, and spent the next five years in frontier service, more especially against the Indians in California, Oregon, and Texas, in which service he displayed an energy and bravery that have been characteristic of his life. His record during these years embraces constant fights and pursuits. He was twice severely wounded, and by virtue of the latter he was, in January 1860, by the surgeon's order, granted a leave of absence as being unfit for duty. In consequence of this he was at the north while his regiment was in Texas at the breaking out of the Rebellion. The regiment having been captured and its officers released on parole, he alone was unembarrassed by the parole and was able to offer his services to the Union Army; he was at once assigned as temporary instructor at West Point. In May 1861, he became captain of the 8th Infantry of the regular army, and in October was made colonel of the 41st Regiment of Ohio Infantry in the volunteer army. During the war he distinguished himself on many occasions, and his commission as major-general was granted him December 13, 1864, for "specific distinguished services," *i.e.* "for long and continued services of the highest character, and for special gallantry and service at Fort McAllister." This placed him fifth in a list of twenty-four officers who had received commissions for distinguished service.

He continued serving on the frontier territories north and west, and was especially active in Indian affairs until 1870, in which year he was allowed leave of absence to visit the seat of war in Europe. The results of his observations and studies during his six months' absence are embraced in a volume entitled "The School and the Army in Germany and France, with a Diary of Siege Life at Versailles" (New York, 1872). This volume contains a very interesting sketch of Bismarck, and an account of the state of affairs in Europe. It contains especially a fair criticism of the relative excellencies of the German and French systems, both civil and military; in a special chapter on that subject he incidentally brought out more prominently some weak points in our own military organisation. It would seem that the courage displayed so brilliantly on the battle-field frequently nerved him to utter not only these but other fearless criticisms of things that were palpably wrong, and some of which have since been corrected.

He was married, February 15, 1871, to Millie, daughter of the Hon. Washington McLean, of Cincinnati, who, with one son, survives him.

On his return from Europe in 1871, he returned to duty in the Indian Territory, and was with his regiment in Kansas and Dakota, except for a short absence, until December 15, 1880, when he was, by President Hayes, appointed Brigadier-General and Chief Signal Officer, and has since then been stationed at Washington. The absence just referred to was occasioned by his again visiting Europe as Military Attaché to the United States Legation at Vienna, for the purpose of studying the operations of European armies during the Turko-Russian War. He was absent on this service from December 1876 to June 1877, and the results of his observations were published subsequently in a highly interesting popular volume.

The general account of his activity during the war of the Rebellion was published by him in his "Narrative of Military Service" (Boston, 1885).

His letters and pamphlets on the "Bad Lands" show that for many years General Hazen had been studying the relations of meteorology and agriculture. After his appointment as Chief Signal Officer, he was indefatigable in his efforts to improve the military and departmental relations of the Signal Service, its scientific character, its practical usefulness to farmers and herders, and its popular influence. His labours in Washington stirred up most virulent opponents, first when it became necessary for him to expose and prosecute the corruption of Capt. Howgate; again, when it became necessary in self-defence to expose the true reasons of the failure of the War Department to properly support and succour the Signal Service Expedition to Fort Conger; and again, when he had occasion to defend the advantages of the military character of the combined Signal Service and Weather Bureau organisation against those who would take it from the army without making a proper provision for its work in any other Department. The records of his successful defence against attacks prompted by implacable hate, official stubbornness, and personal ignorance, are to be found in the proceedings of "Courts-Martial," "Courts of Inquiry," "Committee of Congress on Expenditure," and especially in the "Testimony before the Joint Commission to consider the present organisation of the Signal Service," &c., which latter voluminous report and testimony was presented in June 1886.

General Hazen's interest in meteorology, as before said, properly dated back earlier than 1873, at which time he prepared a letter "On our Barren Lands, or the interior of the United States, West of the 100th Meridian, and East of the Sierra Nevadas." This was published in the *New York Tribune*, February 27, 1874, and led to a discussion in that paper and in the *Minneapolis Tribune* between himself and General A. A. Custer, which is summarised in a pamphlet of the above title, published by Robert Clarke and Co., of Cincinnati, in 1875. The motive of General Hazen evidently was the protection of investors and settlers against the too glowing accounts, which amounted to virtual misrepresentation on the part of the *employés* of the Northern Pacific Railroad. His compilation of climatological data, and his statement of personal experience based on long residence in that region, largely contributed to prevent blind emigration into an inhospitable country, while they doubtless also contributed to direct attention to the really valuable portions of our north-west territory, so that the permanent development of that portion of the United States has been furthered by his action. It was, however, at the time, on his part a very characteristic outspoken exposition of what seemed to him a fraud and imposition perpetrated by unscrupulous financiers upon foreign immigrants and over-confiding settlers and investors.

During his connexion with the Signal Office, General Hazen frequently took occasion to show his appreciation of the fact that the weather predictions were essentially not a matter of mere military routine, but that in all its details the office had need of the work of specially trained experts, that it was a mistake to shut one's eyes to the fact that, in a matter of applied science like this, some of those whom the scientific world recognises as meteorologists and physicists must be employed, and be required to keep the chief fully informed of the progress of science. Perhaps this is best exemplified by a quotation from his letter of March 24, 1886, addressed to a Committee of the House on Expenditures of the War Department:—"At the beginning of the work of the Signal Service the duty of giving notice of the approach and force of storms and floods for the benefit of commerce and agriculture throughout the United States implied that the notices should be correct, reliable, and timely, as none others could possibly be of benefit; it was therefore absolutely necessary to provide for the careful study of the atmosphere. On my accession I found every evidence from popular criticism that still further progress in weather predictions was expected. I therefore emphasised especially the necessity of the study of the instruments and methods of observing, and the investigation of the laws of the changes going on in the atmosphere. . . . . It is evident by these successive steps that in addition to knowledge gained for current work the office is powerfully contributing towards the establishment of a deductive science of meteorology which will eventually give us a solid, rational basis for predictions, thereby improving on the empirical rules by which predictions have generally been made hitherto." And he adds that he was led more especially to assist in the researches on the sun's heat by reason of the encouragement given him by the late President Garfield, whose "last words to me were, 'Give both hands of fellowship and aid to scientific men.'"

As a further illustration of General Hazen's appreciation of the scientific needs of the office must be noted his appointment of Prof. William Ferrel as meteorologist, and of Prof. T. C. Mendenhall as electrician. To the latter, all matters relating to standards, instruments, and instrumental research were also committed. Nor did General Hazen stop here; by appointing several younger men to positions as junior professors he largely increased the amount of study and research that the office was able to perform, and by publishing a series of professional papers and smaller notes, he took the final steps necessary to stimulate every man to do his best.

Labouring in this same direction, he sought to elevate the intelligence and scientific training of the Signal Corps proper by enlisting College graduates as far as possible, by extending the course of instruction for observers, and by establishing a course of higher instruction for commissioned officers.

In still another direction General Hazen showed his devotion to scientific interests, namely, by his desire to conform as thoroughly as possible to the recommendations of the International Meteorological Conferences. These recommendations, as soon as received in the printed Minutes of the Conferences, were, by General Hazen's orders, carefully examined, and instructions at once prepared calculated to introduce methods of observation and publication in conformity with the recommendations of the leading meteorologists of the world.

Among the items specially noteworthy wherein General Hazen developed new paths of activity for this service, may be especially mentioned the study of local storms: first, tornadoes, which were especially assigned to Prof. Hazen so far as a collection of general statistics is concerned, and to Prof. Mendenhall so far as concerns the electrical phenomena proper. The study of atmospheric electricity was especially authorised, in 1884, by an order of the Secretary of War transmitting the resolutions of the International Electrical Conference held in Paris the preceding year. After full consultations with numerous electricians throughout the country, General Hazen decided that a daily map of electric potential showing lines of equi-potential similar to the iso-barometric lines, offered hopeful prospect of eventually leading to a method of predicting the formation and motion of thunderstorms and tornadoes. But the methods of observation and the apparatus needed first to be determined upon after careful experimental work. This whole matter was, therefore, in 1885, committed to the hands of Prof. Mendenhall.

Perhaps the most important item in internal administration, so far as it affects the permanent scientific value of the office work, was the effort heartily furthered by General Hazen to improve the accuracy and international comparability of our instrumental equipment. The standards of the International Bureau of Weights and Measures were recognised by him as being the proper legal standards for this office, and every effort was made to determine the corrections needed to reduce the past as well as the current meteorological observations of the office to agree therewith.

Perhaps the generous breadth of General Hazen's views, the absence of injurious jealousies, and his confidence in the principle that the Weather Bureau would be strengthened by the widest diffusion of an intelligent appreciation of meteorology, are in nothing more clearly shown than in the earnestness with which he stimulated the formation of State weather services and encouraged the study of meteorology in every school and college. He was painfully impressed by the disastrous influence upon individuals and business of the widespread and utterly absurd predictions of the storms and weather of

March 9, 1884, which were distributed broadcast throughout the country, and emanated from Mr. Vennor. He saw clearly that all this harm could only be prevented by increasing the intelligence of the people in scientific matters, and heartily indorsed every effort to diffuse a more correct idea as to what constituted legitimate meteorology.

Although his duties demanded the maintenance of a great central office at Washington, yet General Hazen realised that centralisation could easily be carried too far in scientific matters, and would thus react injuriously upon the work of his office. He was desirous of rapid progress in all directions, and, to secure this, welcomed every prospect of co-operation with other institutions as well as with individuals. One of his first acts was the request for co-operation on the part of the National Academy of Science. He improved the opportunity to help Prof. Langley in the determination of the absorbing power of the atmosphere; he accepted Prof. King's offer to carry observers on his balloon voyages; he heartily furthered Lieut. Greely's efforts to maintain an International Polar Station, and joined with the Coast Survey in establishing a similar station under Lieut. Ray at the northern point of Alaska; he co-operated with the Bureau of Navigation in securing weather reports from the ocean; he powerfully assisted the Meteorological Society in its labours for the reformation of our complicated system of local times, the result of which was the adoption by the country of the present simple system of standard meridians one hour apart.

Equally successful was he in his efforts to co-operate in various methods of disseminating and utilising the knowledge obtained by the Weather Bureau for the benefit of the business interests of the country. With the telegraph companies he published the daily telegraph bulletin. Through the railroad companies, he displayed the railroad train-signals visible to every farmer along the railroads. With local Boards of trade and other business interests he elaborated our system of flood warnings in the river valleys.

General Hazen was especially clear in his views as to the importance of giving personal credit to each man for his own personal work. Routine work was credited to the assistants in charge and not to the impersonal office. Having assigned a special work to the best man available, he took pains to give him the credit and make him personally responsible for its success, thus securing more enthusiasm in the work.

This notice of a few prominent features in the intense activity of General Hazen's life seems eulogistic rather than historical; but the fact is that military life rarely offers a position that requires the promotion of any special science, and still more rarely do official or military circles present an officer who so thoroughly desired, as far as allowable, to relax stringent military law and liberally interpret cumbersome official regulations, so that scientific men might successfully promote their special work.

Washington, February CLEVELAND ABBE

SIR WALTER ELLIOT, K.C.S.I., LL.D., F.R.S.

BY the death at an advanced age of Sir Walter Elliot, we lose one of the few survivors from a group of men who, in the second quarter of the present century, by their contributions to the zoology of British India, laid the foundations of our present knowledge. The subject of the present notice was, however, so widely known for his acquaintance with the history, coins, languages, and ancient literature of Southern India, that his zoological work might easily be overlooked.

Sir Walter Elliot was born in 1803 at Edinburgh. He was the son of Mr. James Elliot, of Wolfelee, Hawick, Roxburghshire, and after being educated at Doncaster, and later at Haileybury, where he received a "highly distinguished" certificate, he entered the East India Company's Madras civil service in 1820. In that service he held many posts of distinction. From 1822 to 1833 he was assistant to the political agent of the Southern Mahratta country, and during this period he collected the information subsequently embodied in his Catalogue of the Mammalia inhabiting the region, and also commenced the series of archæological studies, some of the first-fruits of which in 1836 were presented to the Royal Asiatic Society in the shape of a paper on Hindu inscriptions. With this paper were sent two manuscript volumes containing copies of no less than 595 sculptured records from the Southern Mahratta country and the neighbouring territory.

In 1837 he was private secretary to Lord Elphinstone, then Governor of Madras, and he was subsequently for twelve years a member of the Madras Board of Revenue. The value attached to his linguistic knowledge was shown by his being at one time Canarese translator, and at another acting Persian interpreter to the Government. From 1849 to 1854 he was Commissioner for the Northern Circars. During this period he made the collection of Cetacea subsequently described by Sir R. Owen in the Transactions of the Zoological Society, vol. vi. Finally he was Senior Member of Council in Madras from 1854 to 1859, when he retired from the service, and returned to pass the remainder of his life at Wolfelee, the residence of many generations of his ancestors. Almost his last official act in India was, when in charge of the Madras Government in 1858, to take the principal part in the transfer of the Presidency from the rule of the East India Company to the direct government of the Queen. He was created a K.C.S.I. in 1866, and became a Fellow of the Royal Society in 1878, and he was Deputy-Lieutenant of his county.

In his retirement his attention was much given to numismatics, and despite the complete loss of his eyesight in his later years, he carried to completeness the studies commenced in his "Numismatic Gleanings on South Indian Coins," published in the *Madras Journal of Literature and Science* for 1857. He brought out in 1885, with the aid of Mr. Thomas, General Pearse, and other friends, a general work on the "Ancient and Mediæval Coins of Southern India." Up to the very last his interest in Oriental literature remained unabated. One of his friends received a letter signed by him and dated March 1, the day of his death, containing inquiries as to the forthcoming edition of a Tamil work, and suggesting that the attention of Madras native students should be bestowed upon the early dialects of their own language. During the last ten years numerous notes by Sir W. Elliot have appeared in the *Indian Antiquary*, the latest in the September number of last year. Largely through his efforts the Amravati sculptures, now in the British Museum, were added to the national collection, and this was but one of the valuable additions due to him. His Southern Indian coins, a very large and important series, were presented to the same institution, and his numerous zoological collections enriched the Natural History Museum.

Although his published papers on zoology give but an imperfect idea of his contributions to the science, for many of his observations were freely communicated to other naturalists, and published by them, his "Catalogue of the Species of Mammalia found in the Southern Mahratta Country," which appeared in the *Madras Journal* for 1842, was of unusual merit. It had the peculiar advantage that it was a list, not of museum specimens, but of the wild animals inhabiting the country, several of which, and indeed nearly all the smaller rodents, were discovered by the author. The habits of the larger animals were described from personal observation, not, as has so frequently been the case, from information derived from native collectors.

Personally, Sir Walter Elliot was one of the kindliest of men, with a charming manner and generous disposition. At Wolfelee, as formerly in India, he was widely known and universally respected. W. T. B.

NOTES

He must be a very dull Englishman whose imagination has not been touched by the assembling of the Colonial Conference, an event which may hereafter be seen to have marked the first stage in one of the greatest movements in the history of mankind. In describing the commercial relations of the colonies, Sir Henry Holland, in his opening speech as President, had occasion to bring some very eloquent figures to the notice of the Conference. The imports and exports of the colonies were, in 1885, eleven times what they were in 1837. The British shipping trade with the colonies rose from 3,700,000 tons in 1837 to 56,600,000 tons in 1885, while, in the same period, British exports to the colonies rose from 11,300,000*l*. to 54,500,000*l*. This astonishing material progress, accompanied by an increase of population from 4,204,700 in all the colonies in 1837 to 15,763,072 in 1881, would, of course, have been impossible but for the rapid development of physical science and the steadily increasing application of its principles to the methods of industry. And it is interesting to note that, of all the questions which the Conference will have to discuss, by far the greatest are those most directly connected with the results of scientific investigation—questions relating to the naval and military defence of the Empire, and to the improvement of postal and telegraphic communication. In speaking of telegraphic communication, Sir Henry Holland quoted a striking letter he had received from Mr. Pender. Some of the facts brought together in this letter must have reminded the delegates very vividly of the debt which commerce owes to science. Twenty years ago there were only about 2000 miles of submarine cables, and some of the earlier cables were so badly constructed that they were practically useless. "Science has now, however," wrote Mr. Pender, "aided so greatly in the manufacture of cables that they can at the present time be laid with comparatively little risk of breakage and with an almost certainty of efficient repair." The consequence is that there are now 107,000 miles of submarine cables, which have cost something like thirty-seven millions sterling. The whole of this vast system, with the exception of about 7000 miles, is entirely under British control. To show the relative importance of the submarine cables, Mr. Pender stated that the length of all the land telegraphic lines now in existence in the world is about 1,750,000 miles, representing an estimated cost of 52,000,000*l*.

Dr. Brown-Sequard has been elected President of the Society of Biology, Paris. His immediate predecessor was the late M. Paul Bert.

A Bill was lately submitted to the U.S. Senate, providing for the creation of a Department of Agriculture and Labour. Various amendments were proposed, and among them was one for the transfer of the Weather Bureau from the Signal Office of the Army to the new Department. This amendment was accepted by the Committee on Agriculture, and *Science* says that it would certainly have been passed by the Senate had not difficultie uuexpectedly arisen with regard to the Bill as a whole. The President, it seems, did not wish to have an additional member in his Cabinet. The Bill was therefore referred back to the Committee on Agriculture, and it did not again come before the House. According to *Science*, there can be no doubt that the Bureau will be transferred next year to some Civil Department, public opinion being decidedly in favour of the change. In the meantime General Greely, General Hazen's successor, will retain the position of Chief Signal Officer.

In the Report of the Scottish Meteorological Society, to which we referred last week, it is stated that during the winter Mr. Cunningham, Superintendent of the Zoological Laboratory of the Marine Station at Granton, and Mr. Ramage, have been continually engaged in a systematic study of the Chætopoda of the Firth of Forth. In the course of this work all the specimens obtained by dredging have been determined, and their anatomy has been investigated. Fresh specimens, and ova and young forms, have been collected on the shore at low tide, and by means of low nets; and a large number of drawings and descriptions have been made, among which are accounts of some species new to the district, and additions to the knowledge of anatomy and development. The results of this work are being prepared for publication.

The Report for the year 1884 of the United States National Museum, under the direction of the Smithsonian Institution, has just been issued. It contains (1) the Report of the Assistant Director, (2) Reports of the Curator and Acting-Curators, (3) papers based on collections in the Museum, (4) bibliography of the Museum for 1884, and (5) a list of accessions to the Museum in 1884. Among the papers based on collections in the Museum are two admirable anthropological studies by Mr. Otis T. Mason—one on throwing-sticks, another on the basket-work of the North-American aborigines. There is also an excellent study, by Mr. John Murdoch, of the Eskimo bows in the Museum. These papers are carefully illustrated.

On March 9 a Conference met in the Senate House, Cambridge, to discuss various questions in connexion with the Cambridge University Local Lectures. A report of the proceedings has been printed for the Syndics at the University Press, and it ought to be read by all who are interested in the subject of University Extension. Attention may especially be called to a speech by Dr. Westcott, who argued with much force that the affiliation of local centres to the University might provide an adequate foundation for a national system of higher education. Mr. Browne, Secretary of the Syndicate, who made a financial statement, set forth the claims of the movement to the support of all "who feel that the University Extension system has great powers for good, and has already done excellent work."

Science and Art, the first number of which has just been issued, deserves, and will no doubt receive, a cordial welcome from the class of readers to whom it appeals. Its principal object is to bring the schools of science and art into closer contact with one another. The articles, notes, and correspondence will be on subjects likely to be of especial interest to teachers in those schools, and it is also hoped that the journal may be of benefit to students. Each issue is to contain test-questions in science and art subjects, for which prizes of books and instruments will be given.

On Tuesday last Messrs. Mourlen, Belgian electricians, had an interview at Brussels with M. Granet, the French Minister of Posts and Telegraphs, relative to the establishment of a telephone line from Paris to London.

An excellent "General Guide" to the Natural History Museum, Cromwell Road, has just been printed by order of the Trustees. It contains plans and a view of the building.

Mr. T. B. Coombe Williams has compiled an interesting bibliography of the books, in his own library, on fancy pigeons. The authorship of the works in his list may, he says, be apportioned as follows: English writers, 58; German (including translations), 45; French, 21; Dutch, 3; Latin, 3; Italian, 5; Spanish, 1; Arabic, 1. More books on this subject have been printed in English and German than in any other language.

IN a recent Bulletin of the U.S. Fish Commission, Mr. J. W. Collins describes the finding of a knife of curious workmanship in the thick flesh of a large cod. The "find" was made at Gloucester, Mass., on September 15, 1886, by Capt. John Q. Getchell, when discharging a fare of codfish from his schooner. He had lifted several fish from a tub, and, running his hand over the thicker portion of one of them to call the attention of the by-standers to its fatness, he felt something hard beneath his fingers. Further examination produced a knife. The handle of the knife is of brass, curved and tapering posteriorly, with a longitudinal incision, on the concave side, to receive the edge of the blade. The form is remarkable, and suggests "the handiwork of some savage tribe, or the scrimshaw work of a sailor." The blade, which is of a lanceolate shape, has been corroded a good deal, and the extreme point is very thin. The total length of handle and blade together is 6¼ inches. "As to where the fish got the knife," says Mr. Collins, "we can only conjecture, unless some ethnologist can point out its origin. In any case, the finding of such a remarkable implement in such a strange place must be a matter of interest to the ethnologist and naturalist alike."

THE Colonial Council of Cochin China has decided to grant a sum of 6000 francs a year for life to M. Pierre, the Director of the Botanical Gardens at Saigon, provided he undertakes to finish in Paris the publication of his "Flore de la Cochinchine," and will leave all the manuscripts and collections which he has employed in the preparation of this work to the colony. The same body has granted La Société des Études Indo-Chinoises a subvention of a thousand francs to aid in the publication of its *Bulletin*.

WE have received the numbers of the *Essex Naturalist*, the journal of the Essex Field Club, for January, February, and March of the present year. The steady growth of the Club has led the Council to decide upon the issue of a monthly journal in place of the former Transactions and Proceedings at irregular intervals. It is scarcely surprising that residents of the county of Essex should appreciate the labours of the Society, inasmuch as they are wholly devoted to the county, and are of interest even to persons who know little of Essex. In this respect—namely, the thorough examination of the district lying at their doors—the members of the Essex Field Club set an example that similar Societies elsewhere would do well to follow. Anything relating to the natural history, geology, and prehistoric archæology of Essex is welcomed. Thus, amongst the papers in the three numbers before us, we have a discussion on a curious subsidence near Colchester in 1862; a report on the flowering plants in the neighbourhood of Colchester, by Mr. Shenstone, which is a kind of supplement for that particular district to Gibson's "Flora of Essex," published twenty years ago; notes on the saffron plant in England and its connection with the name of Saffron Walden; a paper on primæval man in the valley of the Lea, by Mr. Worthington Smith; and a paper on the deer of Epping Forest, by Mr. Harting. Apart from a succession of papers such as these, it is scarcely necessary to remind readers of NATURE of such excellent special work as Prof. Meldola and Mr. White's report on the East Anglian earthquake of April 1884, published by the Society. There are few associations in the United Kingdom which perform so adequately and thoroughly the proper functions of a local Field Club or Naturalists' Society, as the Essex Field Club.

EARTHQUAKES are reported from Travnik, in Bosnia, where a shock, lasting for five seconds, and followed by two others, was felt on March 22, about 3 a.m. On March 23 three shocks were noticed about 11.15 a.m. at Campfer and St. Moritz (Grisons). At Stuttgart, on March 25, about 4 a.m., a perpendicular shock was felt in the direction from west to east, followed by oscillations continuing for ten seconds. At Savona, in Italy, an earthquake was noticed about the same time. According to a telegram from Aden, dated the 5th inst., shocks of earthquake had been repeatedly felt there during the previous four days, but no damage had been reported.

MR. EDWARD WOODS, President of the Institution of Civil Engineers, will give a *conversazione* on Wednesday, May 25 (Derby Day). It will take place in the South Kensington Museum by permission of the Lords of the Committee of Council on Education.

THE semi-centennial anniversary of the University of Louisville was celebrated on March 2. The doctorate address on the occasion was delivered by Dr. David W. Yandell, who offered some interesting reminiscences of teachers of medicine in the University. When the institution was founded, it was the fourth medical school west of the Alleghanies. "There are as many schools now in Louisville alone," said Dr. Yandell, "as were then in all the territory which extended from the Ohio River to the Pacific Ocean." Dr. Yandell claimed on behalf of the University that it is "a school where practical medicine is taught in all its branches in a thorough, practical way." "It points to its record with becoming pride, and finds there its guerdon and its hope for the future."

ON April 1 the fine Botanic Garden of Glasgow passed from the hands of the shareholders of the Royal Botanic Institution into the possession of the Corporation of Glasgow. The Garden was founded in 1816. Shortly after this date the Botanic Institution received a Royal Charter, and in consideration of the importance of the teaching of botany in the University, as well as for the general encouragement of the study of this science, a sum of 2000*l.* was granted from the Treasury. A further sum of 2000*l.* was advanced by the University of Glasgow, on condition that special facilities should be given to the Professor of Botany in the University for teaching his science; and it need hardly be said that from this point of view the maintenance of the Garden is of primary importance. The financial history of the Garden has at no time been fully satisfactory, and the Institution has at the end of seventy years found itself in the position of a debtor to the Corporation to the extent of 46,000*l.* The greater part of this sum has been expended in recent years in the erection of fine conservatories, which, in point of condition and extent, place the Garden at the head of provincial establishments. The collections of plants date back to the foundation of the Institution, but the bulk of them have been acquired within the last ten years, very large and valuable donations having been received from Kew, Edinburgh, and Glasnevin, while large contributions have also been made by the leading growers throughout the country. Owing to peculiar municipal complications, following on the totally unexpected rejection of a Bill in Parliament for the annexation of Hillhead and Kelvinside to the city of Glasgow, by a Committee of the Lords, after it had passed through the House of Commons, it is as yet uncertain what line of action the Corporation may adopt with regard to this valuable property which has fallen into their hands. It is in their power to disperse the collections, sell the fine and costly houses, and dispose of the twenty-three acres of land for building-purposes. This course would be deplored not only by the citizens of Glasgow, who would thus lose for ever a most picturesque open space, but also by all who are interested in the botanical progress of the country. Were the establishment maintained on its present footing as a Botanic Garden, the Corporation would do credit to itself, and would materially assist in the advance of that which has always been the most generally popular of the sciences. Already the Corporation has shown that it is disposed to further botanical science by admitting students of the University to the Gardens under certain conditions, while the gates are locked to the general public. It is earnestly to be hoped that this may be the first step towards a permanent policy of encouragement of the study of botany in one of the most densely populated centres in the United Kingdom.

SOME of the American whitefish (*Coregonus albus*) turned into the waters of the Marquess of Exeter at Burghley Park a year ago, were lately caught. They were 7 inches long. This is important evidence as to their adaptability to English waters. The National Fish-Culture Association are incubating a large quantity of the ova of this species for acclimatisation purposes.

SINCE 1878 the Ontario and Western Railway Company has been engaged in re-stocking streams in America within the area of its route. Mr. J. C. Anderson, general freight and passenger agent of the Company, writes to the *American Angler* to the effect that, within the past nine years, 2,220,000 trout have been planted by the Company in the Beaverkill, Willowemoc, Neversink, the east and west branch of the Delaware, and their tributaries.

WE have received vols. xxxix. and xl. of the Proceedings of the Literary and Philosophical Society of Liverpool, containing the principal papers read to the Society during the Sessions 1884–85 and 1885–86. Among the papers of scientific interest in vol. xxxix. are: "Observations on the Nematocysts of *Hydra fusca*," and "The Relationship of Palæontology to Biology," by Mr. R. J. H. Gibson; "On a New Organ of Respiration in the Tunicata," and other papers, by Dr. W. A. Herdman; two papers on "Technical Education," by Mr. F. H. Edwards; "The Armorial Bearings of the Isle of Man, their Origin, History, and Meaning," by Mr. John Newton, and "On the Rocky Mountain Goat," by Mr. T. J. Moore. Vol. xl. contains an address on "Modern Scientific Theories of Man," by the President, Dr. William Carter; "Two Curious Papyri in the Khedivial Museum," by Mr. R. L. Benas; "Recent Locust Plagues in Cyprus and North America," by Dr. Nevins; and "Report on a Successful Importation of Living Soles to the United States," by Mr. T. J. Moore. With vol. xl. is bound "The First Report upon the Fauna of Liverpool Bay and the Neighbouring Seas," written by the members of the Liverpool Marine Biology Committee, and edited by Dr. W. A. Herdman.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus* ♂ ♂) from India, presented respectively by Mr. W. Spooner and Mr. F. A. Adeney; a Purple-faced Monkey (*Semnopithecus leucoprymnus* ♂) from Ceylon, presented by Mr. W. H. Markham; a Black-tailed Godwit (*Limosa ægocephala*), British, presented by Mr. Robert Barclay; a Common Guillemot (*Lomvia troile*), British, presented by Mr. Howard Bunn; a Ring-hals Snake (*Sepedon hæmachates*) from South Africa, presented by Mr. W. L. Holms; a Pinche Monkey (*Midas œdipus*) from Central America, deposited; two Blue-bonnet Parrakeets (*Psephotus hæmatogaster*) from Australia; two Blue-crowned Conures (*Conurus hæmorrhous*) from Brazil, purchased; two Viscachas (*Lagostomus trichodactylus*) born in the Gardens.

OUR ASTRONOMICAL COLUMN

BARON D'ENGELHARDT'S OBSERVATORY.—Baron D'Engelhardt has recently published the first volume of the results of the astronomical observations obtained at his private observatory in Dresden. At first the observatory was erected in the Rue Leubnitz, but was found to be too far from the dwelling-house, and in 1879 the present edifice was erected in the Rue Liebig, close to the Baron's residence, with which it is connected by a covered gallery. The observatory is very completely fitted up. The principal instrument is a fine equatorial by Grubb of 12 inches aperture, replacing one of 8 inches which had been erected in the first observatory. There are two sidereal clocks, a chronograph, a transit-instrument of the bent form, which replaces one by Cook, a very complete Repsold micrometer, and two comet-seekers of special construction. The conduct of the screw of the Repsold micrometer has been very carefully investigated and the inquiry occupies a dozen pages. The observations are principally micrometer measures of nebulæ and star-clusters; but besides these there are very many observations of comets and minor planets, of the phenomena of Jupiter's satellites and of the new stars in the great nebula of Andromeda and near χ_1 Orionis, besides meridian observations of the moon and culminator stars. The volume, which is a very handsome one, contains four plates representing different parts of the observatory. The geographical position of the centre of the transit-instrument is given as lat. = 51° 2′ 19″ N., and long. = 0h. 54m. 54·74s. East from Greenwich.

NEW RED STAR.—Circular No. 16 of the Liverpool Astronomical Society states that on the nights of March 23 and 27 a red star, 7·5 magnitude, was observed 5s. *f* and 3′ *s* of 26 Cygni. There is no star in the D.M. at this place. The spectrum of the new star is a fine specimen of type III. Place of 26 Cygni for 1887, R.A. 19h. 58m. 9s., Decl. 49° 46′·9 N.

THE PARALLAX OF Σ 1516.—It appears, from the researches of M. O. Struve on the relative motion of the components of this double star, that the fainter star does not participate in the proper motion of the brighter component, and that they therefore, in all probability, constitute a merely optical pair without physical connexion. Herr Berberich, from a discussion of a series of measures of distances made by Prof. Winnecke, found the relative parallax of the brighter star, compared with the fainter component, to be 0″·199 ± 0″·05 (*Astron. Nachr.*, No. 2624). Recently, Dr. L. de Ball has made a series of observations with the equatorial of the Cointe Observatory at Liège, extending from 1885 April to 1886 June, for the purpose of determining this quantity. From sixty-seven observations of relative position-angle he finds π = 0″·091, and from sixty-four observations of relative distance, π = 0″·112, and combining these according to their respective weights, π = 0″·104, with mean error ± 0″·008.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 APRIL 10–16

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on April 10

Sun rises, 5h. 18m.; souths, 12h. 1m. 21·4s.; sets, 18h. 45m.; decl. on meridian, 7° 56′ N.: Sidereal Time at Sunset, 8h. 0m.

Moon (at Last Quarter on April 15) rises, 20h. 34m.*; souths, 1h. 47m.; sets, 6h. 50m.; decl. on meridian, 11° 44′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	4 42	10 30	16 18	3 8 S.
Venus	6 15	13 59	21 43	18 32 N.
Mars	5 25	12 14	19 3	8 47 N.
Jupiter	19 44*	0 51	5 58	10 55 S.
Saturn	9 46	17 55	2 4*	22 28 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

GEOGRAPHICAL NOTES

MR. GEORGE GRENFELL has recently made a successful ascent of the great Quango tributary of the Congo. In company with Mr. Bentley, in the steamer *Peace*, he succeeded in reaching the Kikunji Falls, the point at which Major von Mechow, descending the Quango from the south, was obliged to turn back in 1880. About six miles above the junction of the Kasai and the Quango they found another large tributary, the Djuma, entering the river from the east, which presented so great a volume of water that it was a matter of uncertainty which was the larger stream. A little beyond this the course of the Quango veered round, first south-south-west, and then west; at 4° 30′ S. lat. it had come back to its usual northerly course, and maintained it for the remainder of the journey. The Kikunji Falls (5° 8′ S. lat.) are about 3 feet high, and though insurmountable to the *Peace*, are said by Mr. Grenfell to be no obstacle to communication by canoes and small craft.

IN a letter from the Rev. W. G. Lawes, dated Port Moresby, January 20, it is stated that an Expedition is being equipped under the leadership of Mr. Vogan, the Curator of the Auckland Museum, with the intention of attempting, as soon as the rainy season was over, to cross South-East New Guinea, from Freshwater Bay to Huon Gulf.

THE April number of the Proceedings of the Royal Geographical Society is largely devoted to papers on Central Asia. First we have Mr. Delmar Morgan's account of Prjevalsky's journeys and discoveries in Central Asia. Mr. Morgan also contributes a translation in abstract of a recent lecture by M. Potanin on his journey in North-Western China and Eastern Tibet, which is followed by an account of the travels of Messrs. James, Younghusband, and Fulford in Northern and Eastern Manchuria. In this last will be found some welcome details concerning of the country not previously described.

ACCORDING to Dr. Hans Schinz, who has been recently in the Lake Ngami region, that lake is not dried up, though its dimensions are gradually decreasing. The River Okovango forms an extensive marsh on the north-west, which sends very little water a part into the lake during the dry season.

IN a paper by Dr. Ochsenius in the *Zeitschrift* of the Berlin Geological Society, on the age of certain parts of the South American Andes, are some details of geographical and ethnological interest. The author believes that the South American Cordilleras, or at least a portion of them, are no older than the Quaternary (as contrasted with the certainly older coast Cordilleras), and infers, therefore, that Lake Titicaca and the surrounding region must have been raised to its present elevation of about 13,000 feet within the historical period. Dr. Ochsenius therefore maintains that the enormous ruins of the old Inca city Tihuanaco on that lake admit of no other explanation than that these colossal monoliths were not worked at their present elevation, far less transported thither; it is incredible that the highly civilised Incas would have located their emporium on a tableland now almost uninhabitable. The author supports his conclusions by the fact that representatives of the Pacific fauna still live in Lake Titicaca.

NEWS of Herr G. A. Krause, who is now investigating the district between the Gold Coast and Timbuctoo, has reached Berlin. The traveller arrived at Woghodogho, the capital of Mosi, in October 1886. He obtained permission from the King of Mosi to continue his journey in a northerly direction to Duensa, on his way to Timbuctoo. He hoped to reach the former place in seventeen or eighteen days, to arrive at Sarafaram in four or five days more, and then to descend the Niger to Kabara, the port of Timbuctoo. Herr Krause describes the country between Salanga and the capital of Mosi as being perfectly plain at first, and then followed by a district of low hills and another plain. A day's journey north of Walawala, the traveller crossed the Upper Volta, the source of which lies probably in a north-easterly direction.

ON CERTAIN MODERN DEVELOPMENTS OF GRAHAM'S IDEAS CONCERNING THE CONSTITUTION OF MATTER[1]

II.

A QUARTER of a century has elapsed since Graham formulated his conceptions concerning the constitution of matter. I wish now to indicate, as briefly as may be, how these conceptions have developed during these five-and-twenty years.

The idea of the essential unity of matter has a singular fascination for the human mind. It may be that it has its germ in the persistency with which every mind, even that of a child, seeks to get at first principles. The most superficial reader of the history of intellectual evolution cannot fail to perceive how greatly it has modified and directed the development of scientific thought. The whole course of chemistry, for example, has been controlled by this fundamental conception. The half-educated student of to-day may smile at the notion of the transmutation of the metals which held such sway over the minds of the early alchemists, but the men who followed this "*Ignis fatuus*" with weary faltering steps, and who frequently sank under the burden of disappointed hope and the sense that to them it was not given to know the light, felt that this idea rested on a rational basis. They, like we, could give a reason for the faith that was in them. And yet no article of scientific doctrine has in these later times suffered greater vicissitude. Men's ideas concerning the essential unity of things must have received a rude shock when it was found that such a thing as water was not only complex, but was made of bodies strangely contrasted in properties; that the air was still less simple in composition; and that, as it appeared, almost every form of earth could, by torture, be made to give up some dissimilar thing. The brilliant discoveries of Davy, which made the early years of this century an epoch in the history of science, seemed to open out a vista to which there was no conceivable ending. The order of things was not towards simplification: it tended rather towards complexity. And yet Davy himself seemed unable or unwilling to push his way along the path of which the world regarded him as the pioneer. It may be that he was unable to shake himself free from the domination of the schoolmen, or that he unconsciously felt the truth of the principles to which his own discoveries seemed opposed. It is difficult otherwise to account for the tardiness with which he accepted the hypothesis of Dalton; even to the last the Daltonian atom had nothing distinctive to Davy beyond its combining weight. Davy never wholly committed himself to a belief in the indivisibility of the atom: that indivisibility was the very essence of Dalton's creed. In arguing with a friend concerning the principle of multiple proportion, Dalton would clinch the discussion by some such statement as "Thou knows it must be so, for no man can split an atom." Even Thomas Thomson, whom I have already characterised as the

[1] The Triennial "Graham Lecture," given in the Hall of the Andersonian Institution, Glasgow, on March 16, by Prof. T. E. Thorpe, F.R.S. Continued from p. 524.

first great exponent of Dalton's generalisation, was torn by conflicting beliefs until he found peace in the hypothesis of Prout and Meinecke that the atomic weights of all the so-called elements are multiples of a common unit, and which he sought to establish by some of the very worst quantitative determinations to be found in chemical literature. It is curious to note the bondage in which the old metaphysical quibble concerning the divisibility or indivisibility of the atom held the immediate followers of Dalton. Graham, however, never felt such trammels. To him the atom meant something which is not divided: not something which cannot be divided. With Graham, as with Lucretius, the original atom may be far down.

Every philosophic thinker to-day has, I should imagine, come to be of this opinion. Not many years ago it was the fashion to maintain that Stas's great work had for ever demolished the doctrine of the primordial *ylé*, and that Roger Bacon's aphorism that "barley is a horse by possibility, and wheat is a possible man, and man is possible wheat," was henceforth an idle saying. Stas's work is a monument of experimental skill, and it has furnished us with a set of numerical ratios which are among the best determined of any physical constants. It may be that it demolished Prout's hypothesis in its original form, but it has not touched the wider question. Whether indeed the wider question is capable of being reached by direct experiments of the nature of those of Stas is very doubtful, unless the weight of the common atom is some very considerable fraction, say one-half or one-fourth, of that of the hydrogen atom. Dumas has, as you know, modified Prout's hypothesis in this sense, by assuming as the common divisor half the atomic weight of hydrogen, but there is no *a priori* reason why we should stop at this particular subdivision. The exact relation of Stas's work to Prout's law has, I think, been fairly stated by Prof. Mallet at the conclusion of his admirable paper on the atomic weight of aluminium, in the Philosophical Transactions for 1880 (vol. clxxi. 1033). Stas's main result, says Mallet, "is no doubt properly accepted if stated thus, that the differences between the individual determinations of each of sundry atomic weights which have been most carefully examined are distinctly less than their difference, or the difference of their mean from the integer which Prout's law would require. But the inference which Stas himself seems disposed to draw, and which is very commonly taken as the proper conclusion from his results, namely, that Prout's law is disproved, or is not supported by the facts, appears much more open to dispute. It must be remembered that the most careful work which has been done by Stas and others only proves by the close agreement of the results that fortuitous errors have been reduced within narrow limits. It does not prove that all sources of constant error have been avoided, and, indeed, this never can be absolutely proved, as we never can be sure that our knowledge of the substances we are dealing with is complete. Of course, one distinct exception to the assumed law would disprove it, if that exception were itself fully proved, but this is not the case. As suggested by Marignac and Dumas, anyone who will impartially look at the facts can hardly escape the feeling that there must be some reason for the frequent recurrence of atomic weights differing by so little from accordance with the numbers required by the supposed law." Prof. Mallet, in tabulating the atomic weights which may be fairly considered as determined with the greatest attainable precision, or a very near approach thereto, and without dispute as to the methods employed, points out that out of the eighteen numbers so given ten approximate to integers, within a range of variation less than one-tenth of a unit. And he then proceeds to calculate the degree of probability that this is purely accidental, as those hold who carry to the extreme the conclusions of Berzelius and Stas, and he finds that the probability in question is only equal to 1 : 1097·8. And he concludes that not only is Prout's law not as yet absolutely overturned, but that a heavy and apparently increasing weight of probability in its favour, or in favour of some modification of it, exists, and demands consideration.

It would be impossible for me to attempt to traverse the whole ground of this question which has been opened up during the past fifteen or twenty years. Even if I could claim the time and your indulgence, there is hardly the necessity for such a demand on your patience. Mr. Crookes, only so recently as September last, gave an admirably complete exposition of the present state of the case in his address to the Chemical Section of the British Association at the Birmingham meeting, and for me to go over the ground again with you would be simply to plough with Mr. Crookes' heifer. Some years ago Mr. Norman Lockyer, as you doubtless know, approached the subject from another point of view, and in his recent work, "The Chemistry of the Sun," you will find a summary of the evidence which the spectroscope has afforded us concerning the dissociation of "elementary" matter at such transcendental temperatures as we have in stars like the sun.

Now, when we pass in review all this evidence; when we reflect upon the mode of distribution of the elements, and especially their tendency to associate in correlated groups; when we bear in mind the absolute analogy which exists in the general behaviour and mode of action of the radicles which are confessedly compound with those which are assumed to be simple; when we have regard to the phenomena of allotropy, isomerism, and homology,—the mind insensibly appeals to the principle of continuity, and refuses to believe that the seventy and odd "elemental" forms, to which our processes of analysis have reduced all the kinds of matter we see around us, differ in essence from bodies which are known to be compound.

The connexion between the properties of the "elements" and the relative weights of their atoms, as developed by Newlands, Mendelejeff, Lothar Meyer, Carnelley, and others, has served to strengthen this conviction. The discovery that the physical and chemical properties of the elements are as periodic functions of their atomic weights, is unquestionably the most important generalisation we have had in chemical philosophy during the last five-and-twenty years. Its bearings upon the question of the origin of the "elements" have been worked out in the Presidential address I have already referred to. Mr. Crookes, like Mr. Lockyer before him, in seeking to apply to this question of the genesis of the elements the same principles of evolution which Laplace has already applied to the creation of the heavenly bodies, and which Lamarck, Darwin, and Wallace have applied to that of the organic world, is again appealing to the law of continuity. The mind which holds that Nature is one harmonious whole is fain to believe that the probability that the elements have originated by chance and are eternally self-existent is just as remote as that the animals and plants of to-day are primordially created things. I think in what I am now saying I may fairly claim to be reflecting the opinion on this matter of every philosophic thinker of to-day. Nay more, you must allow that the germ which has been kept alive for so many centuries, and which has come down to us through the brains of a succession of thinkers like Leucippus, Aristotle, Lucretius, Bacon, Newton, Dalton, and Graham, has become quickened and endowed by the light which modern science has shed upon it from all sides, with a vitality which will persist and strengthen.

Having thus traced the development of the idea held by Graham of the essential oneness of matter, let us spend the few remaining moments in considering, in the most general way, how the science of the last twenty-five years has worked out and extended his conceptions concerning the properties of the atom and its mode of motion.

The treatment which "the few grand and simple features of the gas," to quote Graham's phrase, have received at the hands of Clausius, Clerk Maxwell, Helmholtz, Sir William Thomson, and a score of workers in this country and on the Continent who have been actuated by their influence, has served to dispel much of the metaphysical fog which has enshrouded the notion of the atom, and to-day we are able to reason about atoms, as physical entities, having extension and figure, and of their number and dimensions and peculiarities of movement, with the confidence which is based on well-ascertained facts.

We have, of course, not yet attained to a complete molecular theory of gases. But we know the relative masses of the molecules of various gases, and we have calculated in miles per second their average velocity. The phenomena of diffusion indicate that the molecules of one and the same gas are all equal in mass. For, as was pointed out by Clerk Maxwell, if they were not, Graham's method of using a porous septum would enable us to separate the molecules of smaller mass from those of greater, as they would stream through porous substances with greater velocity. We should thus be able to separate a gas, say hydrogen, into two portions, having different densities and other physical properties, different combining weights, and probably different chemical properties of other kinds. As no chemist has yet obtained specimens of hydrogen differing in this way from other specimens, we conclude that all the molecules of hydrogen are of sensibly the same mass, and not merely that their mean mass is a statistical constant of great stability (see art. "Atom," "Encyclopædia Britannica," 9th edition). This line of argument has, it seems to me, an important bearing upon a question which has been raised by Marignac, Schutzenberger, and others, and which has again been raised by Mr. Crookes in the address I have already referred to. Mr. Crookes thinks that it may well be questioned whether there is an absolute uniformity in the mass of every ultimate atom of the same chemical element, and that it is probable that our atomic weights merely represent a mean value, around which the actual atomic weights of the atoms vary within certain narrow limits, or in other words that the mean mass is a statistical constant of great stability. The facts of diffusion would seem to lend no support to such a supposition.

Graham was still living when Loschmidt published what Prof. Exner calls his "epoch-making paper" on the "Size of the Air Molecule." Although the numerical estimate which Loschmidt deduced from the mean free path of the molecules and their volume has now only an historical interest, it has exercised a profound influence on the development of molecular physics in demonstrating that in dealing with molecules we are dealing with masses of finite dimensions, and further that these dimensions are by no means immeasurably small. The very manner in which Loschmidt stated his conclusions was well calculated to rivet attention. He showed that these magnitudes, small as they are, are yet comparable with those which can be reached by mechanical skill. The German optician Nobert has ruled lines on a glass plate so close together that it requires the most perfect microscopes to observe the intervals between them; he has drawn, for example, as many as 4000 lines in the breadth of a millimetre, that is about 112,000 lines to the inch. Now, if we assume, with Maxwell, that a cube whose side is 1/4000 of a millimetre is the smallest volume observable at present, it would follow that such a cube would contain from 60 to 100 millions of molecules of oxygen or nitrogen, and if we further assume that the molecules of organised bodies contain on an average 50 "elementary" atoms it further follows that the smallest organised particle visible under the microscope contains about two million molecules of organic matter. And as at least half of every living organism is made up of water, we arrive at the conclusion that the smallest living being visible under the microscope does not contain more than about a million organic molecules. I could have wished, had time permitted, to have dwelt a little upon the intensely interesting questions which such a conclusion at once raises. In the article "Atom" in the present edition of the "Encyclopædia Britannica," from which I have quoted, you will find Clerk Maxwell points out its relation to physiological theories, and especially to the doctrine of Pangenesis. Molecular science, says Maxwell, "forbids the physiologist from imagining that structural details of infinitely small dimensions can furnish an explanation of the infinite variety which exists in the properties and functions of the most minute organisms."

In the year following Graham's death Sir William Thomson still further developed the modes of molecular measurement, and from a variety of considerations based upon the kinetic theory of a gas, upon the thickness of the films of soap-bubbles, and from the electrical contact between copper and zinc, he arrived at estimates which, although sensibly different from that of Loschmidt, are still commensurable with it. In a subsequent lecture to the Royal Institution, given about four years ago, he extended the lines of his argument and arrived at the conclusion that in any ordinary liquid, transparent solid, or seemingly opaque solid, the mean distance between the centres of contiguous molecules is less than 1/5,000,000 and greater than 1/1,000,000,000 of a centimetre. And in order to give us some conception of the degree of coarse-grainedness implied by this conclusion he asks us to imagine a globe of water or glass as large as a football to be magnified up to the size of the earth, each constituent molecule being magnified in the same proportion. The magnified structure would be more coarse-grained than a heap of small shot, but probably less coarse-grained than a heap of footballs (NATURE, vol. xxviii. p. 278).

Here I think we may leave the subject, at all events for to-night. I am painfully conscious that I have left unsaid much that ought to have been said, and possibly said some things that might well have been left unsaid. But my main purpose will have been served if I have succeeded in indicating to you Graham's position as an atomist, and in showing you how his ideas respecting the constitution of matter have germinated, and, like the seed which fell upon good ground, have borne fruit an hundredfold.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 17.—"On the Total Solar Eclipse of August 29, 1886 (Preliminary Account)." By Arthur Schuster, F.R.S.

The instrument intrusted to me by the Eclipse Expedition was similar to that employed in Egypt during the eclipse of 1882. The equatorial stand carried three cameras, one of which was intended for direct photographs of the corona, while the two others were attached to spectroscopes.

Photographs of the Corona.—The lens had an aperture of 4 inches, and a focal length of 5 feet 3 inches; giving images of the moon having a diameter of about 0·6 of an inch.

During the first minute of totality the corona was covered by a cloud, which was, however, sufficiently transparent to allow the brightest parts of the corona to show on the ten photographs exposed during that time.

During the remaining time, that is to say, during about two minutes and a half, the sky was clear, but there were clouds in the neighbourhood of the sun.

The time of exposing the photographs which had been fixed beforehand had to be altered in consequence of the uncertainty of the weather, and for this reason I can only give the actual times of exposures very approximately and from memory. One photograph on sensitive paper shows only little detail; but three photographs on glass were obtained, which, as regards definition, I believe to be equal to those obtained in Egypt. The approximate exposures were 15 to 20 seconds, 10 to 15 seconds, and about 5 seconds.

With the view of possibly increasing the amount of detail which it has hitherto been possible to obtain on the photographs of the corona, I have, on this occasion, given considerable attention to the different adjustments, so as to fix the cause which at present limits the definition, and I have come to the conclusion that, if we are to obtain better photographs of the corona, we can only hope to do so by means of a better mechanical arrangement for moving the camera.

Photographs of the spectrum of the corona were obtained by means of two instruments, one being identical with that employed at Caroline Island in 1883. This spectroscope has two prisms of 62° refracting angle, the theoretical resolving power being about 10 in the yellow. (The unit of resolving power is the resolving power which allows of the separation of two lines differing by the thousandth part of their own wave-length.) The slit of this spectroscope was placed so that it was tangential to the image of the sun formed by the condensing lens. One plate was exposed during the whole of totality. The results are good; a number of lines belonging to the prominences and to the corona are very distinct and can be measured with fair accuracy. The difficulty of measurement lies in the multitude of lines. I have measured at present between forty and fifty distinct corona lines between the solar lines F and H, and a number remain unmeasured.

A comparison between the photographs of 1882 and 1886 shows that, although the lines seem to be in the same position, their relative intensity has greatly altered. The strongest corona line during the last eclipse had a wave-length of about 4232; it is slightly but distinctly less refrangible than the strong calcium line at 4226.

The second spectroscope had its slit placed so as to take a radial section of the corona. It had one large prism giving a theoretical resolving power of 11·4; slightly larger therefore than the two-prism spectroscope.

The film was one prepared by Capt. Abney so as to be more sensitive in the green than the ordinary plates.

The photograph obtained is faint, but I believe will ultimately give good results.

A good drawing of the corona was obtained by Capt. Maling at the station occupied by Capt. Darwin and myself.

The plates were prepared by Capt. Abney, whose valuable help I have had in the whole of the preliminary arrangements.

March 24.—"Preliminary Note on the 'Radio-Micrometer,' a New Instrument for measuring the most Feeble Radiation."[1] By C. Vernon Boys.

The author considered that, if the thermo-electric power of a

[1] I have learnt that an instrument essentially the same in principle as the radio-micrometer was made and shown by M. D'Arsonval to the French Physical Society; it is hardly necessary to say that I was not aware of this before reading the paper.—C. V. B.

junction were properly utilised, a more sensitive instrument would be made than the bolometer, which depends on the change of resistance of a conducting filament with temperature. After showing the defects of the ordinary thermopile, he explained the construction of his instrument. A circuit is made of one turn of 1 square centimetre, of which three sides are thin copper wire, and the fourth is a compound bar of antimony and bismuth, each piece being $5 \times 5 \times \frac{1}{6}$ mm., soldered edge to edge. This circuit is supported by a thin rod, to which is fastened a mirror, and the whole is hung by a torsion fibre, so that the circuit is in the field produced by a powerful magnet with suitable pole pieces.

When radiant energy falls on the centre of the bar, the circuit is deflected, and the amount of the deflection measures the energy. The instrument supplies the most delicate means of detecting radiant heat yet made. For instance, the particular instrument made by the author—having proportions which he now knows to be not the best, and with the keeper on the magnet, so that the field was one of 100 units only—was capable of showing the heat which would be cast on a halfpenny by a candle-flame at a distance of 1168 feet, and as the sensibility is proportional to the strength of the field, it would be fully ten times as sensitive with the keeper off.

By calculation it may be shown that an instrument made with certain given proportions, which are easily obtainable, would be capable of showing a change of temperature of the junction of 1/100,000,000 of a degree of heat.

The author also showed a motor consisting of a cross of metal, the centre being antimony and the arms bismuth, to the ends of which are soldered four copper wires, whose free ends are joined by a ring of copper which rotates rapidly when the spark at the end of a blown-out match is held near it.

If the spark is held on the right-hand side of the north pole, the motor will start itself oscillating through angles which increase until it at last begins to revolve, which it will do indifferently in either direction. If the spark is held on the left-hand side, the motor at once stops.

This is interesting in that it is an electro-magnetic motor which goes, having neither sliding nor liquid contacts.

The author promises, shortly, a complete paper in which the best proportions for the various parts are given, and to show an instrument in which these proportions are employed.

Geological Society, March 23.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—Notes on the structure and relations of some of the older rocks of Brittany, by Prof. T. G. Bonney, F.R.S. These notes are the results of a visit to some of the more interesting geological sections in Brittany, in the autumn of last year. The author is greatly indebted for information to the Rev. E. Hill, who took part in the summer excursion of the Société Géologique de France, and to Dr. Charles Barrois, who has for long been engaged in investigating the geology of Brittany. (1) The author briefly noticed the glaucophane-amphibolites and the associated schists of the Ile de Groix, which have been already admirably described by Dr. C. Barrois. (2) The next part of the paper treated of sections in the district about Quimperlé. (3) In this part of the paper were noticed the crystalline rocks of Roscoff, and (more briefly) the Palæozoic strata about Morlaix, with the mineral and structural modifications due to pressure and to the action of intrusive igneous rocks. The author pointed out that, in the latter case, the results either of pressure-metamorphism or of contact-metamorphism differ much from the crystalline schists, which, both in Brittany and elsewhere, are regarded as of Archæan age; and that here in the north at Roscoff, we have a series of banded gneisses, less modified by subsequent pressure than in the south, the structures of which are very difficult to explain on any theory of a "rolling out" of a complicated association of igneous rocks, but which are such as would naturally result from some kind of stratification of the original constituents. The result of the author's work is to strengthen the opinion which he has already expressed, that while the structures of some foliated rocks may be regarded as primarily due to pressure operating on suitable materials, the structure of others seems opposed to this explanation. At any rate the latter rocks appear to have assumed a crystalline condition with a semblance of stratification in Pre-Cambrian times; so that, whatever may be their genesis, they are rightly called Archæan gneisses and schists.—The rocks of Sark, Herm, and Jethou, by Rev. E. Hill.—In opening the discussion which took place after the reading of these papers, the President remarked on the value attaching to Prof. Barrois's work in Brittany, and on the interest of the observations made on the country by Prof. Bonney. The conclusions as to the Archæan age of the lower gneissose rocks would probably be generally accepted; but a question which must still be regarded as an open one was, whether foliation ever corresponded with original bedding. The supposed instances of unconformity and current-bedding depended on the assumption that such was the case. Mr. Becker, Mr. Rutley, and Dr. Hicks, also took part in the discussion.—Quartzite boulders and grooves in the Roger Mine at Dukinfield, by Mr. James Radcliffe. The statements made in this paper were discussed by Mr. W. W. Smyth, Prof. Boyd Dawkins, Mr. Blanford, and Prof. Bonney.

Royal Microscopical Society, February 9.—Annual Meeting.—Dr. Dallinger was re-elected President for the fourth time. We have already printed the remarks made by Dr. Dallinger in his annual address on the value of the new apochromatic lenses. Having dealt with this subject, he proceeded to record the results of experiments as to the changes of temperature to which the lower forms of organisms can be adapted by slow modifications. For nearly seven years continuous experiments and observations were made, with the result that several organisms had gradually become adapted to live and thrive under a high temperature. Commencing at the normal temperature of 60° F., the first four months were occupied in raising the temperature 10° without altering the life-history. When the temperature of 73° was reached, an adverse influence appears to be exerted on the vitality and productiveness of the organisms. The heat being left constant for two months, they regained their full vigour, and by very gradual stages of increase 78° was reached in five months more. Again a long pause was necessary, and during the period of adaptation a marked development of vacuoles was noticed, which again disappeared when it was possible to raise the temperature farther. The farther history of the experiments presented practically the same features—long pauses, vacuolation, slow advance—until at last the high temperature of 158° F. was reached, when the research was accidentally terminated. It is because it is so difficult to observe the effects of changes through a sufficient number of generations of larger animals that results obtained on the simpler forms are so valuable. Darwin distinctly insisted on the slowness of the process of adaptation. The organisms examined by Dr. Dallinger are incessantly multiplying by dividing, the longest interval being four minutes: half a million generations must therefore have been observed, giving the "countless generations" required. At the end of the series the organisms were found to be fully adapted to a change in the essential condition of life, sufficient to produce death originally.

March 9.—Mr. W. T. Suffolk, Vice-President, in the chair.—Mr. E. C. Bousfield exhibited photomicrographs of *Amphipleura pellucida*, to show what may be expected from the employment of Prof. Abbe's new lenses. The objective employed was a very fine 1/8 apochromatic homogeneous-immersion 1·4 N.A. He also exhibited photomicrographs of salicine crystals as viewed by polarised light, and the colours were purposely selected to test as severely as possible the capacity of the plate used—a Dixon's orthochromatic.—Dr. Crookshank exhibited two photomicrographs of flagellated Protozoa of the blood. These were taken with Zeiss's 1/18 homogeneous-immersion from a preparation stained with magenta. The amplification (1750) was obtained by enlargement from the original negatives. They illustrated the employment of the Eastman bromide paper, and the value of photomicrographs for teaching purposes. The flagella and the delicate longitudinal membrane were clearly demonstrated.—Mr. W. Watson exhibited and described the Watson-Draper microscope, which he had made on the designs of Mr. E. T. Draper. The microscope is an elaboration of the Watson-Crossley form, and the idea of the designer is "that when the object is on the stage, either it may be made to rotate in any direction, horizontal or vertical, round a fixed beam of light without the light ever leaving the object, or the stage may be kept fixed while the light is revolving round it in any direction, horizontal or vertical, always however remaining upon the object."—Mr. J. Mayall, Jun., described the Nelson model microscope exhibited by Mr. C. Baker.—Two papers were read: by Mr. G. Massee, on the differentiation of tissues in fungi; and by Drs. H. J. Johnston-Lavis and G. C. J. Vosmaer, on cutting sections of sponges and other similar structures with soft and hard tissues, and specimens of sections of sponges were exhibited of exceptionally large size.—An arrangement by Mr. W. A. Haswell was exhibited for mounting series-sections to the number of thousands on one disk for consecutive examination.

EDINBURGH

Royal Society, March 7.—Sir W. Thomson, President, in the chair.—The President read a third communication on the equilibrium of a gas under its own gravitation alone. He finds that a large part of his former conclusions has been anticipated by Mr. Homer Lane.—Sir W. Thomson also communicated a paper on Laplace's nebular theory, considered in relation to thermo-dynamics. In the light of thermo-dynamical principles, Laplace's theory is seen to be not a mere plausible hypothesis but a statement of actual fact.—Dr. Thomas Muir read part of a paper on the history of the theory of determinants, treating of authors from Hindenburg (1784) to Reiss (1829).—Dr. Muir also communicated papers on a class of alternating functions, and on the quotient of a simple alternant by the difference-product of the variables.—Mr. J. Aitken read notes on solar radiation, and on hoar-frost.—An account of researches on the influence of certain rays of the solar spectrum on root-absorption and the growth of plants, by Dr. A. B. Griffiths, was submitted by Prof. Crum Brown.

March 21.—Lord Maclaren, Vice-President, in the chair.—Prof. Nicholson read a communication on variations in the value of the monetary standard.—Mr. J. Y. Buchanan read a paper on ice and brine, and another on the distribution of temperature in the Antarctic Ocean.

PARIS

Academy of Sciences, March 28.—M. Janssen, President, in the chair.—On the calorimetric bomb and measurement of heats of combustion, by MM. Berthelot and Recoura. The improvements are described which have been made in this apparatus, originally invented by MM. Berthelot and Vieille for the purpose of measuring the heats of combustion of organic compounds. The method, already applied to slightly volatile substances and gases, may now be easily extended to all volatile compounds, and is consequently a universal method.—On aërial vortices, by M. D. Colladon. The author announces that he has succeeded in carrying out on a small scale the experiment alluded to in his note of March 3, demonstrating that in a fluid there may be set up a vortex with vertical axis and ascending movement.—On the variation of solubility of substances according to the amount of heat liberated, by MM. G. Chancel and F. Parmentier. The experiments here described show that to a solubility increasing with the temperature there does not necessarily correspond an absorption of heat, so that one of the relations established by M. Le Chatelier must be rejected.—Extracts from various reports of the local engineering service on the effects caused by the earthquake of February 23, communicated by the Minister of War. Among the results recorded at Nice were the fissures produced in the Barbonnet Hill running along its entire elevation almost vertically to the magnetic north pole.—The same earthquake as observed at Moncalieri, by M. F. Denza. The diagram is given which was traced by the seismograph (Cecchi system) at the Moncalieri Observatory.—On the latent heats of vaporisation of some very volatile substances, by M. James Chappuis. The process here applied to the study of the chloride of methyl, sulphurous acid, and cyanogen is based on the employment of the Bunsen calorimeter, by means of which may be determined with considerable accuracy the latent heats of ebullition at 0° under the maximum tension corresponding to the melting of snow. The mean results obtained were for the chloride of methyl, 96·9; sulphuric acid, 91·7; cyanogen, 103·7.—On the determination of the coefficient of self-induction, by MM. P. Ledeboer and G. Maneuvrier. The method here employed to determine this quantity consists of a new adaptation of those of Maxwell and Lord Rayleigh to a particular case in which the coefficient is too weak to produce an appreciable shock in the galvanometer. It possesses the advantage of dispensing with the use of the ballistic galvanometer, and of rendering possible the employment of an ordinary galvanometer with mirror.—A study of the alkaline vanadates, by M. A. Ditte. With a view to determining the place that vanadium should occupy in a classification of simple elements, the author here begins a study of the little-known metallic vanadates, taking first the vanadates of potassa: (1) VO_5,KO; (2) $2VO_5,KO$; (3) $3VO_5,2KO$, &c.—Double phosphate and arseniate of strontian and soda, by M. H. Joly.—On some ammoniacal combinations of the chloride of cadmium, by M. G. André. This subject, already treated by Croft and Hauer, is here resumed chiefly from the stand-point of the comparisons that it suggests between the three metals zinc, copper, and cadmium, whose oxides are soluble in ammonia.—Action of nitric acid on the solubility of the alkaline nitrates, by M. R. Engel.—On the metallic propionates, by M. Adolph Renard. Among the propionates here studied are those of aluminium, barium, calcium, cadmium, chromium, cobalt, copper, lithium, magnesium, manganese, lead, potassium, sodium, strontium, and zinc.—Age of the upheaval of the Montagne Noire, French Pyrenees, by M. A. Caraven-Cachin. This upheaval is regarded as comparatively recent, being referred to the beginning of the Upper Eocene. It is more recent than the profoundly dislocated Lutetian and Bartonian beds, but older than the Ligurian system.—On the dolmens of Enfida, Central Tunisia, by M. Rouire. For the first time a systematic description is given of this remarkable group of dolmens, about 800 of which are found concentrated in a space of some 250 hectares, disposed without any apparent order, at distances of from 10 to 50 metres from each other. All belong to a perfectly uniform type, consisting of a long horizontal slab resting on upright stones joined at right angles. Except in a few depressions of the ground, none are covered with heaps of earth or stones so as to form true mounds or barrows, and all that were examined had the entrance on the east or south-east side. Like those of Constantine (Algeria), they are all of small size, the vertical stones scarcely exceeding 1 metre in height, and varying from 0·20 to 0·25 metre in thickness. In the few that were opened, little was found except some human bones and very coarse pottery, now deposited in the Ethnographic Museum.

BERLIN

Physiological Society, March 11.—Prof. Munk in the chair.—Dr. A. Baginski communicated the results of his observations and experiments respecting acetonuria in children. He found that acetone was present in small quantities in the urine of healthy children, though not in all; and that in the case of fever attending any of a very wide range of diseases, the quantity of acetone present in the urine was increased. When children were affected with eclampsia, attended, as such disease mostly was, by serious disorders in the digestion, a larger proportion of acetone was regularly observed in their urine. In regard to the formation of acetone in the blood, experiments in feeding, on different sorts of animals, showed that it was not produced by carbo-hydrates, as might be conjectured from the composition, $CH_3—CO—CH_3$, but from the decomposition of albumen. A longer course of flesh food yielded a very considerable increase in the secretion of acetone, whereas during a course of feeding with farinose and fatty foods, the yield of acetone very rapidly declined, and at length ceased altogether. When a large deposit of albumen occurred in the animal body, after the period of lactation for example, no acetone was found in the urine, even though food rich in albumen was administered. No causal connexion between acetonous urine and eclampsia could be demonstrated either clinically or experimentally. In rhachitis, in which eclamptic attacks often occurred, no acetone was found in the urine, nor was the administration of large quantities of acetone, even though continued for a considerable length of time, found to produce any effect on the nervous system.—Dr. Frenzel produced a long series of zoological and anatomical preparations preserved in accordance with his method. The preparations were hardened by means of alcohol containing sublimate, and injected with glycerine. The glycerine injection was effected first with a more diluted and then with a more concentrated solution, to which a solution of sugar was added as an ingredient. The relative proportion of glycerine and sugar was determined by the nature of the object.—Dr. Blaschko demonstrated, by drawings and very beautiful microscopic preparations, the structure of the epidermis. Starting with the assumption that the final endings of the nerves of feeling must be sought in the layer of the epidermis and not in the cutis, he had studied the structure of the upper skin at the boundary between epidermis and cutis. He distinguished the main parts of direct feeling (the hairless parts of the skin) from the parts of indirect feeling (the hairy parts of the skin). The former possessed on the under side of the epidermis very beautifully developed grooves (*Leisten*) forming a reticular system with spiral longitudinal and transverse lines. The hairy parts of the skin were influenced in their structure by the hairs, which likewise stood in spiral series, and had but very indistinct reticulations in the intermediate spaces.

Physical Society, March 4.—Prof. von Helmholtz in the chair. —Dr. Pringsheim reported on a further research into the chemical action of light on mixed hydrogen and chlorine gas (*Chlorknallgas*). This investigation respected the peculiar inductive action of light observed by Bunsen and Roscoe, during which the formation of hydrochloric acid was not effected, although the mixture of chlorine and hydrogen absorbed light, and at all events became changed, seeing the further influence of the like quantity of light at the end of the induction produced a chemical combination of the gases. In a former research (*vide* NATURE, vol. xxxiii. p. 287), Dr. Pringsheim showed that during the inductive action of the light an increase of volume in the gas mixture took place. If by means of electric sparks he illuminated the gas mixture in a glass globe above water, and shut off by a water index, then, on subjection to the first and each following spark up to the fourth, there occurred each time only an increase of volume which rapidly passed away; with the fifth and following sparks the effect was an increase of volume succeeded by a diminution; the latter a proof that hydrochloric acid was now formed and absorbed by the water. The speaker demonstrated at length that the assumption of a thermic influence as the cause of the increase of volume was excluded. On the contrary, he argued, there could here be a case only of chemical change in the gas mixture. It was probably an intermediate condition we had here to deal with, which of course refused explanation from the contemplation of the two gases Cl and H. Seeing that aqueous vapour was also present in the glass globe, the part it played in the reaction was now examined, and the fact was established that its presence was absolutely indispensable in effecting the chemical light effect. Dry chlorine and hydrogen did not unite into hydrochloric acid under the influence of the light; or the process was in such a case effected only very slowly. In all probability, therefore, the induction would have to be explained on the ground that intermediate products with larger volume were formed from the molecules ClCl, HH, and HHO, products whose chemical nature it had not yet been possible to determine.—Prof. Neesen made some supplementary communications respecting the tuning-forks filled with quicksilver, and stated that they had been constructed at an earlier date by Herr König.—Prof. von Bezold described a simple method of presenting complementary colours by means of prism, lens, and a special screen.—Prof. Vogel produced three fluids in three flat phials—one yellow and two blue fluids—which he made use of in demonstrations regarding colour-mixture in order to dispel the belief which prevailed very largely amongst the public that yellow and blue when mixed yielded only green. Phial 1 contained "acid yellow" (*Säuregelb*); phial 2, solution of ammoniacal copper; phial 3, aniline blue. 1 and 2 superimposed on each other gave green; 1 and 3 a fiery red.

Chemical Society, February 14.—Prof. H. Landolt in the chair.—F. Tiemann gave an account of Kiliani's research, according to which arabinose-carboxylic acid has the same composition as gluconic and galactonic acids. Arabinose is regarded as an aldehyde of normal pentahydroxypentane.—Amongst the other papers may be mentioned:—A contribution to our knowledge of secondary and tertiary quinones, by R. Nietzki and F. Kehrmann.—Tetramidobenzene and its derivatives, by R. Nietzki and E. Hagenbach.—Substitution of the amido-group in aromatic compounds, by the groups SH and SO_3H, the change being effected by means of a new diazo-reaction, by P. Klason.—The six toluenedisulphonic acids, by the same.—The constitution of pyrene and its derivatives, by E. Bamberger and M. Philip.—The action of chlorine on acet-α-naphthalide, by P. T. Cleve.

February 28.—A. W. Hofmann, President, in the chair.—G. Kraemer gave an account of the work done by himself in conjunction with W. Böttcher on the constituents of mineral naphtha. They have examined naphthas from Tegernsee, Pechelbronn, and Oelheim, and find they consist of a mixture of hydrocarbons which are not acted on by concentrated sulphuric or nitric acid, and of such as are dissolved by the acids with formation of sulphonates and nitro-derivatives; also small quantities of acids. The indifferent hydrocarbons are distinguished by their low specific gravity; they constitute the greater portion of the naphtha, and they consist partly of paraffins and partly of hydrocarbons isomeric with the olefines; these are called naphthenes. The authors consider the non-aromatic hydrocarbons which are soluble in acid to be derived from the naphthenes by condensation, in the same way as naphthalene, anthracene, &c., are derived from benzenes. The authors also discuss the question of the origin of mineral naphtha.—Amongst the other papers may be mentioned:—J. W. Brühl, on J. Thomsen's theory of the heat of formation of organic substances.—C. Gottig, on a new hydrate of soda.—Claisen and Lowman, on a new method of producing benzoyl-acetic ether.—A. Piutti, synthesis of trimesic ether.

A NATURALIST IN SOUTH AMERICA[1]

Notes of a Naturalist in South America. By John Ball, F.R.S., M.R.I.A., &c. (London: Kegan Paul, Trench, and Co., 1887.)

II.

LEAVING Valparaiso, and steering southwards amongst the evergreen islands of the South Chilian Archipelago and Fuegia, Mr. Ball encountered all the disagreeables of those inhospitable and desolate regions, signalised by a fall of the barometer and thermometer, gales of wind, the rolling seas of a tempestuous ocean, fogs, and darkness. And here he observes (and the observation is new to us) that one of the main features of the Andes suffers a great change. The western chain, which runs for 900 miles as an almost continuous range of high land on the coast of Chili, from lat. 40° S. to the Straits of Magellan becomes separated from the range to the east of it by a broad belt of low country including several large lakes. Further south the chain first dips under the ocean, to emerge as the great Island of Chiloe and the Chonos Archipelago, after which it joins the continent again at Cape Tres Montes. Further south is the Gulf of Peñas, forty miles wide, beyond which are the famous channels that lead into the Straits of Magellan. The new geographical features are accompanied by a change of climate, and this again is marked by the appearance of many types of the so-called Antarctic (or rather Fuegian) flora, which may be traced northward from Fuegia to the Mountains of Valdivia, and some few of which types, profiting by the fogs of the desert region of the Andes, straggle northwards into Northern Chili. In Messier's Channel, lat. 50° S., the wild celery of Europe was found, of which Mr. Ball says: "Growing in a region where it is little exposed to sunshine, it has less of the characteristic smell of our wild plant, and the leaves may be eaten raw as salad, or boiled, which is not the case with our plant until the gardener, by heaping soil about the roots, diminishes the pungency of the smell and flavour." "The 5th of June," he goes on to say, "my first day in the channel, will ever remain a bright spot in my memory. Wellington Island, which lay on our right, is over 150 miles in length, a rough mountain range, averaging apparently about 300 feet in height, with a moderately uniform coast-line. On the other hand, the mainland presents a constantly varying outline, indented by numberless coves and several deep narrow sounds rnnning far into the recesses of the Cordillera. In the intermediate channels crowds of islands, some rising to the size of mountains, some mere rocks peeping above the water, present an endless variety of form and outline. That which gives the scenery a unique character is the wealth of vegetation that adorns this seemingly inclement region. From the water's edge to a height which I estimated at 1400 feet, the rugged slopes were covered with an unbroken mantle of evergreen trees and shrubs. Above that height the bare declivities were clothed with snow, mottled at first by projecting rocks, but evidently lying deep upon the higher ranges. I can find no language to give any impression of the variety of the scenes that followed in quick succession against the bright blue background of a cloudless sky, and lit up by a northern sun that illumined each new prospect as we advanced."

In another passage the scenery is compared to that of the Upper Lake of Killarney, where the evergreen beeches of Fuegia are represented by the arbutus; and where, Mr. Ball might have added, similar climatal features nurture a similar wild variety, profusion, and luxuriance of cryptogamic plants, mosses, ferns, and hepaticæ, and especially broad foliaceous lichens that grow nowhere else in the northern hemisphere in like number and variety. A further similitude between Fuegia and the south-west of Ireland may be traced in the rock-girt deep sounds that run far into the land of both, and which harbour a marine vegetation that has perhaps no parallel for variety, luxuriance, and beauty in their respective hemispheres.

The meeting with floating masses of glacier ice in Eyre Sound suggests some excellent remarks on the well-known phenomenon of the depression of the snow-line and of glaciers in this region, as compared with the northern hemisphere. Threading a devious course through the Straits of Magellan, Mr. Ball's enthusiasm rises to a white heat, that warms the land- and sea-scapes of the grim "Land of Desolation." In his eyes, Fuegia's midwinter glows with brilliant hues. It would make Magellan and Del Canot, Narbough and Davis turn in their coffins could they but read Mr. Ball's ecstasies over the features of the countries in which they starved and froze, and where so many of their ill-starred comrades left their bones, after their bodies had endured incredible sufferings. No doubt we may attribute much of the rapture experienced by our traveller to the contrast which the luxuriant vegetation and picturesque scenery of Fuegia presented to the dismal sterility of the Peruvian and North Chilian coasts, and more to the keen interest which he took in the botany of the region. Still, though "Tantus amor florum" may account for a good deal, there is a large measure of beauty in the scenery of Fuegia that he has been the first to analyse, appreciate, and describe with truth and picturesqueness. Take his picture of Mount Sarmiento, for example, a mountain 7000 feet high. "Sole sovereign of these Antarctic solitudes, I know of no other peak that impresses the mind so deeply with a sense of wonder and awe. As seen from the north, the eastern and western faces are almost equally precipitous, and the broad top is jagged by sharp teeth, of which the two outermost—one to the east, the other to the west—present summits of apparently equal height." Speculating on its geological age, he considers it evident that it is not of volcanic origin, for that no volcanic rock can retain slopes so nearly approaching the vertical. He regards it as a portion of the original rock-skeleton that formed the axis of the Andean Chain during the long ages that preceded the great volcanic outbursts that have covered over the framework of the western side of South America, and that in the course of upheaval its flanks have been carved by marine action to the nearly vertical form which impresses the beholder.

[1] Continued from p. 531.

After a short stay at Sandy Point, a Chilian settlement at the eastern mouth of the Straits, Mr. Ball proceeded to Monte Video and Buenos Ayres, from whence he ascended the Uruguay River; and, passing Fray Bentos, the great factory of "Liebig's Extract of Beef," finally reached Paysandu, equally familiar to English housekeepers for its preserved tongues. This digression gave him a fair view of the aspect of the flora of a great extent of the Argentine Confederation, which, with its Pampas, Salinas, and riparian vegetation differs wholly from that of all the regions he had hitherto visited. For the Argentine Confederation he proposes the term "Argentaria," a good one, which will, we hope, be acceptable to biologists, and to geographers too.

Santos, in South Brazil, was the next point visited, and from there Mr. Ball took the rail to Sto. Paolo, and thence on to Rio de Janeiro. Here he is upon ground familiar to naturalists, and we need only allude to the singular speculation to which his observations on the geology of that part of Brazil, and his reading of the observations of others on the same subject, have given birth. After dwelling on the enormous area of Brazil occupied exclusively by granite and gneiss, and the extent and depth of the deposits of the disintegrated materials formed out of the same matrix, including 200,000 square miles of the plateau of Brazil, the Argentine Pampas, and Paraguay, he goes on to say: "To my mind the conclusion is irresistible that ancient Brazil was one of the greatest mountain regions of the earth, and that its summits may very probably have exceeded in height any now existing in the world." And it is these mountains which he regards as the probable birthplace of the chief types of the phanerogamous vegetation of South America. A few peculiar types, indeed, may have been developed in the Andes, but not such as have stamped their features on the vegetation of the continent. Mr. Ball further correlates this speculation with another as bold, which he gave to the Geographical Society in 1879 (Proceedings, p. 464), and which is, that the chief types of existing flowering-plants originated in the higher mountain regions of the globe "at a period when the proportion of carbonic acid gas present in the atmosphere was very much greater than it has been since the deposition of the Coal-measures." To discuss these novel ideas would be out of place here; but we must, in justice to our author's candour, add his avowal that he regards them "as having no claim to rank as more than probable conjectures, but that, as they rest on some positive basis of facts, they may be serviceable to the progress of science by stimulating inquiry."

It remains to add that the work concludes with two appendixes—one "on the fall of temperature in ascending to heights above the sea-level," which is a model of painstaking research into the methods and observations hitherto adopted, but which leaves this complex subject no further advanced; the other, "on Mr. Croll's theory of secular changes of the earth's climate," is a really valuable contribution to that fascinating inquiry. And here we take leave of Mr. Ball, congratulating him heartily on having added to our library of South American travels a volume that well deserves a corner of the shelf that contains those of Humboldt, Darwin, and Bates.

PALÆOLITHIC MAN IN NORTH-WEST MIDDLESEX

Palæolithic Man in North-West Middlesex. By J. A. Brown. (London: Macmillan and Co, 1887.)

THIS work has two faults by no means peculiar to itself, but which it shares with many books on science.

One of these is the large amount of introductory matter that bars the way to the special subject of study. Thus we do not get into Middlesex until reaching page 42, and then we quit it again after p. 120, to return at p. 185. Certainly, our author shows us how much trouble he has taken in looking up authorities on palæolithic and savage man in general; but he should remember that some folk don't like their whisky to be over-watered.

The second fault one must allude to with sorrow. Why is it that so many scientific scribes have such a weakness for slipshod English? Is it that they feel the advance of science to be so rapid that their works will be passed by in a few years, as out of date, so that it is not worth while to cultivate style, and grammar is hardly essential? Or is it that they expect the bad language of to-day to be the good language of the future, by an evil process of evolution, the survival of the unfittest? Let Prof. Lankester note this as a possible case of degeneration.

One cannot resist giving some examples. On p. 11 we are told that "abundant traces of man in the Neolithic Age are found on the surface of the ground, which may be picked up on ploughed fields." The surface of the ground is usually a good deal picked up on ploughed fields; but of course that is not what is meant. An author who has written much on prehistoric man might perhaps be justified in bringing an action for libel for the remark on p. 67 that "the fauna—as Prof. Dawkins says—is the same, and are referable to the same geological horizon." On p. 90 it is said of a certain tool that "it certainly has the appearance of greater antiquity as an implement, than do a very large proportion," &c. In the middle of p. 94 three successive sentences begin with "It," but that awkward little word in two cases stands for one particular implement, whilst in the third the general type to which that implement belongs must be referred to, as the particular "it" cannot have been found, in these unmiraculous times, in three distinct places: at Ealing, in Kent, and in Surrey. At p. 112 the singular "No. 131" is shortly followed by the plural "They," the latter being meant to refer to other numbers as well.

Having said this much as to things in general, we may say that Mr. Brown's book is a praiseworthy account of a particular district, and that it would not be amiss if other districts had as careful an observer in their midst, eager to see every section, and to record every find. It is a work that London antiquaries and geologists should possess.

Up to the time when Dr. Evans's great work on stone implements was published, but few specimens of worked flints had been recorded from the metropolitan district; but in the same year, Colonel Lane-Fox (now General Pitt-Rivers) recorded the finding of a large number in the gravels round Ealing. Notwithstanding this, however, hardly any addition was made to London implements for some years, when Mr. Worthington Smith developed the marvellous faculty of finding them in nearly every gravel-pit he went into. Our author makes a good third to these two, and that is saying a great deal. It is to be hoped that his book may lead other observers to join in the work that he has so much advanced, and to do for other parts of London and the surrounding country what he and the above-named authors have done on the north-west and north-east, and Mr. F. Spurrell on the south-east.

The antiquity of man is so controversial a subject that anyone who writes on it must expect to find more foes than friends. Mr. Brown, therefore, must not be surprised at exception being taken to some of his views, and in noticing his work one may fairly point out some matters on which opinions are likely to differ.

The remark, on p. 13, of piles (for dwellings) having been found at Moorfields received a curious illustration whilst it was in the press; for a building in that district was then being underpinned, on account of part of the pile-structure on which it was based having decayed; that building being none other than the lecture-hall of the London Institution.

The name "chalky boulder clay" was given by Mr. S. V. Wood, Jun., and not by Mr. Skertchly, as the footnote on p. 27 says.

That the brick-earths of Erith, Crayford, &c., are preglacial few geologists will be found to believe; perhaps, indeed, only Prof. Dawkins; and our author wisely throws the burden of this belief on that gentleman (p. 33).

As to the Tilbury man, alluded to on p. 42, there can be no doubt that his remains were found in a very late post-glacial deposit, simply the alluvium of the Thames. Mr. T. V. Holmes has set this question at rest (Trans. Essex Soc.).

By a slip, on p. 45, hard chalk, flint, and greywethers have been classed amongst rocks that do not occur in the valley of the Thames.

Probably there are geologists who would be disposed to question the strictly glacial origin of the furrowed gravel and the bent loam carefully described on pp. 45-47. Such irregular surface-deposits are so common in districts far from undoubted glacial beds as to leave their origin doubtful.

"The large encroachments of the sea which have taken place . . . in historic times" are no proof of depression (p. 48). They are simply the result of denudation along coasts.

The term "alluvium" should be confined to the deposits of rivers and not applied generally to surface-soil, as on p. 50, in which case it becomes a useless synonym.

The peculiar black bands often seen in gravels have troubled many observers, but from finding particles of carbonised wood occasionally in them Mr. Brown is not justified in saying that "there seems to be no doubt that such black strata are due to vegetable life," especially as he recognises the fact that the *colour* (which is what he refers to) is generally due to oxide of iron or of manganese. And even were the blackness due to vegetation, it is by no means a reasonable assumption that the beds were land-surfaces (p. 54), for the vegetable remains may have been carried down by water. That the white beds occasionally seen are "probably the result of decomposition of animal or vegetable matter" is also rather doubtful, the colour (which here again is what the author refers to, though his language implies the beds themselves) being often the result simply of the washing-out of the iron-oxide, which gives the usual brown tint, by percolating water.

There may be some doubt whether, when man first invaded England, the connexion of our country with the mainland was caused "by the uprise of the bottom of what is now the . . . North Sea." The present severance need not have been brought about by depression, but perhaps is owing simply to denudation, so that there is no need to invoke uprise to account for former connexion. There is also some difficulty in the uprise in question, as Mr. Brown thinks that Middlesex, &c., "was slowly emerging from the sea," and therefore must have been at a lower level than now. It is most likely indeed that at that time the whole land was higher than now, as otherwise it would be hard to account for the greater size of the rivers, as compared with their present descendants, for higher land would give greater rainfall, and greater rainfall means stronger streams. If "man beheld the land now under the 300-foot contour in Middlesex as an arm of the sea," there could have been nothing worthy the name of river, or even of brook, in the county, and the deposition of such coarse matter as our river-gravels would be out of the question (pp. 67, 68), those gravels certainly not being marine deposits.

In the picture of a Palæolithic scene from Castlebar Hill (pp. 185, &c.), it would seem as if the author were, as is often the case with geologists, a little too much impressed with the present features of the country, so as to allow too little for the amount of denudation that has happened since the time his picture represents. Instead of water then occurring over the whole of the low clay-country to the north, is it not possible that the tract in question was much higher than now, a great sheet of clay having been gradually swept off it since? Indeed, the author distinctly recognises the great amount of denudation that has occurred south of Castlebar Hill, along the valley of the Thames (pp. 191, 192), and of course there is no possibility of the process being confined to one side of the ridge.

The conclusions of Dr. Hicks as to the Glacial or pre-Glacial age of man in North Wales, noticed at the end of the work, are not altogether accepted, and should be considered as still waiting for the verdict of geologists.

Mr. Brown is clearly a positivist, as far as worked flints are concerned, and one is tempted to speculate on his direct descent from Palæolithic ancestors, for, as if by some hereditary instinct, he is enabled to be quite positive as to the uses to which sundry implements have been put, to an extent, indeed, to which probably few of even that highly imaginative class of men, antiquaries, will follow him. Some examples of this positivism may be noticed. Thus certain flakes were "evidently intended for spear-heads" (p. 58); and certain "triangular stones . . . could hardly have been intended for use in any other way" than as arrow-heads, "they were no doubt hafted" (p. 117); but from the figures given of some of these stones one would be inclined to regard them as little else than castaways (Nos. 167, 169). In another case, "as the greater part of one side is flat . . . it is evidently done for the purpose of being held in the hand" (p. 86). Again, "the object of making such an instrument is clear," namely, "for insertion in a club" (pp. 94, 95). "There can be no doubt that . . . they have been, or were intended to be, inserted into sockets" (p. 109). No. 159, in which "we have a shaft-smoother, borer and knife included in one object" (p. 116), must have been the delight of some Palæolithic schoolboy! Where statements of opinion occur in such form as "*I* have no doubt," they are of course justifiable; but in this sceptical age it is risky to say "there can be no doubt." It is quite refreshing to hear that there are implements whose "use is almost beyond conjecture" (p. 98). Most likely differentiation in the use of tools did not go far in Palæolithic times.

In the illustrations it would seem that in some cases justice has hardly been done to the specimens, or we should not be told by so experienced a person as the author that No. 144 (Plate ii.) is "the finest example of Palæolithic work" that he has seen. There is, too, a deficiency that should be supplied in another edition: a map and a general section of the district would much help most readers; and these could well be given instead of some of the foreign objects, such as the eternal carved reindeer, &c., without which no anthropological work seems to be thought complete, and which, by frequent repetition, have grown to be nearly as irritating as the faces and figures ever obtruding themselves from the advertising columns of newspapers and magazines.

The frontispiece, by Mr. Worthington Smith, should be acceptable to the advocates of women's rights. The woman is represented as the skilled artist, whilst the man is the mere labourer!

OUR BOOK SHELF

Hand-book of Practical Botany for the Botanical Laboratory and Private Student. By Prof. E. Strasburger. Edited from the German by W. Hillhouse, M.A., F.L.S. (Swan Sonnenschein, Lowrey, and Co., 1887.)

PROF. STRASBURGER'S well-known work, "Das botanische Practicum," has already been reviewed in the pages of NATURE (vol. xxx. p. 214), so that a short notice may suffice for the present hand-book, which is essentially a translation of the *smaller* German edition. Only the account of the fall of the leaf (pp. 156–59) has been taken from the larger work.

The present edition has been fully revised by the author, and also contains a considerable number of editorial notes and additions. The latter are usually indicated by being inclosed in brackets. It would, perhaps, have been better if this had been done throughout, especially in the introduction. A number of additional figures have been inserted by the editor. These are almost all reproductions of familiar text-book illustrations. Many of them certainly come in well, but we cannot help feeling that the constant reappearance of old figures has become rather wearisome, and that in this instance it tends to take off from the freshness which was so pleasant a characteristic of Prof. Strasburger's "Practicum."

We much regret that no account of any of the seaweeds finds a place in this edition. The admirable description of Fucus in the larger treatise of the author might well have been introduced here, while we think that the editor would have been well advised to add an example of the red seaweeds on his own account, or at least to reproduce Prof. Strasburger's description of the fresh-water Batrachospermum. It is easy to see why the author, writing for German elementary students, omitted all reference to seaweeds in his smaller edition. In England we are in a very different position, and it is a pity that students should not at once be made acquainted with plants which are so instructive and so easily accessible.

As the editor explains in his preface that the translation was executed at a time of serious pressure, it would be unfair to enter into any detailed criticism. It must, however, be admitted that the signs of haste are very frequent, and that there is much need for revision in a future edition. There are one or two instances of this which cannot be quite passed over. At p. 11, "durchschnittlich," which means *on the average*, is translated "sectionally," while at p. 49 we have "carefully," where the author says "with advantage" ("mit Vortheil"). At p. 169, note 2, "perfection" should be "development," while on p. 208 the statement that "we *know* the angular outline of the crystals [in Spirogyra] even without reagents," has an odd effect. The word should of course be *recognise.* At p. 67 the use of the word "pits" for the deep depressions ("Grübchen") which lead down to the stomata in Aloe, &c., seems to us likely to confuse the beginner. The phrase "starch-builders" (p. 43, &c.) strikes us as awkward, and is certainly not accurate as a translation. The use of the term *laticiferous cells*, in speaking of Chelidonium, is unfortunate. The organs in question of course come under the head of laticiferous *vessels.*

In conclusion we may express a doubt whether the un-English form "fibro-vasal" has any advantages over the familiar word "fibro-vascular."

The appendices have been much expanded from the original indices of the author, and should be of great use to the student, to whom the book as a whole will be extremely welcome. D. H. S.

Elementary Practical Biology—Vegetable. By Thomas W. Shore, M.D., B.Sc. (London: Churchill, 1887.)

THIS book is welcome more as a sign of the ever-growing attention paid to plant-structure than for any peculiar merit it has as a guide to the subject. The author fairly expresses his indebtedness to such practical books as Bower and Vines's, and claims originality only for his arrangement and treatment of the subject. The arrangement is as follows:—First comes an introduction dealing with the necessary apparatus and the preparation, &c., of objects. This is very concisely and sensibly done. Part I. deals with general vegetable morphology, treating in due sequence of the cell, the tissues, the systems of tissues, the apices of stems and roots, and cell-multiplication or cell-reproduction. Part II. is devoted to the Cryptogamia, beginning with the Fungi and working up to the vascular forms. Part III. is confined to the Gymnosperms, and Part IV. to the Angiosperms. So much for the arrangement. There may be no guide to practical work covering precisely all these types in this way, but text-books are by no means wanting which contain this arrangement of matter. The originality here is therefore not at all striking—perhaps fortunately so. As for the treatment, the student is conducted through the course with a baldness in the directions to note this and observe that, which reminds one of the style of a personal conductor through an historic building. The book has a purely practical aim, with the excellent purpose of preventing "cram"; but a student who should undergo this course of instruction, noting and observing no more than he is here directed to do, would find himself, at the end of it, the dispirited possessor of a mass of information which would result in a sad fit of mental indigestion. A practical guide of this kind throws too much of the burden of instruction upon the lecturer whose course accompanies it. The style of the whole book leads one to doubt the author's claims as a botanist to write it, and though it it may be a suitable guide to those who have to acquire a knowledge of botany in the course of their studies, it is practically useless for the rearing of botanists. Though one is reluctant to attribute a wrongly-spelt word to other than the conveniently necessary printer, the occurrence of Felicineæ, not once, but regularly, and, moreover, in the boldest and most conspicuous type of the headings of sections, does tempt one to think that the printer's fault lay in not having corrected it. A detailed criticism of the book would exhibit the author's imperfect acquaintance with the types discussed and his errors in description. Such, however, is beyond the scope of this notice.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

A Plant which destroys the Taste of Sweetness

DURING his tenure of office as Governor of Madras, Sir Mountstuart Grant Duff found time, in a way at which I never ceased to marvel, to correspond with this establishment about every kind of detail connected with the botanical productions of Southern India. In one of the last letters which I received from him at the close of last year, before his departure from India, he writes:—"I send you inclosed in this a portion of that delightful plant *Gymnema sylvestre*, an Asclepiad. I shall be curious to know whether when it gets to you it retains the very interesting property that, if you chew carefully two or three leaves of it, it absolutely abolishes for the time the power of tasting sugar. This is no fable, for three of us, I being one, tried it this morning at breakfast with the most complete success. I ate pounded sugar after it without the faintest perception of its saccharine character. I also drank coffee without any sugar in it, and tasted it just as well as I ever did.

"General Elles has just been up to my room to tell me that he also found it abolish the power of enjoying a cigar. Do try it, and report to me, when we meet, whether it stands the long journey. This Gymnema might conceivably be important medically."

We found that the leaves sent by Sir Mountstuart Grant Duff did retain the property he described in a marked way. I immediately wrote to Mr. Lawson, the Director of Public Gardens and Plantations, Ootacamund, to endeavour to procure some seed which we might grow at Kew, so as to obtain material for future experiment. In a letter received from him this morning he promises to do this when the fruit is ripe. He has, in the meantime, been so good as to inclose in his letter a paper by Mr. Hooper, the Government Quinologist, which appears to me to well deserve the wider publicity of the pages of NATURE.

The whole matter is a good illustration of the useful work which can be done by scientific men in distant parts of the Empire, which indeed could hardly be done in any other way.

W. T. THISELTON DYER

Royal Gardens, Kew, April 11

[Mr. Hooper's paper will be found on pp. 565–67.]

Units of Weight, Mass, and Force

IT is not easy to follow Mr. Greenhill in his letter which appeared in NATURE of March 24 under the above heading. His main contention appears to be that "weight" connotes not "force" but "mass" in engineering formulæ. Surely it would be more correct to say that the primary idea among engineers is that of force, mass being of secondary consideration and being measured by means of force: the force most commonly referred to being that of gravitation, which is *the* force, *par excellence*, with which the engineer has to deal. And I think it would be impossible to find any ordinary engineering formula involving W (which is generally supposed to stand for *weight*) in which W does not mean gravitation force. Also, in formulæ which have nothing to do with gravitation, and in which M (or *mass*) would naturally appear, the engineer puts $W \div g$ instead of M, so as to enable him to express it in terms of his unit of force, the weight of a pound. Thus, the kinetic energy of a moving body is $\frac{1}{2}Mv^2$ (where M is its mass and v its velocity), and is quite independent of its position in space. Engineers, however, who only care about bodies near the earth's surface, express the energy in terms of the merely local phenomenon, the weight or gravitation force acting on the body, which is sufficiently constant for their purposes, and write $\frac{1}{2}Wv^2 \div g$. There is consequently a struggle between engineers and physicists as to whether "*pound*," "*ton*," &c., shall connote the fundamental engineering quantity, namely, *weight*, or the fundamental physical quantity, namely, *mass*; and, naturally, neither side is very willing to give way. The easiest way perhaps would be for the physicists to give another name to the mass-unit, and leave engineers to the enjoyment of their use of the word "pound"; though meanwhile the word might very well connote either *mass* or *weight* (*i.e.* gravitation force) according to the context, the terms pound-mass and pound-weight being used when special clearness is desired. But do not let us, as Mr. Greenhill seems to desire, use weight and mass as synonyms, so losing the advantage of a good word for no good reason.

But Mr. Greenhill's most incomprehensible attack is on the formula $W = Mg$.

The equation means fundamentally neither more nor less than that the force of gravitation on any mass near the earth's surface gives, or tends to give, to that mass a constant acceleration called "g," and is to be measured by mass and acceleration conjointly, in accordance with Newton's second law, the fundamental law connecting force and motion. The symbol = means "equivalent to," as it often does.

From this fundamental equation can be deduced special *numerical* equations by means of definitions of arbitrary standards. Thus a "poundal" is the force which will produce in a pound-mass an acceleration of a foot-per-second per second;

$$\therefore W(\text{in poundals}) = M(\text{in pounds}) \times g(\text{in ft.-per-sec. per sec.})$$
$$= M(\text{in pounds}) \times 32, \text{ approximately},$$

this equation being merely a *numerical* equation deduced from the fundamental physical equation above. For W (in poundals) means the ratio of the weight of a body to the force called a poundal, or weight per poundal, or $\frac{\text{weight}}{\text{one poundal}}$, and so is a mere number depending on the particular mode of measuring W: and similarly with the other quantities.

Again, a pound-weight is the force which produces in a pound-mass the acceleration g;

$$\therefore W(\text{in pound-weights}) = M(\text{in pound-masses}),$$

or *ambiguously*

$$W(\text{in pounds}) = M(\text{in pounds}),$$

which is another merely numerical equation, and of course also only an approximate one; as Mr. Greenhill incidentally shows by means of his hypothetical balance at the coal-pit.

Too much importance can hardly be laid on the radical distinction between a physical equation and the various numerical equations which by choice of special units can be deduced from it. This must be my excuse for dwelling so much on the above example. It throws light on the way in which the error cited by Mr. Greenhill in his last paragraph can creep in. Thus, if the mass of a body of weight W is $W \div g$, it really follows that the mass of a body whose weight is W pounds (*or*, less ambiguously, W pounds-weight) = W pounds-weight $\div g$; but by definition one pound-weight $\div g$ = one pound-mass, $\therefore$ the mass = W pound-masses. In Mr. Greenhill's example W is a mere number, and he shows the error caused by trying to insert it in a formula where W means a weight.

In conclusion, if Mr. Greenhill insists on the abolition of the equation $W = Mg$, will he kindly say how he would symbolise the connexion between the force of gravitation on a freely falling body and the induced acceleration g? ALFRED LODGE

Cooper's Hill, March 30

The Association's "Geometry"

AS the President of the Association for the Improvement of Geometrical Teaching did me the high honour to mention with special approval my work on geometry in his remarks before the

Association, printed in the twelfth Annual Report, 1886, I feel impelled, on at length receiving to-day, at this frontier outpost of scientific civilisation, a copy, long ordered, of the Association's "Plane Geometry," Part 2, to say a few words suggested by it, favouring accord in these fundamental matters.

The very first definition and first theorem show the glaring need in English for a word which the Germans have in *Strecke*. Such a word, meaning a piece of a straight line, is needed in the first definition, the definition of a circle, for all straight lines are infinite in size, and radii are pieces of straight lines, and not whole straight lines. This is unconsciously recognised, even in the first theorem, where for "piece of a straight line" the undefined word *distance* is used, inappropriate because of its association with ideas of measurement by a unit and length, and because of its different and confusing use in the phrase "shortest distance."

In the demonstration of this first theorem, "straight line" is used in its proper sense, though just before, in the first definition, it was bunglingly used in the sense here given to *distance*. For the part of a straight line between two definite points I have long used the word "sect," which, carried over to the sphere with the meaning part of the spherical line less than half, gives the key to two-dimensional spherics.

And this suggests another objection to the same first definition. It says a circle is a plane figure. Now one cannot even think of spherics without seeing how immeasurably better it is to define a circle as a curve. It will be so defined as soon as the student reaches analytics, so why have him learn something only to unlearn?

In the fourth definition we have an over-used word, "conjugate." Two arcs which together make a circle should be called *explemental*. Explement is a natural third to complement and supplement. Again *converse* is a term of logic, and does not mean what it is here used to mean, that is, *inverse*.

In the introductory remarks to the fourth book I think it is a mistake to call hunger, love, courage, talent, wisdom, *magnitudes*.

A magnitude is whatever can be added to itself, so as to double. The very first sentence says: "In this book the subjects of the propositions . . . are magnitudes in general;" but the whole treatment is founded upon *multiples*, and is only applicable where multiples can be made. Not only must we have an exact criterion of equality, we must be able to add without shrinkage.

A little farther on we meet the absurd statement, "Fundamentally, number is *counting*."

Now we know that counting is establishing a one-to-one correspondence between the individuals of an aggregate and of a standard group which was primarily the fingers. But a number is fundamentally a picture of an aggregate which for all counting purposes is as good as the aggregate itself—a picture consisting of a mark for each distinct individual in the aggregate, as III.; and then secondarily a symbol for that picture, as 3.

It is questionable whether Book IV. Part 1, has any valid excuse for existing. Proportion for commensurable magnitudes neither calls for nor warrants treatment by multiples. Sandeman, in the preface to his "Pelicotetics," speaks of "the phenomenon of incommensurability, through which alone arises any need of ratio, either the thing or the name." Euclid's marvellously elegant treatment of proportion is only admirable because of the difficulty it so deftly overcomes. To use it on commensurables is to use a Gatling gun on a plucked chicken. The illustration given under Definition 4 of this Part 1 (which definition needs the word commensurable inserted in it), "4 half-crowns = 5 florins," reminds one how badly England needs a decimal system of coinage, weights, and measures. No light is thrown on the compounding of ratios, but the error of A. J. Ellis is avoided. He says: "The ratio of B to A means the order in which the multiples of B are distributed among those of A."

These are points suggested in first turning the leaves of a new book of most gratifying soundness. May it ward off from England the misfortune America now suffers, in that our most popular book on geometry makes the fundamental blunder of basing the treatment of parallels on direction, uses in its proofs the stultifying formula, "a straight line is the shortest distance between two points," and from one end to the other makes us wish for an American Association for the Improvement of Geometrical Teaching. GEORGE BRUCE HALSTED

University of Texas, Austin, Texas, March 3

The Svastika as both Sun and Fire Symbol

THE late Prof. Dr. Worsaae ("Industrial Arts of Old Denmark") claims the ring-cross , as he terms it, as a sun symbol, and a small cup-shaped hollow for the moon; both these he places as belonging to the *later* Stone Age of Scandinavia, and, apparently, the only recognised emblems of that period. He observes, in one place: "How many hundred years, or, indeed, how many thousand years, before the Christian era the earlier Stone Age began, it is impossible to say."

The same writer places amongst the emblems of the *later* Bronze Age the wheel-cross  (the chariot wheel of the sun?). To this day, both in Denmark, Holland, and in parts of Germany, a wheel is frequently placed on the roof of a stable or other building, which is thus deemed protected from fire, especially if a stork can be induced to make its nest upon the wheel. The stork, owing to his red legs, was not inaptly considered an emblem of fire; he was also the herald of summer—he brought light and warmth. The Moqui symbol for the sun (as described by Dr. Dryer in NATURE, Feb. 10, p. 345) exists also on articles classed by Prof. Worsaae as belonging to the later Bronze Age in Scandinavia, with the exception of the three marks of which he speaks, as indicating the eyes and mouth of a face.

According to Hyde ("Persian Religion," p. 38), "Idolaters as well as sun-worshippers existed in ancient Persia, and the worship of fire and that of idols were combined at one period."

Quintus Curtius, when describing the march of the army of Darius (writing, however, long after date), says:—"Darius was accompanied by an image of the *sun*, placed in a crystal, and the sacred *fire* carried on a silver altar."

The sun, which was regarded as a wheel, a store of gold, an eagle, was also styled the eye of Varuna.[1] The worship of Mithra was likewise a worship of the sun; Mithra was the god of daylight. He and Varuna were fabled to journey at even in a brazen car. From this has probably arisen the horse-sun and the wheel-sun. Euripides gives the sun a winged car; and, on coins from Eleusis, Dêmêter is represented riding in such a car drawn by two serpents.

The *svastika*  has been very generally allowed to be a symbol of Thor, who, to the Scandinavians, was the god of thunder and lightning and of the domestic hearth, and therefore of fire also. The arrows in the hand of Jove, the thunderer of Roman mythology, resemble somewhat a compressed or crushed *svastika*. The above form of this symbol, with a very slight variation 
, may be seen on a slab taken out of a Christian catacomb in Naples, and now in the National Museum there. A very natural inference is, that this stone sealed the grave of one who had suffered martyrdom by fire.

The *svastika* has been held to be an emblem of fire, as being the way in which that element was first produced by primitive peoples—a method which is said to be in use in certain Hindú temples at the present day. It consists in two crooked sticks being laid one across the other, and a hole drilled through both; a pointed stick being there inserted, this is rapidly twirled by the hands until the five points of contact become ignited.

[1] To the Persians, Varuna was the god of the clouds and of the celestial sea. When this branch of the Aryans reached Southern India, he there became to them the god of the earthly sea. To the Greeks he was Ouranos; and to the Germans and Anglo-Saxons, the eye of Woden.

The ground-plan of some well-known Hindú temples in India is that of the Greek cross. The lightning, another of the attributes of Thor, the thunderer, from its zigzag course, may not unnaturally have been likened to a serpent. A Hermes, or torso, in the Museum at Arles, and labelled "A Statue of Mithra," shows that the serpent had its place in the celestial mythology of the ancients. This figure is entwined in the folds of a huge serpent, and between these are sculptured the signs of the zodiac.

During the Bronze Age, which, as regards Scandinavia, Dr. Worsaae fixes at from about 500 B.C. to 100 A.D., the form of the *svastika* received several modifications: amongst others, it became what he styled the single , or the double  thus, and also the three-armed figure , or triskele. In another place he says (*ibid.*): "Curiously enough, in the new Runic alphabet which was adopted at this time (later Iron Age or Viking period), the letter S, which recalls one of the old sun symbols, was called Sol or Sun."

The connection of the triskele with the serpent may possibly seem to some far-fetched, but a tolerably certain proof that it is not so is shown in a bronze brooch found, a few years ago, when excavating the Roman camp on the Saalberg, near Frankfort-on-the-Maine. This ornament is now in the local Museum of Homburg-v.-d.-Hohe. Inclosed in a ring of bronze is a triskele; each arm has a distinct serpent's head; they all turn the same way, as, it may be observed, do the arms of the *svastika* (or Crux Gammata). The connection of this symbol with the serpent survived even down to the so called "cinque-cento" period. It survived in Christian times—under the name of the *fylfot*—even down to the fourteenth or fifteenth centuries, and is alluded to by Sir J. Gardner Wilkinson ("Dalmatia and Montenegro," vol. i. p. 23). He speaks of finding this emblem, in the form of two snakes  entwined, "as a device upon some tombs in those provinces"; and adds:—"This symbol was used in early Christian times in England and other countries, among ornamental devices, in manuscripts, on tombs, and on church ornaments and vestments, from about 1011 to 1400 A.D., after which it is not met with in England. It is very common on monumental crosses of the fourteenth century, and was a favourite ornament of the Greek Church, whence it probably came into England and Western Europe: it is known in heraldry as the fylfot."

In the treasury of the Cathedral at Valencia, in Spain, there are two richly embroidered altar frontals, which (as stated by the officials in charge) formerly belonged to the church of old St. Paul's, in London, having been sold into Spain by our King Henry VIII. The needlework is a triumph of art. On each of these frontals is represented a portion of the old church. On one of them—which depicts our Blessed Lord going to crucifixion—a soldier of the Roman army, or of one of their allies, is represented holding a pennant on which is a *svastika* of the fylfot type.

In this brief sketch I have endeavoured to show the relations between sun- and fire-worship, both of which may have existed contemporaneously amongst primitive peoples, since light and warmth were naturally highly prized by them.

The Greek cross, or cross of Savoy  (the centre of the ring-cross of the later Stone Age), appears to be the earliest known form of that symbol. A form of *svastika* of the Bronze Age—the triskele—may still be traced in the trinacria of the arms of Sicily and the Manx-man of our isles.

Did space permit, much more could be said regarding the *svastika* as a pre-Christian and a Christian cross.

Great Brampton, Hereford

HARRIET G. M. MURRAY-AYNSLEY

Important Points in the History of Earthquake Investigation in Japan

As the various instruments for recording earthquakes which have been invented in Japan appear destined to play an important part in future seismometrical investigations, and as the authorship of many of these instruments has recently formed the subject of a discussion, in which, although my name has been freely used, my distance from Europe practically prevents me from taking part, and which, so far as I can see, can only result in confusing those who are unacquainted with the work done in Japan, I venture to give the following notes as an outline of the more important points in the history of seismometry in this country.

In 1872, Dr. Verbeck, of Tokio, obtained approximate measurements of the range and direction of earthquake motion by means of an instrument consisting of a heavy slab resting on balls, the slab being the steady-point (Trans. Seis. Soc. vol. i. p. 23). The resemblance of this instrument to the lighthouse tables the invention of the late Mr. Stevenson is apparent.

In 1879, results which were probably more accurate than those of Dr. Verbeck were published in the Transactions of the Seismological Society (vol. i. p. 91), and the residents in Japan were astonished to learn that the amplitude of what were apparently severe earthquakes were to be measured in millimetres and fractions of millimetres rather than in inches. The results were obtained partly by Dr. Wagener and partly by myself. I worked with pendulums writing their records by what I still find to be the most delicate kind of pointers upon the surface of smoked glass. Dr. Wagener used a pendulum which was practically "dead-beat," and a pointer which gave a multiplied representation of the earth's movement. This was the first time that the necessity of multiplying-levers was recognised.

Shortly after this I published examples of diagrams of earthquake motion obtained by allowing smoked glass plates, at the time of a disturbance, to move for a period of three or four seconds beneath the pointers of a pendulum. The diagrams were short, but the results obtained respecting period, amplitude, and quantities calculable from these data, have not been shown by subsequent investigations to have been unsatisfactory (Trans. Seis. Soc. vol. i. p. 91, &c.).

About this time Prof. Chaplin and Mr. T. Gray independently constructed bracket seismographs (Trans. Seis. Soc. vol. i. p. 25). Mr. Gray's bracket seismographs were never specially described, but they still exist in the Imperial College of Engineering. Mr. Gray's next invention was a torsion pendulum seismograph, which, being suspended from horizontal levers which in turn were held up by horizontally placed springs, also recorded vertical motion. A curious feature in this instrument was that the horizontal levers were so supported that for slight displacements they had a constant leverage. In the same paper describing this instrument, Mr. Gray emphasises the importance of having seismographs so constructed that the steady-point should be in neutral equilibrium (Trans. Seis. Soc. vol. i. p. 48).

The next advance was made by Prof. Ewing, who, by using a bracket seismograph with a pivoted weight and a multiplying-lever writing on a continuously moving plate, obtained diagrams which inasmuch as they extended over a considerable portion of time were superior to all that had preceded them.

This instrument was described in Europe and Japan without the briefest mention of the fact that bracket seismographs, multiplying-levers, smoked glass plates, continuous records, &c., had a previous existence. Two of such publications are before me (Trans. Asiatic Soc. of Japan, vol. ix. p. 40, and Trans. Seis. Soc. vol. ii. p. 45).

At the time this excited no *public* comment, and it was not until Prof. Ewing distinctly claimed at least a joint authorship, not only of all bracket seismographs, but of all instruments which might involve the same principle, like the various forms of rolling spheres, rolling cylinders, conical pendulums, double brackets, &c., the inventions of Mr. Gray, that discussions arose. For one of these discussions see Trans. Seis. Soc. vol. iii. p. 9.)

Although Mr. Gray distinctly stated that he had experimented with bracket seismographs prior to the one introduced by Prof. Ewing (Trans. Seis. Soc. vol. iii. p. 5), and although I personally acquainted Prof. Ewing with this fact, so far as I am aware Prof. Ewing has never in any manner whatever referred to this. Mr. Gray's seismograph for registering vertical motion, which in its principle was a new departure in seismometric methods, was constructed and described in April 1881 (Trans. Seis. Soc. vol. iii. p. 137).

At the following meeting of the Seismological Society, Prof. Ewing described an instrument of a similar nature, and only differing from the one described by Mr. Gray in the details of an arrangement for compensating the variable leverage, an arrangement practically adopted by Mr. Gray in the above-mentioned torsion pendulum. This seismograph is now distinctly claimed by Prof. Ewing as his own (NATURE, December 23, 1886, p. 172).

In June 1881, Mr. Gray suggested several methods by which a pendulum might be rendered astatic (Trans. Seis. Soc. vol. iii. p. 145). This was followed by Prof. Ewing's device to obtain the same result by an arrangement which was closely foreshadowed by Dr. Wagener, who *endeavoured* to compensate the movement of a pendulum by a heavy-headed recording index (Trans. Seis. Soc. vol. i. pp. 66 and 67).

In addition to the seismographs here referred to, there are many others that might be mentioned. Amongst them we find the parallel-motion instrument of Mr. West, which was immediately followed by parallel-motion instruments the invention of Prof. Ewing and Prof. Alexander (Trans. Seis. Soc. vol. iv. pp. 22 and 30).

The development of the parallel-motion instruments may be taken as illustrative of what has happened with regard to nearly all the other seismographs, which in great measure have been gradually developed from something which preceded them.

By improving the bracket seismograph, Prof. Ewing made a considerable advance in seismometry, for which the workers in this country undoubtedly accord him their hearty thanks; but while describing a beautifully constructed, but at the same time inconvenient and obsolete arrangement of seismographs (NATURE, vol. xxx. pp. 149 and 175, and vol. xxxiv. p. 343), it is hardly fair that his fellow-workers, especially Mr. Gray, the most prolific of earthquake inventors, should be passed by unnoticed, and have their work practically appropriated.

Tokio, February 10 JOHN MILNE

Supposed Suicide of the Cobra

THE following observations may be of interest as bearing on the reputed suicide of snakes.

Yesterday, while riding over a bare sandy plain I caught sight of a large black cobra moving leisurely along. Having no other weapon with me but a ·450 express rifle, I halted my camel and fired, at about 50 yards, just as it was disappearing down a rat-hole. The bullet passed through the middle of its body without severing the spine; the head was immediately withdrawn from the hole, and the snake began to writhe in agony, rearing its head, spreading its hood, and striking wildly in all directions. I was about to put it out of its agony by a second shot when it struck close to its own tail, and my orderly cried out that now it had bitten itself and would soon die.

Though I had clearly seen that it did not bite itself, I thought this a good opportunity of seeing whether there was any truth in the popular superstition, and if not whether I could obtain any light on the mode of its origin. The following is the result.

The snake repeatedly reared its head, and after holding it reared, struck wildly at some piece of grass or stick; twice again it struck at its own tail, and on each occasion the natives with me declared it had bitten itself. This, however, I can assert, it did not: on one occasion it stopped just short of the skin; on the other, being apparently unable to check itself, it swerved slightly and struck the ground close alongside. It appeared to me that the snake in its agony struck wildly at the first thing that caught its eye and irritated it; in three cases this was its own tail, but as soon as it realised what it was doing—so far from there being a deliberate attempt at suicide—it did all in its power to prevent a fatal result.

It is conceivable that, under similar circumstances, owing to loss of control over its own actions a snake might actually bite itself, and there would be what might pass for a well-authenticated case of suicide; but such a case, did it ever occur, would probably be due to an accident and not to deliberate intention. I have no doubt, however, that the popular superstition finds its support in cases like that described; for the natives with me, if questioned, would reply that the snake had certainly bitten itself three times, the other apparently aimless strikes at sticks or grass having escaped their notice.

A similar explanation of the reputed suicide of scorpions was given in NATURE some time ago, but not having the file with me I cannot give the reference. R. D. OLDHAM

Camp near Pokran, in the Indian Desert, March 4

THE RETIREMENT OF DR. TYNDALL

WE have had on more than one occasion during the last six months to refer with regret to Dr. Tyndall's impaired health brought about by overstrain. Our readers will have gathered from the daily papers during the present week that although much recruited by rest, Dr. Tyndall has yet sent in to the managers of the Royal Institution his resignation of the Chair of Natural Philosophy, which he has held since 1853, and that the resignation has been accepted.

The managers and members, cordially appreciating Prof. Tyndall's services, and being anxious to mark their sense of the benefits he has conferred on the Institution during his long connexion with it, have done what was still open to them in the way of honourable recognition and regard. He has been nominated for election as Honorary Professor, a title previously borne by Sir Humphry Davy and Prof. Brande; and one of the annual courses of lectures will be called "the Tyndall Lectures." He has also been requested to sit for his bust, to be placed in the Institution, in memory of his relations with it.

At the monthly meeting held last week the following letter was read:—

Hind Head, April 3, 1887

DEAR SIR FREDERICK BRAMWELL,—I have halted in my reply to your letter of March 23, through sheer inability to express the feeling which the action of the managers, at their meeting on the 21st, has called into life.

And my reply must now be brief, for I hardly dare trust myself to dwell upon the "resolutions" which you have conveyed to me. Taken in connexion with the severance of my life from the Royal Institution, and with the flood of memories liberated by the occasion, this plenteous kindness, this bounty of friendship, this reward so much in excess of my merits, well-nigh unmans me.

And, let me add, the noble fullness of style and expression, which I owe to yourself, and in which the good will of the managers takes corporate form, is in perfect harmony with the spirit which it enshrines.

Of the managers existent when I joined the Institution, one only remains upon the present Board. The beneficent work of many of them is for ever ended; but I do not forget the sympathy and support which they extended to me during their lives. And now the long line of kindnesses culminates in words and deeds so considerate and appreciative—so representative of their origin in true gentlemanhood and warmth of heart—that they have almost succeeded in converting into happiness the sadness of my farewell.

With heartfelt prayers for the long-continued honour and prosperity of the Institution which I have served so long, and loved so well, believe me, dear Sir Frederick, most faithfully yours, JOHN TYNDALL

However much it may be regretted that Prof. Tyndall has felt himself compelled to withdraw from the onerous duties of a particular office, we may hope that, so far from this being a withdrawal from science itself, further leisure and rest may soon be followed by the old vigour, and that a fresh series of services may reward the labours of future years; for the work in which Profs Huxley and Tyndall have been the best known among the pioneers is not yet half accomplished.

On this subject the *Times* writes as follows:—

"Dr. Tyndall's name, in conjunction with that of Mr. Huxley, stands for a symbol of the nationalisation of natural science as an educational instrument. Sir Humphry Davy and Michael Faraday, in the same position, flashed the light of science into minds already prepared by leisure and cultivation to receive it. Dr. Tyndall's professorship in Albemarle Street has synchronised, and by no casual coincidence, with the recognition of the claims of the masses to be scientifically instructed. Contracted as Sir John Lubbock complains the domain of natural science is still among educational appliances in general, it is extraordinarily large in proportion to the place permitted it when Dr. Tyndall commenced his courses a third of a century back. Scientific truth was valued and sought by the few then as now. They themselves scarcely regarded it as a subject which concerned the rest of the community. At large the most extraordinary obtuseness prevailed. The feeble attempts to impart a little superficial information in schools and lecture-halls rendered the darkness more visible. From the Royal Institution, as from the several centres occupied at various times by Mr. Huxley, poured a continuous expostulation against popular ignorance of the very bases of physical existence. The force of the appeals lay in their tone of moral anger at an apathy represented as a degrading baseness. Their special virtue was the determination, which never flagged, to abandon nothing of the exactness of science in popularising it. Prof. Tyndall, like his constant fellow-worker, has never for an instant looked upon the masses as entitled only to second-rate knowledge. They have had it of the highest and purest which it was within his means to supply. He has admitted no distinction between esoteric and exoteric teaching. He has not put off an audience even of children with the modern equivalents for the worsted orreries and Prince Rupert's drops of elementary philosophy fifty years ago. In his hands science for the most rudimentary educational purposes has been treated as reverentially as for the most transcendental. It has walked with head as erect in the Royal Institution theatre during the Christmas holidays as at a session of the Royal Society or the British Association. The result has been that, if the country has not learnt all it might and ought, it has learnt little which it will have to unlearn. It has not been condemned to drink either scientific dregs or scientific scum."

We regard the appearance of the article from which the above quotation has been taken as one of the results of the increased appreciation of science which has followed from the crusade in which Prof. Tyndall has played so important a part, and we confess it is not without misgivings that we contemplate a future, which we trust may be a distant one, in which Prof. Tyndall's unswerving advocacy of research for its own sake, and the example of his devotion to science, unsullied by considerations of filthy lucre, are no more among us.

We believe that all the arrangements at the Institution consequent upon Prof. Tyndall's retirement are not yet completed, but we learn that Lord Rayleigh has all but agreed to take some part, at all events, of the duties of the Chair.

This will be good news to all true friends of science. The Institution has a long and noble reputation to keep or to lose. In Lord Rayleigh's hands we know it will be safe.

PRIMROSES

THE very word awakens the pleasantest memories that remain to us from the time when we almost lived in the open air and enjoyed the intense delight of plucking wild flowers without let or hindrance; a pure and unalloyed delight actually experienced only in childhood, though it lives evergreen in our hearts, and leavens the more serious pleasures of riper years. The primrose of primroses for all Britons is the wild yellow primrose that adorns woods, hedgerows, and banks from Cornwall and Sussex to the Shetlands, Orkneys, and Hebrides; for none is more lovely, though many among the endless variety spread over the north temperate and cold regions excel it in warmth and brilliancy of colouring. It is now about a year since botanists and gardeners met at South Kensington, whither they had brought their collections of living plants, comprising a large number of species and varieties of *Primula*, solely for the purpose of seeing and talking about primroses, polyanthuses, and auriculas; and the vast amount of information contained in the report of the proceedings of those assembled merits the attention of all naturalists, to say nothing of those who love flowers merely for the pleasure they afford the eye. Being hardy, primroses were among the first plants cultivated in this country when ornamental flower-gardening began, little more than three centuries ago. The old masters—Turner, Gerard, and Parkinson—introduce us to them, the first including in his "Libellus" only the *prymerose;* but at that date (1538) there seems to have been no such thing in England as the cultivation of flowers for their beauty alone. Gerard's first catalogue of plants cultivated in his garden at Holborn, and published in 1596, contains "primroses, birds eies, paigles, cowslips, and beares eares": respectively *Primula vulgaris*, *P. farinosa*, *P. veris*, and *P. auricula;* and this is the earliest English catalogue of professedly cultivated flowers. Parkinson describes in his "Paradisus" (1629) twenty-one sorts of "beares eares" or auriculas, and he mentions that the varieties cultivated were much more numerous than he intended describing. In the report alluded to, Shirley Hibberd states that in the year 1570 many artisans, driven from the Netherlands, settled in this country, bringing with them their favourite flowers, including the best of their auriculas. Thus it would appear that the auricula was one of the very earliest "florists' flowers" cultivated in this country; and it is hardly necessary to say that it is one of the chief favourites of the present day. One of the questions discussed at the Conference was the parentage of the true auriculas and the Alpine auriculas, a question upon which florists and botanists did not quite agree; and the only way of obtaining a solution of the problem is by experiment. It is nearly certain, however, that more than one species has been concerned in the production of the various cultivated races. On the one side it has been argued that the presence of true blue is almost absolute proof that they cannot all have descended from a species having yellow flowers; and it is true that both wild and cultivated plants which exhibit great variety in the colour of their flowers rarely offer both pure blue and pure red. The china-aster (*Callistephus chinensis*) is an exception, but whether both colours exist in the wild plant I cannot ascertain. Philip Miller, who was the first to cultivate it in this country, states that he received seeds from France of the red and white varieties in 1731 and of a blue in 1736. Amongst our native plants a very large number of those having normally blue or red flowers frequently produce white varieties; and I have myself picked red as well as white varieties of the bluebell (*Scilla nutans*), though it is true the red was not a very pure one. On the other hand, normally yellow flowers rarely sport into other colours.

To return to the primroses: the introduction in 1820 of the Chinese primrose added a permanently popular greenhouse flower, which is now raised by hundreds of thousands, indeed one might say millions, annually; and almost every florist of note has his special "strains" or varieties, varying in colour from pure white to crimson, and equally in the size and cutting of the leaves and flowers, which are either double or single. The double-flowered varieties are relatively difficult to cultivate, as they are propagated by offsets, and are less vigorous in constitution. Like the china-aster, this was unknown in a wild state until recently, when the Abbé David discovered it in the province of Hupeh.

Persons familiar only with the species of *Primula* hitherto mentioned can form no idea of the amount of variation exhibited by the whole genus, which embraces at least 110 distinct species, widely spread in the temperate and cold regions of the northern hemisphere, rare in warmer countries; and one is found in the extreme south of America. But some further particulars of their distribution may be interesting. The forms in Europe are numerous, and the number of species to which they may be referred varies from twenty to nearly forty, according to the views of different botanists. They are most numerous in the Alps, where they constitute one of the most charming features of the vegetation. In Asia, too, the genus is generally diffused, though by far the greatest concentration of species is in the mountains of Northern India, where upwards of fifty species occur, some of them ascending almost to the altitudinal limits of flowering plants. Quite recently Mr. Franchet has described a dozen new species from Eastern Tibet and the Chinese province of Yunnan; and Eastern China and Japan possess their peculiar species; one at least of the latter (*P. japonica*) being now common in English gardens. An isolated species, the gigantic *Primula imperialis*, inhabits the mountains of Java, and the genus is represented in South-Western Asia, in Arabia, even to the neighbourhood of Aden, by *P. verticillata*, the same species recurring in Abyssinia; yet none apparently is found in the mountains of Morocco. In America the distribution of the genus is peculiar, no species having been found in Eastern North America south of Canada, while in the western and central regions three or four endemic species inhabit New Mexico, Arizona, and California, though in the last-named country the genus does not extend south of the Yosemite Valley, where the charming *Primula suffrutescens* is at home. The latest discovery is a new species in the Santa Rita Mountains, near the Mexican boundary. Altogether, nine species are now known from North America, five of which, those in the Arctic regions, are also natives either of Europe or Asia, or both. But the most remarkable fact in the distribution of the genus *Primula* is the presence of a species in the extreme south of South America—a species so closely allied to the northern *P. farinosa*, which is common to Europe, Asia, and North America, that it has been alternately held as a variety of it and an independent species. When writing his "Flora Antarctica," Sir Joseph Hooker could find no character whereby to distinguish the South American primrose as an independent species; but in his recent "Flora of British India" he states that it differs in having large granulate seeds. On the other hand, Dr. Asa Gray ("Synoptical Flora of North America") treats it as the same as *P. farinosa*; yet it is probable that he did not examine the South American plant, although he includes South America in the range of *P. farinosa*, therefore it can hardly be cited as an expression of opinion on the subject. The plant is common in Fuegia and the Falkland Islands. Even admitting that it is sufficiently distinct to be admitted as a species, the genetic connection with *P. farinosa* is so close that as a phenomenon in distribution the question is immaterial. The southern limit of *P. farinosa* in North America, so far as known, is Colorado; therefore there is a break of nearly 90° of latitude.

The greatest diversity is exhibited by the Asiatic species, alike in stature, foliage, and floral structure. In a comparatively restricted region of the Himalayas grow the moss-like species, scarcely an inch high, including the flower, such as *P. minutissima*, and the tall *P. sikkimensis*, with an umbel of twenty to thirty delicate yellow flowers on a scape 2 to 3 feet high. Between these extremes there are all sizes and several distinct types of foliage. The Javan species alluded to above is perhaps the largest of the genus, having whorl above whorl of golden flowers, though it is closely approached by the beautiful and many-coloured *P. japonica*.

The recent novelties from Tibet and Western China include some of the most distinct and peculiar forms of the genus, but none of them is in cultivation.

There are many other interesting things connected with primroses, but I have perhaps already covered too much space. I may add, however, that by far the richest collection of living species was contributed to the show by the Royal Gardens, Kew—a collection largely brought together by Mr. G. C. Churchill, part author of the well-known book on the Dolomite Mountains, and cultivated by Mr. Dewar. It contained about fifty species, besides many hybrids and seminal varieties.

The report from which some of the foregoing particulars were extracted forms a part of the seventh volume of the Journal of the Royal Horticultural Society.

W. BOTTING HEMSLEY

ON THE ESTABLISHMENT OF THE ROMAN DOMINION IN SOUTH-EAST BRITAIN

BEFORE entering upon the matter which I have stated as the subject of this paper, I think it will be well to premise three notes: (1) on the general authority for the accuracy of the history; (2) on the geography of the approaching coasts of Gaul and Britain; (3) on the pronunciation of names delivered to us in the spelling of the Greek language.

(1) The account of the invasions which I adopt is that of Dion Cassius. His history, in general, is orderly and full. He appears to have been a man of rank, and doubtless had command of State documents. He seems to have been well acquainted with every movement in the Courts of several successive Emperors. He has carefully explained why he was unable to continue his Roman history beyond the time of Severus with due accuracy. The time of the invasion of Britain was about 170 years before the composition of his history—an interval almost equal to the length of our Hanoverian dynasty; and his account of the wars in Britain may claim to be considered as trustworthy as our histories of the campaigns of Marlborough.

(2) In regard to the geography, it is to be observed that the coast-tract in the north of France, apparently from the mouth of the Seine to the mouth of the Scheldt, is called Γαλατία (Galatia). This name occurs at least twice, in separate books of Dion. By Ptolemy it is called Κελτογαλατία Βελγική.

(3) The English writers who have given any attention to this history have had, I believe, no knowledge of the pronunciation of the Greek words. Mitford, however, in his "History of Greece," had pointed out some of its peculiarities. The difficulty is now greatly removed by the publication, at Boston, U.S., of the "Grammar of Modern Greek," by E. A. Sophocles. I extract the substance of his notes which apply best to the present purpose:—

β is the English *v*, or sometimes *bh*.
δ is the English *hard th*, as in *that*, *those*.
θ is the English *soft th*, as in *thin*, *thorn*.
μπ is the English *b*.
νδ or ντ is the English *d*.
ι is the English *ee*, as in *seen*.
ου is the English *oo*, as in *soon*.

There is no reason to think that the pronunciation has changed for many centuries. In the Byzantine Greek histories of the Crusades, there are many opportunies of making comparisons of the Greek and the Latin names of places and persons, which appear to follow the same rules as at the present time.

Thus, the name given by Dion to the lady who commanded the Britons in their grand movement against the Romans is spelt by him Βουνδουΐκα. Interpreted by the list of equivalents just given, it becomes in English letters and sounds, Voo-doo-ee-ka; and this I believe to be the true rendering of the name. Still, I dare not depart from the established custom; and I shall therefore (unwillingly) adhere to the long-used English spelling, "Boadicea."

I now enter upon the national history.

In the reign of the Emperor Claudius (there is no farther indication of time) Kunobellin reigned at Camalodunum (undoubtedly the modern or Saxon Colchester, "the fortress on the River Colne": the Latinised original name is literally "Camal-hill" or "Camal-fort" (a name somewhat similar to this occurs in Arthurian legends). Kunobellin is mentioned by others as King of the Trinobantes. Dion remarks, "they (the people) were not self-governors, but lived under kings."

Vericus (Βέρικος), a political exile from Camal-dun, persuaded the Emperor Claudius to given him military assistance (apparently for restoration); and the Roman general Aulus Plautius was sent from Galatia, and (after a ridiculous mutiny of the soldiers) landed in England. Remarking that he had no motive for entering Kent, and that his object was to reach Camal-dun as soon as possible, I think it likely that he rounded the North Foreland, and debarked at Southend on the west side of Shoeburyness; where there is an excellent beach two or three miles long, sheltered from the open sea, for landing; and a good plain, for temporary encampment.

Without detailing all the affairs of Plautius with Kunobellin and Kunobellin's two independent sons, Kataraktos and Togodumnos, I shall only say that, after a very unsuccessful struggle with the Britons, apparently among the woods and marshes of the Crouch (a complicated river), Plautius retreated, in veritable flight, towards the west. He had, however, made peaceable terms with the Vothuni (a tribe not otherwise known, I believe); and, leaving a guard there, proceeded till he came to a river, deep but fordable, which he passed with some difficulty. This river, I have no doubt, was the Lea, the largest of the Essex rivers, and running in a valley which is in some parts marshy. In crossing this river, he was greatly assisted by the Κέλτοι, who were accustomed to cross rivers in their armour. (It seems not improbable that these Κέλτοι had been levied in the eastern parts of Galatia and the regions of the Scheldt.) The Roman army, by this real flight, reached the tract opposite London. We have now to consider the state of land and water before them.

So far as we can judge, there had never been any power in the country which could have embanked any of the marshes as we see them now. The sea-water, scarcely salt (much fresh water having entered from the Thames and the smaller rivers) ran up with an insignificant tide, above Rotherhithe and to the borders of Southwark, in a great arm of the sea, never less than two miles wide. This gulf is called by Dion Ὠκέανος. It was shallow, in some places actually bearing trees. (See Mr. Spurrell's "Early Sites and Embankments on the Margin of the Thames Estuary," *Archæological Journal*, vol. xlii.) To the point opposite London applies the sentence of Dion, "ἐπὶ τὸν Τάμεσσαν ποταμὸν, καθ' ὸ ἔς τε τὸν Ὠκέανον ἐκβάλλει." And this was Dion's mouth of the Thames, and here was the head of the gulf. There was a bridge at a small distance, which I conceive to have been near the site of William the Conqueror's bridge or modern London Bridge. It is remarkable that there is no mention of a town; but probably Southend was the real port of Britain, and the march of the Romans was on the harbour-road.

The sea-water, after the long passage up the shallow gulf, had almost lost its tidal character, and become a mere lake. The Kelts of the army forded the water, and the Romans crossed at the bridge. And now the army, much shattered, was in Kent or Surrey. The Emperor Claudius, on hearing the state of affairs, sailed in person with troops to Marseilles, crossed France to the north coast, and landed in Britain to join Plautius. There can be no doubt that he landed at one of the southern ports of Kent, as Winchelsea or Rye (the whole of Kent being evidently held in perfect quiet); and the question arises, Where was Plautius waiting? and where did Claudius join him?

It is possible that Plautius may have waited in the neighbourhood of London Bridge; but I offer a conjecture which I think more probable. In the grounds of Holwood (near Farnborough) at the eastern corner of Hayes Common, at an easy day's march from London, and in the direct line from London to the south-eastern ports, are the extensive remains of the earthworks of a large fort, in the best style of Roman permanent encampments. In its straight lines of outline (where circumstances permit), its rounded angles, its lofty inner rampart and its lower second rampart, it admits of comparison with the most complete of those which Agricola established in his marches through the Scotch Highlands, and which are described in General Roy's "Military Antiquities." It is called, in the neighbourhood, Cæsar's Camp. The little river Ravensbourne (which ultimately joins the Thames at Deptford Creek) rises in a strong spring close to the entrance. I think it probable that Plautius wintered here, and was joined here by Claudius.

The united armies marched at once for Camal-dun, and captured it. And it would seem probable that they immediately gave it its present form, and a fairer or nobler provincial and military capital (as adapted to ancient warfare) within my knowledge nowhere exists. It is planted on a steep parallelogrammic hill. The slope of the ground at the east gate was eased, within my recollection, in the year 1816. On the south side, a little less steep than the other sides, the ground has been heavily scarped, and faced with a stone wall. The whole town is surrounded by a stone wall at the brow of the slope, rounded at the angles; the little river Colne is on the north side, and there the wall is lower in the valley. The dells on the south and west sides converge to an angle, near which is placed the principal gate of the town. The great streets are in the true Roman form of capital **T**, and all the small streets are at right angles. The citadel, I suppose, was in the space on the north side of High Street, in which the castle (a Norman building) now stands.

It would appear that the Romans, as residing in a country which was likely to be troublesome, took early steps for making a great road across it; and then was made the great western road by Marks Tey, Coggeshall, Braintree, Dunmow, to Stortford, on the River Stort (which is the largest affluent of the Lea); and then was formed the large intrenched camp of Wallbury, about two miles south of Stortford, on the Essex side of the river.

And after this was made the road to London. The reason for my placing its date subsequent to that of the western road is singular, but certain. The road to London does not start independently from Colchester: the western road is used as far as Marks Tey, and there the London road branches off at an angle of about 40° (roughly estimated). I have personally surveyed this, taking views from the neighbouring grounds, and can assert that the road from Colchester to Coggeshall passes straight through Marks Tey, totally unaffected by the London road. The same thing is exhibited clearly on our Ordnance map.[1]

All appeared to be peaceably established. And now came the terrible outbreak.

Dion suddenly states that two cities were destroyed (their names or positions are not mentioned), and 80,000 of the Romans and their allies killed, and that this was done by a woman, to the great shame of the Romans; that this was foretold by divine inspiration (τὸ θεῖον); that there came from the Senate-house (βουλευτήριον), at night, barbarous noises, with laughter; from the theatre came a sound of tumult with lamentation, when nobody was near; some houses were seen under water in the Thames; the ocean between Britain and Galatia was disturbed, and had a bloody colour. The cause of the war was the exaction, by Claudius, of money raised by confiscation (δήμευσις), which Claudius gave to the principal men of the Britons

[1] The modern name Marks Tey is an error for Marks Tye, Tye being the customary word in Essex and Suffolk for a bifurcation of roads.

(if I have correctly translated the passage); and Decianus Kalus (the Superintendent of the island) asserted that these sums were to be treated as contributions (ἀναπόμπιμα) to be sent to Rome. To this was added that Seneca—who was not only philosopher, poet, and Minister of State, but also the greatest usurer in Rome—having lent (δανείσας) ten millions (χιλιάδας μυριάδας; which if in sestertii would amount to about 80,000*l*.) ἀκουσιν (I do not understand this word) on sound hopes of interest, suddenly, and with violence, exacted the return of the whole; that it was Boadicea (Voo-doo-ee-ka) who principally caused the rising of the Britons. In the usual history of this lady there is much to be corrected. She was *not* Queen of the Iceni, though of the royal family (γένους τοῦ βασιλείου). She had *no* husband or children. There is not the slightest allusion to *any* personal insult. She did *not* die in battle, but died from disease (νόσῳ) after the battle.

Boadicea, as Dion remarks, was greater than woman. She collected the army of about 120,000 men. She mounted a βῆμα, made in the Roman fashion, to raise her from the mud. She was tall in person, very awful in countenance, with keen eyes and a rough voice; her abundance of yellow hair fell far down her body; she had chain-armour of gold, a variegated vest, and a thick cloak.

A very long speech is given, of which the following are the principal heads:—The superiority of liberty to slavery; the criminal character of the taxes, some even levied from the dead; the Britons themselves are the cause of these evils, not having resisted them soon enough; the habits of our enemies expose them to far greater difficulties than those which we endure; and other remarks, finishing with a kind of enchantment over a hare.

The Britons proceeded to terrible and savage excesses, the worse because Plautius was absent, having gone to Μῶννα; which, if it be the same as the Μόνα of Ptolemy, is the Isle of Anglesey. But this appears to me to be, etymologically, very doubtful; and, practically, I think it very improbable that, in such a state of affairs, Plautius would have gone, by a difficult march, to such a distance. Plautius however returned, and a battle soon took place.

There is no difficulty in fixing on the site of this, one of the great battles of history. In the neighbourhood of Linton, at the north boundary of Essex, in a space perhaps of two square miles, are places which still bear the names of Shudy Camps, Castle Camps, Camp's End, Camp's Green, Camp's Castle. Every one of these has undoubtedly been the scene of a desperate struggle. And, finally, there are the three mighty mounds, known as the Bartlow Tumps, which, as I understand, have been identified as containing Roman remains.

Dion has given a long account of the various phases of the battle. Boadicea died of illness (νόσῳ), and the Britons were driven off the field. The battle was sufficiently decisive to prevent the re-appearance of the Britons in force; but still it appears, I think, not to have made a complete conquest.

The news was welcomed at Rome with very great interest by the Emperor, the Senate, and every rank of society.

G. B. AIRY

THE EUROPEAN PREHISTORIC RACES

IT would be difficult to overrate the scientific value of the discovery of human remains made last summer in Belgium, and briefly noticed in NATURE of February 24 (p. 405). Hitherto serious doubts have prevailed regarding the true character of the Canstadt, Neanderthal, Eguisheim, Olmo, and four or five other skulls, which are collectively referred to the oldest known race in Europe, but which, owing to their apparently exaggerated simian features, have been looked on with suspicion by Pruner, Virchow, and others, as possibly exceptional or even mere pathological specimens. But these doubts have at last been set at rest by the lucky find made last June by MM. Max Lohest and Marcel de Puydt, who, during their explorations of a cave on the slope of a wooded hill on the banks of the Orneau, in the commune of Spy, province of Namur, came upon numerous remains of two individuals amid hitherto undisturbed Lower Quaternary deposits, and in association with the bones of *Rhinoceros tichorinus*, *Elephas primigenius*, *Ursus spelæus*, *Hyæna spelæa*, *Felis spelæa*, the horse, wolf, sheep, and other now extinct and surviving Pleistocene animals. These remains have been carefully examined by M. Julien Fraipont, Professor of Animal Palæontology in the University of Liége, who unhesitatingly refers them to the Palæolithic race, to which King's expression "*Homo neanderthalensis*" may now be confidently applied. Taken especially in combination with the peculiarities of other parts of the skeleton, such as the evidently angular position of femur and tibia, implying a non-erect or stooping attitude in standing or walking, the skulls of the two Spy men show clearly that those of the Canstadt and Neanderthal men are in no way aberrant, but perfectly normal specimens. They obviously represent a Palæolithic and pre-Glacial race, the earliest of which there is any distinct record, which was already spread over West Central Europe in early Quaternary times, and which De Quatrefages and Dr. Hamy now believe may ultimately be traced back to the later Tertiary epoch.

A far better idea of the physical characteristics of the *Homo neanderthalensis* can be had from the remains of the Spy men, than from any others hitherto brought to light. Prof. Fraipont, who devotes a lengthy memoir to the subject in the *Bulletin* of the Royal Belgian Academy for December, gives detailed osteological descriptions of the two more or less perfect skeletons, from which it appears that of one there are extant: the skull, relatively very complete; the right portion of the upper jaw, with five molars; a fragment of the left portion, with the two premolars, incisor and canine; the under jaw, nearly complete, with sixteen intact teeth *in situ*; a left clavicle; the right humerus, less the upper epiphysis; the left humerus, less both epiphyses; the left radius; the right femur, nearly complete; the left femur, complete; the left tibia, complete; the right heel. Several of the parts here missing are supplied by the second skeleton; and there are also numerous vertebræ, fragments of ribs, &c., which cannot with certainty be referred to one rather than the other.

The first skull (No. 1) includes: the frontal bone from the superciliary arches and naso-frontal suture to the parieto-frontal suture; the right parietal, nearly complete; the upper half of the left parietal; the occipital, less a considerable portion of the region of the cerebellum. Of the second skull (No. 2) there remain: the frontal, very nearly complete; the right and left parietals, complete all but a few fragments of the former: the right temporal, nearly complete; the left temporal, complete; the occipital, less a portion of the region of the cerebellum.

The first is very long, very depressed from above, and narrow, being decidedly platidolichocephalic, with cephalic index 70, as compared with 72 of the Neanderthal skull, and 67·65 of the Clichy. The second is sub-platidolichocephalic, with apparent index 74·80, and general characters less pronounced than those of No. 1, but not to such a degree as to prevent the two from being referred to the same race. Of both, the longest antero-posterior diameter is about the same, 200 and 198 to 200 mm. respectively, the former corresponding exactly with the Neanderthal. But the transverse differs considerably, being 140 and 150, between which comes the Neanderthal with 144 mm. On the other hand, the antero-posterior frontal curve of the first coincides exactly with that of the Neanderthal, the frontal itself being, like it, low and retreating. Another typical feature of this frontal is the great development of the superciliary arches, although slightly less prominent than those of the Neanderthal and Eguisheim. The distance between their outer extremities is no less than 122 mm., while the arches converge at the very root of the nose, leaving a slightly depressed intervening glabellar region, this region differing perceptibly from that of the Neanderthal, in which the glabella is prominent.

Although otherwise well preserved, the under jaw of No. 1 unfortunately lacks the condyles, which would have enabled us to settle the important question of its relative prognathism. This jaw is very high and massive, and the well-preserved teeth of both present the general characters found amongst the New Caledonians and other modern races of low type. The canines and incisors of the under jaw are worn obliquely and outwardly, those of the upper jaw obliquely and inwardly, although in general to a less extent than amongst the Neolithic races.

The right femur of No. 1 is not large, but very strong and heavy, and is specially remarkable for its typical forward curvature. The great posterior development of the articular surface of its condyles, taken in connection with the general curvature of the body, shows that the Spy men walked with the knees bent forward, the thigh being obliquely curved forward and downward, and the leg reversed backwards. In other words, the femur was adjusted obliquely to the tibia, which was itself strong, thick and heavy, but very short.

The discoveries at Spy are specially valuable because found associated with other remains which enable us to determine approximately the epoch of analogous finds elsewhere. The already mentioned fauna, as well as the character of the coarse flints occurring in the same undisturbed strata, would seem to indicate that both the Spy men, and their Canstadt and Neanderthal congeners, must have flourished in the *époque Moustiérienne* of French writers, that is, during the early period of the mammoth, and long before the beginning of the Reindeer Age. They were consequently more recent than the race of the *époque Chelléenne*, which was contemporary with *Elephas antiquus*, but of which no actual remains, beyond the objects of its industry, have yet been discovered. That they belonged in any case to pre-Glacial times seems evident from the remarkable absence of the reindeer, which is not numerously met in West and Central Europe till the Ice period.

M. Fraipont's comparative study of these remains makes it thus abundantly evident that they belong to the Neanderthal type. The two skulls even serve as a sort of missing link between the Neanderthal and the others usually referred to the same race. This race, whose presence in Europe during the early Mammoth Age has now been clearly traced from Stængenæs in Scandinavia to Olmo in Italy, seems in a way to have been resuscitated by the fortunate discovery in the limestone cave on the banks of the Orneau. Their dry bones again assume flesh and blood, and science is enabled confidently to describe the men of Spy as a short, but far from "feeble folk," thick-set, robust, walking knees foremost, and with a figure somewhat analogous to that of the modern Lapps, who also still waddle and are nearly all more or less bandy-legged. Their broad shoulders supported a long, narrow, and depressed head (different therefore from that of the true Papuan, which is long, narrow, and high), with very prominent superciliary arches, enormous orbits, low and retreating brow, high and massive cheek-bones, receding chin. No modern race, however low in the scale of humanity, is collectively characterised by all these traits, so that it may be safely affirmed that the ethnical type of the men of the Mammoth Age has become practically extinct, either through further evolution within itself, or by extirpation, or more probably by fusion with men of a higher physical standard.

It is noteworthy that the points which most separate the men of Spy from the present inhabitants of the globe are precisely those which bring them into closer relation with the anthropoid apes in general, rather than with any particular species of anthropoids. These points, which may thus fairly be described as pithecoid or simian, are chiefly: the prominent superciliary arches, normal in the young male gorilla and adult female orang; the extremely low retreating frontal, constant in the chimpanzee of both sexes and all ages; the almost chinless receding lower jaw, highly typical of gorilla and chimpanzee; lastly, the peculiar curvature of the femur, combined with its adjustment to the tibia, suggesting in the vertical position an attitude somewhat analogous to that of chimpanzee and gorilla. On the other hand, all the other features of cranium, trunk, and limbs are distinctly human, while the cranial capacity alone would suffice to justify the claim of *Homo neanderthalensis* to membership with the human rather than with the simian family. However great the distance separating him even from the lowest of modern races, far greater, undoubtedly, is the interval between him and the highest of the modern anthropoids. At the same time this interval becomes perceptibly diminished by Gaudry's discovery of *Dryopithecus fontanii*, an anthropoid ape of the middle Miocene epoch certainly less simian, or rather more human, than any of its present congeners. Its lower jaw is perceptibly less receding than that either of the gorilla, orang, or chimpanzee. The interval tends to be still further reduced when we remember that, although the *Homo neanderthalensis* is the earliest human type of which any bodily remains have hitherto been discovered, there is a still more primitive race revealed to us by the rude palæolithic implements frequently occurring in association with *Elephas antiquus*, and in later Tertiary deposits considerably older than the Lower Quaternary of the Spy cave. Whenever any characteristic remains of this primæval race come to light, a distinct approach will have been made towards a solution of the difficult questions connected with the genetic descent of mankind.

A. H. KEANE

AN EXAMINATION OF THE LEAVES OF GYMNEMA SYLVESTRE[1]

GYMNEMA SYLVESTRE (R. Br.) is an asclepiadaceous plant growing in the Deccan peninsula, from Concan to Travancore; it is also met with in Assam, and on the Coromandel coast, and is distributed in the continent of Africa. It is a stout woody climber, with long slender branches.

The leaves are opposite, entire, from 1½ to 3 inches long, and from 1 to 2 inches broad, elliptic or obovate, acute or cuspidate, rarely cordate at the base, membranous, thinly pubescent on both sides, the upper surface of a darker green than the lower. *Gymnema sylvestre* is mentioned in the non-official list in the Pharmacopœia of India (1868), and in Dr. Dymock's "Materia Medica of Western India." The powdered root has for a long time been known among the Hindus as a remedy for snake-bites; in such cases it is applied locally to the part affected, and also taken internally in the form of a decoction. But the most curious circumstance connected with this plant was first noticed by Mr. Edgeworth, who discovered that by chewing some of the leaves it destroyed the power of the tongue to appreciate the taste of sugar; he found that powdered sugar, taken immediately after masticating some of the leaves, tasted like so much sand in his mouth, and this effect lasted for twenty-four hours. Dr. Dymock, reviewing this property, said he was unable entirely to confirm this statement; his experience was that sugar taken into the mouth after chewing the fresh plant had a saltish taste, but was still easily recognisable.

[1] A paper read at a meeting of the Nilgiri Natural History Society Ootacamund, by David Hooper, F.C.S., March 7, 1887.

Some authentic leaves were procured by Mr. Lawson from Guindy Park, Madras, who placed them at my disposal for chemical examination. They had a bitterish astringent and slightly acid taste. After chewing one or two leaves it was proved undoubtedly that sugar had no taste immediately afterwards; the saltish taste experienced by others was due to an insufficiency of the leaf being used. Sugar in combination with other compounds in dietetic articles is plainly destroyed as to its taste after using these leaves. In ginger-bread, for instance, the pungency of the ginger is alone detected, the rest is tasteless meal; in a sweet orange the taste of the sugar is so suppressed and that of the citric acid consequently developed that in eating it resembles a lime in sourness. Among the several kinds of foods, drugs, and beverages which affect the palate Gymnema does not pretend to render them all tasteless; it does not affect pungent and saline things, astringents, and acids. It is limited to apparently two diverse substances, sweets and bitters. It has been noted that sugar taken after the leaf tastes like sand, so I have found that sulphate of quinine taken after a good dose of the leaf tastes like so much chalk. I am not going to propose its use in the administration of nauseous drugs, until the medical properties of the Gymnema have been more studied, otherwise the quantity of the vehicle taken may prove to counteract the effect of the medicines. The experience of several friends as well as my own is that the effect does not last for twenty-four hours as stated, but for only one or two hours; after that time the tongue resumes its appreciation of all that is sweet or bitter.

The powdered leaves were submitted to the action of various solvents, and by this means it was ascertained that the peculiar property of Gymnema leaves was dissolved out by alcohol, and, as it occurred in the aqueous extract of the residue, it was therefore soluble in water. As benzene and ether took from the leaves certain principles of the same appearance and weight, it was conceived that nothing would be gained by using both solvents; the preliminary extraction was therefore made with ether rectified from water and spirit. The ether extract consisted of chlorophyll and two resins separated by their solubility in alcohol. The resin insoluble in spirit formed the larger portion; it was soluble in chloroform, bisulphide of carbon, and benzene. It was elastic and tenacious, decomposed by warming with nitric acid, the product being precipitated with water; only partially saponified with caustic potash. Sulphuric acid dissolved it in the cold, giving a green solution. It seemed to consist principally of a neutral resin. The resin soluble in spirit was readily saponified with soda, and gave a permanent bluish-green colour with sulphuric acid; like the former resin, it was of an acrid nature, and left a tingling sensation in the throat.

The alcoholic solution of the leaves was almost entirely soluble in water; in fact, by treating the leaves separately by alcohol and water, 36·37 per cent. organic matter was extracted; by treating the drug with water alone 36 per cent. was removed. By direct experiment it was found that in the former extract 0·47 per cent. was an acrid resin similar to those found in the ether extract. The aqueous solution of the substances soluble in alcohol had a decidedly acid reaction; it gave no coloration with ferric chloride, showing absence of tannin. It was deepened in colour with alkalies, but gave a bulky precipitate with sulphuric, nitric, hydrochloric, and acetic acid. It reduced Fehling's solution on boiling, and gave a cloudiness with Nessler, a precipitate with lead acetate, but none with tannin or picric acid. The precipitate caused by sulphuric acid was collected on a filter and washed till it ceased to give a cloudiness with barium chloride. It yielded a greenish powder, insoluble in water, but soluble in alcohol, ether, benzene, and chloroform. With potash, soda, and ammonia it afforded fine red solutions with orange-coloured froth, but they were both precipitated on the addition of the mineral acids. It dissolved in concentrated sulphuric and nitric acids with intense red colour, but in both mixtures it was destroyed and precipitated by water. It fused at about 60° C. into a blackish brittle mass. Heated in a test-tube it gave off fumes of creosote, but no crystals were obtained in a subliming apparatus. Gently ignited it burned with a bright flame, leaving no ash. It was thrown down as a bulky gray mass by acetate of lead; the lead salt decomposed by sulphuretted hydrogen in water left the substance in the reddish evaporated filtrate from the lead sulphide. The body just described has the characteristics of an organic acid related in some particulars to chrysophanic acid, but having some distinctly peculiar reactions, and possessing the anti-saccharine property ascribed to the leaves. I propose to call it *Gymnemic acid.*

Gymnemic acid forms more than 6 per cent. of the constituents of Gymnema leaves, in combination with a base which has not been isolated. Another organic acid was present in the lead acetate precipitate, which was identified as tartaric acid. The filtrate from the insoluble lead compounds was treated with sulphuretted hydrogen gas, and the clear liquor after evaporation was examined for sugar. Glucose was detected in some quantity by its immediate and abundant reduction of Fehling's solution; the sugar examined in a polariscope had a left-handed rotation.

Chloroform agitated with an alkaline solution of the leaf left a crystalline residue of a brownish colour; it had a bitter taste, and acted as a sialagogue. With the ordinary alkaloidal reagents it afforded coloured precipitates, but was a neutral principle. Its further examination together with that of gymnemic acid are reserved for further investigation.

The leaves after being exhausted with ether and then alcohol were treated with water. The gum was detected and estimated in the usual manner. A carbohydrate, optically inactive, and, after boiling with acid, reducing Fehling's solution, was found in this extract.

Diluted soda removed a brownish liquid which consisted of albuminous matters only partially soluble in alcoholic and acetic acid. These were not weighed but calculated by difference.

A solution of 1 per cent. hydrochloric acid was employed to remove the oxalate of calcium. A microscopical examination of the powdered leaves showed a fair sprinkling of the conglomerate crystals or raphides so well known to exist in rhubarb. The dilution of the acid menstruum rendered this process very tedious, so a stronger acid was used and the marc washed with it until ammonia produced no cloudiness. The collected liquors were allow to deposit, the sediment was then collected on a filter, dried and weighed; then incinerated and weighed again. The calcium carbonate was calculated into oxalate, and the difference between this and the first weighing was reckoned as pararabin. No oxalic acid was found in a free state.

The ash of *Gymnema sylvestre* is very high, a fact in accordance with the amount of lime salts it contains. Gentle ignition of the air-dried leaves left as much as 11·65 per cent., and about one-half of this was calcium carbonate. One hundred parts contained—

15·41 soluble in water.
78·71 soluble in acid.
5·88 sand and siliceous residue.

The cellulose was estimated by steeping the leaves in sulphuric acid of specific gravity 1·50 for 30 hours, washing, drying, burning, and deducting the ash; this result did not differ materially from the weight of the totally exhausted powder treated with chlorine water.

The following is a tabulated analysis of the powdered and sun-dried leaves:—

Ether extract (chlorophyll and resins) ...	5·51
Alcoholic extract (gymnemic acid, tartaric acid, glucose, neutral bitter principle, resin, &c.)	19·50
Aqueous extract (gum 1·45 per cent., glucose, carbohydrate, and extractive) ...	16·87
Alkaline extract, by difference (albuminous and colouring matters)	8·15
Acid solution { calcium oxalate	7·64
Acid solution { pararabin...	2·74
Ash (balance of)...	5·69
Cellulose	27·86
Moisture	6·04
	100·00

NOTES

THE Conference called by the French Government to consider the means to be adopted for the construction of a photographic chart of the heavens, meets at Paris on Saturday next. We believe that the Astronomer-Royal and Mr. Common have been delegated to represent the Royal and the Astronomical Societies.

THE Rev. S. J. Perry and Dr. Copeland have accepted Dr. Bredichin's invitation to observe the total solar eclipse in August next at his residence near Moscow.

WE regret to announce the death of Dr. Daniel Rutherford Haldane, who was for some time President of the Royal College of Physicians of Edinburgh. In response to a request by that body he represented the College in the General Council of Medical Education and Registration in the United Kingdom. He died at his residence in Edinburgh on Tuesday last.

THE annual Conference of the National Union of Elementary Teachers, which has met this week at Portsmouth, has been remarkably successful. It has been attended by about 400 delegates from the different affiliated associations, and by a number of individual members. In his inaugural address, Mr. Girling, the President, made some sensible remarks on technical education in elementary schools. Handicrafts could not be taught in elementary schools, but he was decidedly of opinion that our system of primary education ought to be better adapted to fit children for work when they leave school. He testified to the enterprise and public spirit of the City Guilds, and their Secretary, Sir Philip Magnus, who had started handicraft classes for elementary teachers in London. But he would ask them to co-operate in helping to make our educational system a more rational one. Then the teachers would have most valuable aid in preparing the future working-men of the country on intelligent lines, and the technical training of children, now so well begun in our infant-schools through the medium of kindergarten exercises, might be carried still further in the senior schools. At the meeting on Tuesday, a resolution was unanimously passed in favour of the appointment of a Minister of Education. Mr. Salmon, by whom this resolution was proposed, maintained that many educational questions of the highest importance could be adequately settled only by a Minister of much ability and wide experience, invested with large authority and bearing direct and undivided responsibility. Given such a Minister, with great power and noble opportunities, they could justly look to him for great efforts and noble issues.

THE fourth Bulletin of Miscellaneous Information, issued from the Royal Gardens, Kew, contains papers on Manilla hemp, plantain and banana fibre, and pine-apple fibre. Manilla hemp is one of the most important of cordage fibres, and the whole supply comes from the Philippine Islands. Everything made from it can be easily converted into paper of excellent quality. A plant of Manilla hemp may be seen in the Palm House at Kew; and sets of exhibits in the Kew Museum, No. 2, include the raw fibre, cables, ropes, twine, fine muslin fabrics, "half-stuff," and paper of all kinds, the latter being made from old Manilla ropes. Manilla hemp plants have been introduced from Kew to Jamaica, and to other portions of the West Indies. In favourable situations they grow well, but not so readily as the ordinary bananas and plantains. As the fruit is valueless, they can only be grown for the sake of the fibre, and this alone does not appear to offer sufficient inducement to plant up large areas.

AN Exhibition of the products of the Philippine Archipelago is to be opened at Madrid on June 1. It is to be divided into eight sections, with corresponding sections in the Central Commission at Manilla. Amongst these the following are of specially scientific interest:—(1) For the study of the geography, meteorology, terrestrial magnetism, orography, hydrography, anthropology, geology, and mineralogy of the Philippines; (4) the botanical geography of the archipelago, its fauna and flora; (8) general education, public instruction, and the arts and sciences in the Philippines generally. Sub-commissions have been appointed in all the chief places in the archipelago to collect objects for exhibition and information, to be forwarded to the Central Commission, and thence to Madrid.

DURING the next three months a course of lectures on zoology will be delivered at the Zoological Gardens, Regent's Park, by Prof. Beddard. The lecturer will try to make the subject intelligible and attractive to young people, and as the cost will not exceed the bare price of admission to the Gardens, it may be hoped that the course will be largely attended. The arrangements have been made by the Association for the Extension of University Education.

A SMALL Industrial Exhibition was opened on Tuesday last at the Flora Gardens Board School, Hammersmith. Its object is to encourage home industries among the poor.

THE twelfth annual meeting of the members of the Sunday Society was held on Monday, April 4, at the Conduit Street Galleries, Mr. R. Carter in the chair. Mr. Mark H. Judge, Hon. Sec., read the annual report, which claimed for the past year that never before had there been so many or such decisive expressions of public opinion in favour of the Society's object.

A REMARKABLE illustration of the puzzling migratory habits of the herring has just been observed on the south-west coast of Norway, at the so-called Jæderen, between the towns of Stavanger and Egersund. This district used to be one of the richest herring-fishing grounds in Norway during the spring, but about twenty-five years ago the fish suddenly and completely disappeared from the coast. Last month enormous shoals once more came under shore, first "striking land" at the same spot as in former times. The quality of the herring is exactly the same as it was twenty-five years ago, and the shoals were accompanied by numerous "herring" whales.

THE first and second parts of a Catalogue of the remains of Siwalik Vertebrata contained in the Geological Department of the Indian Museum, Calcutta, have been sent to us. The work is compiled by Mr. Richard Lydekker, who says that the magnificent Siwalik collection in the Indian Museum is equalled only by that of the British Museum.

AN Exhibition of Seeds will take place at Trondhjem, from July 4 to 10, in connection with the eighth general Norwegian Agricultural Meeting. At the same time, lectures on the subject will be delivered to the meeting, and a Fisheries Exhibition will also be held.

Dr. Franz Boas, who visited the Indian tribes of British Columbia in the autumn of 1886, has presented in a preliminary Report some of the results of his journey. The large wooden huts of these tribes, their canoes, their fishing-gear, and hunting-methods have often been described, but Dr. Boas points out that their traditions, religious ideas, and social organisation are not equally well known. The principal figure in the mythology of several of them is a raven, who created all things, not for the benefit of mankind, but "in order to revenge himself." Cannibalism is practised by some tribes in connexion with the winter dances; and there is a Kwakiutl tradition, to the effect that one of their ancestors descended from heaven, wearing a ring of red-cedar bark, and taught the people the cannibal ceremonies. These ceremonies have been adopted only in part by the Qomoks, who content themselves with eating "artificial" bodies, which they prepare "by sewing dried halibut to a human skeleton." Among the Tsimpshian, the Tlingit, and the Haida, children belong to the mother's gens; among the Kwakiutl and Selish tribes they belong to the gens of the father. In some tribes there are as many as from fifteen to twenty gentes. Members of the same gens are not allowed to intermarry.

A work on "Physiological Psychology," by Prof. George T. Ladd, of Yale, will shortly be published. The writer, according to *Science*, maintains "a philosophical and psychological stand-point, while admitting to their proper place the conclusions reached by physiology respecting the nature and functions of the nervous system."

The new numbers of "Studies in Microscopical Science," edited by Mr. A. C. Cole, deal with defoliation, spermatozoa in the Invertebrata, acute parenchymatous nephritis, fibrosis of kidney, and microbes.

The seventh Deutsche Geographentag will be held at Carlsruhe to-day. The chief papers will relate to the German African colonies.

Shocks of earthquake were felt at Friedau (Carniola) on March 27, and at Travnik, in Bosnia, on March 31, at 3.30 a.m. In the night of April 1 there was a severe shock at Forli, in Italy.

We have received from the Johns Hopkins University a new number (vol. iii. No. 9) of the series of "Studies from the Biological Laboratory." These "Studies," issued from time to time, contain most of the original scientific papers published by members of the Biological Department of the University. The editor and associate-editor are Dr. H. Newell-Martin and Dr. W. K. Brooks. The present number is a paper, by Dr. J. R. Duggan, on the influence of alcohol on the conversion of starch by diastase.

In a statistical work which is being published, M. E. Levasseur, of Paris, shows that the chances of living long at any given age are much greater now in France than they were before 1789. Of 2000 infants (under one year) 1186 survived in 1789; 1460 survive at present. In 1789, 738 persons out of 2000 reached the age of 40; the number now is 1110. In 1789, 144 persons out of 2000 lived to the age of 75; the number now is 360. The death-rate of France is much the same as that of England, being rather superior at some ages, and inferior at others.

Dr. Dudgeon, of Pekin, has at last published in Chinese a complete work on anatomy, at which he has been working for some years past. The printing was done by the press of the Tung-Wên or Foreign Language College, and the whole expense was borne by the Chinese Government. In accordance with Eastern custom, the title-page of the book is written by one of the Chinese Ministers who is celebrated for his beautiful calligraphy, and there are several prefaces by some of the highest officials of the Empire commending the work to the study of their countrymen. There are in all six volumes, two containing the illustrations, six hundred being plates. The latter were cut on blocks by native artists. Copies were presented to all the Ministers and other high officials. The companion work on physiology is almost ready for the press.

In an article on "The Phylogeny of the Camelidæ," lately printed in the *American Naturalist* extra, Mr. E. D. Cope points out that the development of the camel in North America presents a remarkable parallel to that of the horse. The ancestors of both lines appear together in the Wasatch or lowest Eocene, and the successive forms develop side by side in all the succeeding formations. Both lines died out in North America, and of the two, the camels only have certainly held their own in South America. The history of the succession of horses in Europe, although not so complete as that in America, extends over as wide a period of time. Not so with the camels. There is no evidence of the existence of the camel line in the Old World before the late Miocene epoch; and so far as the existing evidence goes, the New World furnished the camel to the Old.

In the *American Meteorological Journal*, Mr. M. W. Harrington is giving a full and very interesting account of the Chinook winds. The "Chinooks" are warm, dry, westerly or northerly winds occurring on the eastern slopes of the mountains of the north-west, beginning at any hour of the day, and continuing from a few hours to several days. Mr. Harrington says they may occur when a cyclone or anticyclone passes on such a course that the air is forced over the mountains from the western to the eastern slope. They are, therefore, winds similar to the "föhn" of Switzerland. In adding them (as Mr. G. M. Dawson, of the Geological Survey of Canada, had already done) to the class of winds of which the "föhn" is the type, Mr. Harrington points out that he is simply adding another to an already extensive list. Dr. Jelinek, in 1867, called attention to the fact that winds on the eastern slopes of the Caucasus were of this character. A similar wind occurs under the lee of the Elburz Mountains. Trebizond is in the lee of a high range of mountains, and has similar winds. They are common on the north side of the Pyrenees, and on the south coast of the Bay of Biscay. A similar wind has long been known in West Greenland, and Hoffmeyer proved, some years ago, that it is of the same character as the "föhn." It has been felt as far north as $82\frac{1}{2}°$ of latitude. Mr. Scott suggests that the hot winds of South Africa and parts of Australia are of the same character, while the analogy is proved complete for the hot "north-westers" of the Canterbury Plains of New Zealand.

The first number of the American journal *The Stevens Indicator*, in its new form as a quarterly, contains an article giving a glowing account of the general prosperity of the Stevens Institute. The advance secured is attributed mainly to the wise and energetic leadership of President Morton. "To him," says the *Indicator*, "belongs the honour of realising, more than twenty years ago, when the Institute was first planned, that it would find its most useful work in the then almost unoccupied field of mechanical engineering, and that to this work it should confine, for a series of years at least, all its resources and efforts. How well the plans have succeeded is borne out by the long list of graduates who have been sent forth into positions of honour and trust, of influence and remuneration, by Stevens Institute during the last twelve years."

Capt. Gates, of the ship *L. Schepp*, has reported to the U.S. Hydrographic Office that on April 19, 1886, when he was off Cape Horn, on a voyage from San Francisco to Liverpool, the temperature of the water suddenly rose from 42° to 44°. Thinking that the vessel was too close in shore, he hauled off three points, and, after he had stood four hours on this course, he found that the temperature had fallen to 42°. On a previous voyage Capt. Gates noticed this warm belt.

COMMISSIONER COLMAN, of the Department of Agriculture in the United States, has issued a Circular relating to the so-called Australian rabbit. He points out that this animal—the common rabbit of Europe—has been very mischievous in Australia, and expresses his belief that its introduction into America would be an unnecessary and hazardous experiment. Mr. Colman is of opinion that Congress should pass a law conferring upon the Commissioner of Agriculture the power to prevent the landing of any animal, bird, or other pest that might be injurious to agriculture; and he cites the case of the English sparrow as an example of the harm that may be done by species taken without due consideration from the Old World to the New.

THE Swedish Government is anxious to acquire a colony in Africa, and is consequently preparing an Expedition under the direction of Lieut. A. Wester, formerly Chief of the Congo Station, Leopoldville. At the last meeting of the Stockholm Society of Anthropology and Geography, Lieut. Wester reported on the subject. The Expedition may probably start next summer, and will be absent about a year, making Cameroon its base of operations. The cost will be about 160,000 kroner (8000*l.*).

MR. PAUL BEDFORD ELWELL will publish shortly, with Messrs. Whittaker and Co., an English translation of Gaston Planté's work on "The Storage of Electrical Energy."

THE eighth volume of the Journal of the Royal Horticultural Society, just issued, consists of a valuable Report on the effects of the severe frosts on vegetation during the winters of 1879-80 and 1880-81. The Report has been prepared by the Rev. Geo. Henslow, Honorary Secretary to the Scientific Committee of the Royal Horticultural Society. Most of the facts were obtained by means of schedules issued in 1880 and 1881.

A WORK entitled "The Australasian Federal Directory of Commerce, Trades, and Professions," will shortly be published in London under the direction of Mr. J. W. F. Rogers, of Melbourne and Sydney. It has been compiled by the assistance of some thousands of persons, many of them Colonial Government officials, and will give both in an alphabetic and a classified form the business addresses for over three thousand Australasian towns, large and small. Reviews of the social and commercial development of the eight colonies of this group will appear in the Directory, with maps and gazetteer.

AN ingenious system of gas-lighting by electricity has been introduced by Messrs. Woodhouse and Rawson. Gas can be turned on, lit, and turned off from any convenient position irrespective of where the gas-fittings are placed. The principle of attachment is like that of the portable electric gas-lighter—*i.e.* the gas is lighted by an electric spark—but the general arrangements are for permanent fitting.

WE have received the fifth and sixth parts of the fourth volume of Dr. L. Rabenhorst's elaborate "Kryptogamen-Flora von Deutschland, Oesterreich, und der Schweiz." The subject dealt with is Bryineæ: Stegocarpæ (Acrocarpæ). The text is finely illustrated.

THE second part of the Report for 1885 of the Chief Signal Officer of the United States, is a separate treatise by Prof. William Ferrel, entitled, "Recent Advances in Meteorology, systematically arranged in the form of a Text-book, designed for use in the Signal Service School at Fort Meyer, and also for a Hand-book in the Office of the Chief Signal Officer." It is an octavo volume of 440 pages, and is published by the U.S. Government.

THE sixty-fourth number of the Journal of the Society of Telegraph-Engineers and Electricians, contains "The Pre-Determination of the Characteristics of Dynamos," by Mr. Gisbert Kapp; "Some Experiments on Secondary Cells," by Mr. James Swinburne; and "Some Magnetic Problems," by Prof. George Forbes. Reports of the discussions on these papers are also given.

A PERMANENT matrix excluder of draught and dust has been sent to us by Mr. T. J. Porter, the inventor. The excluder is made of a special composition inclosed in long, narrow strips of warm-coloured cloth, and moulded into a suitable form. The application of hot water enables the excluder to be formed into a long, narrow, solid, and permanent matrix round doors and windows. Mr. Porter says that it makes a practically air-tight joint, and entirely precludes the passage of draught and dust between doors and their casings, and windows and their casings.

A HALIBUT weighing thirty-four pounds and measuring 41 inches in length was captured lately in the lower Potomac, near Colonial Beach. It has been preserved in alcohol by the Smithsonian Institution, and a cast has been made and placed on exhibition in the U.S. National Museum. *Science* says this is the first authentic case of a halibut in fresh water.

THE additions to the Zoological Society's Gardens during the past week include a Short-tailed Wallaby (*Halmaturus brachyurus*) from Australia, presented by Mr. Herbert Maude; an American Flying Squirrel (*Sciuropterus volucella*) from North America, presented by Mr. A. R. Verschoyle; an Egyptian Mastigure (*Uromastix spinipes*) from North Africa, presented by Mr. V. J. Chamberlain; a Nepal Hornbill (*Aceros nepalensis*) from Nepal; a Tuberculated Iguana (*Iguana tuberculata*) from the West Indies, deposited; a Burchell's Zebra (*Equus burchelli*) from South Africa; two Adorned Ceratophrys (*Ceratophrys ornata*); an Anaconda (*Eunectes murinus*) from South America, purchased; a Rhesus Monkey (*Macacus rhesus*), a Sambur Deer (*Cervus aristotelis*), two Collared Fruit-Bats (*Cynonycteris collaris*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

ORBIT OF THE BINARY STAR 14 (*i*) ORIONIS.—In the *Monthly Notices* for March, Mr. J. E. Gore publishes elements of the orbit of this binary, which is identical with O Σ 98. Mr. Gore's results, which he regards as only provisional, give a period of 190·48 years, time of periastron passage 1959·05, eccentricity 0·2465, and semi-axis major 1″·22. A comparison of places computed from these elements with the observations extending from 1844 to 1887, shows considerable discordances in the position-angles, whilst the distances agree very closely. The orbit of this double star does not appear to have been previously computed.

THE WASHINGTON OBSERVATORY.—Capt. R. L. Phythian, U.S.N., the Superintendent of the U.S. Naval Observatory, has published the programme of work to be pursued at the Observatory during the year 1887. From it we learn that with the 26-inch equatorial the observations of double stars, of the fainter stars in the Pleiades, and of the conjunctions of the five inner satellites of Saturn with the minor axis of the ring, and of the angles of position and distances of Hyperion will be continued during the year. The small equatorial will be used for observations of comets and of occultations of stars by the moon, as well as of stars and asteroids required for purposes of identification. With the transit-circle it is proposed to complete the observations of miscellaneous stars for the forthcoming transit-circle catalogue and also to observe the sun, moon, planets (major and minor), and stars of the American Ephemeris. Photographs of the sun will be taken daily, when practicable, with the photo-heliograph of the Transit of Venus Commission pattern.

NAMES OF MINOR PLANETS.—Minor planets Nos. 263 and 265 have been named *Dresda* and *Anna* respectively.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *APRIL* 17–23

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on April 17

Sun rises, 5h. 2m.; souths, 11h. 59m. 33·9s.; sets, 18h. 57m.; decl. on meridian, 10° 28′ N.: Sidereal Time at Sunset, 8h. 39m.

Moon (New on April 23) rises, 3h. 3m.; souths, 7h. 53m.; sets, 12h. 49m.; decl. on meridian, 14° 2′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury ...	4 29	10 22	16 15	2 9 S.
Venus ...	6 6	14 5	22 4	20 54 N.
Mars ...	5 8	12 7	19 6	10 45 N.
Jupiter ...	19 11*	0 20	5 29	10 37 S.
Saturn ...	9 20	17 29	1 38*	22 26 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

April	h.	
18	21	Mercury at greatest elongation from the Sun, 27° west.
20	21	Mercury in conjunction with and 0° 31′ north of the Moon.
21	11	Jupiter in opposition to the Sun.

Variable Stars

Star	R.A. h. m.	Decl. ° ′		h. m.

δ Cephei ...	22 25·0	57 50 N.	,, 20,	4 0	*M*
			,, 23,	22 0	*m*

M signifies maximum; *m* minimum.

Meteor-Showers

The most interesting shower of the week is that of the *Lyrids*, April 18–20, R.A. 268°, Decl. 33° N. Other showers are as follows:—Very slow meteors from a radiant between Boötes and Virgo, R.A. 213°, Decl. 9° N.; very swift meteors from near π Herculis, R.A. 255°, Decl. 37° N., and from Vulpecula, R.A. 299°, Decl. 24° N.

VALENCY AND RESIDUAL AFFINITY[1]

I.

In my address to the Chemical Section of the British Association at Aberdeen, I specially called attention to the "affinity" of *negative* elements—chlorine, oxygen, sulphur, &c.—for negative elements; and I sought to show that the formation of so-called *molecular compounds* is largely, if not entirely, an outcome of this peculiarity of negative elements. I also ventured to suggest "that in electrolysing solutions, the friction arising from the attraction of the ions for each other is perhaps diminished, not by the mere mechanical interposition of the *neutral* molecules of the solvent—in the manner suggested by F. Kohlrausch—but by the actual attraction exercised by these molecules upon the negative ion in virtue of the affinities of the negative radicles." In this passage I but vaguely hinted at a modification of the current theory of electrolysis which had occurred to me: as further consideration of the question, especially of Ostwald's electro-chemical studies, has strengthened my views, I am led to think that it may be justifiable to submit them for discussion.

It is usual to divide bodies into three classes according to the mode in which they are acted on by an electromotive force: metals forming one class, electrolytes a second, and dielectrics a third. In making this division, perhaps the fact is not sufficiently borne in mind that some compounds—silver chloride, for example—are *per se* electrolytes, while others—such as hydrogen chloride and water—are *individually* dielectrics, but behave as electrolytes when conjoined. On this account, it appears to me desirable to distinguish between—

(*a*) *Metals.*

(*b*) *Simple* electrolytes—compounds like silver chloride which in the pure state are electrolytes.

(*c*) *Pseudo*-dielectrics — compounds like water, hydrogen chloride, and sulphuric acid, which behave as dielectrics when *pure*, but as electrolytes when mixed with other members of their own class. Conducting mixtures of members of this class may conveniently be termed *composite electrolytes.*

(*d*) Dielectrics.

Simple Electrolytes.—It is undoubtedly a fact that only a limited number of binary compounds are simple electrolytes; and it is especially noteworthy that, with the single doubtful exception of liquefied ammonia, no hydrogen compound—whether binary or of more complex composition—can be classed with the simple electrolytes. Indeed, all the simple electrolytes with which we are acquainted are either compounds, such as the *metallic* chlorides; or *metallic* salts—nitrates, sulphates, &c. Including metallic chlorides and their congeners and the corresponding oxides and hydroxides among salts—regarding water as an acid, in fact—and denying the title of salts—hydrogen salts—to the acids, Hittorf's proposition (*Wied. Ann.*, 1878, iv., p. 374), "Electrolyte sind Salze" may be safely upheld. But only some of the binary metallic salts are electrolytes: beryllium chloride, for example, belongs to the class of "pseudo-dielectrics" (Nilson and Petterson, *Wied. Ann.*, 1878, iv., p. 565; Humpidge, Phil. Trans., 1883, p. 604); and in the case of those elements which readily form two classes of salts—so-called *ous* or *proto*-salts and *ic* or *per*-salts, the *ous* compounds alone appear to be electrolytes.

It is highly remarkable that whereas fused silver chloride is easily decomposed on passage of a current of low electromotive force, hydrogen chloride is a "pseudo-dielectric" which forms when coupled with the "pseudo-dielectric" water a readily conducting "composite electrolyte"; while mercuric chloride conducts with great difficulty—possibly not at all when pure—not only in the fused state, but even when coupled with water. No explanation of these facts seems to be afforded by thermo-chemical data.

The consideration of these and other similar cases, I think, can but lead to one conclusion: that electrolysability is conditioned both by the nature of the elements in the compound and its molecular structure.

The remarkable difference in the electrical behaviour of two compounds of the same element, such as stannous chloride, in which the ratio of tin to chlorine atoms is as 1 to 2, and stannic chloride, in which Sn : Cl = 1 : 4—the one being a simple electrolyte, the other a pseudo-dielectric, if indeed it be not a dielectric—would appear almost to justify the conclusion that in the case of per-salts such as stannic chloride the metal is, as it were, enveloped in a non-conducting sheath of the negative radicle. But whether this be so or not, if—as appears to be the case—all simple electrolytes are *metallic* compounds, and if only proto-salts are electrolytes, may it not be that electric conduction in simple electrolytes is of the nature of ordinary metallic conduction, differing from it only in the circumstance that the compound is decomposed as a consequence of the passage of the current?

This would lead to the conception of an electrolyte as being a metallic compound of such elements, and so constituted, that electric conduction may take place through its mass in a manner similar to that in which it takes place through a mass of metal: in fact, through the agency of its metallic atoms. On this view, it is essential that the metallic atoms in the molecules comprising a mass of an electrolyte should be in proximity—as they probably are in proto-salts, but not in many per-salts. The conductivity of two-metal alloys is in many cases much less than that of either of the contained metals: for example, the conductivity of the alloy $SnCu_4$ is about one-fourth that of tin and about one-thirtieth that of copper. The specific conductivity of metals may, therefore, be much reduced by association with one another; and this being the case, it appears probable that the specific conductivity of a metal would be still more reduced by association with a non-metal, and that if the metal were one of low specific conductivity, it might thus practically become altogether deprived of conducting power: perhaps the "excep-

[1] Revision and extension of a paper by Prof. H. E. Armstrong, F.R.S., communicated to the Royal Society last year.

tional" behaviour of mercuric and beryllium chlorides is to be explained by considerations such as these.

To discuss such questions at all satisfactorily, however, we require to know much more of the electrical behaviour of *pure* fused salts. It is surprising how little accurate knowledge we possess on this subject.

Composite Electrolytes.—I assume it to be admitted that neither water nor liquid hydrogen chloride, for example, is an electrolyte, although an aqueous solution of hydrogen chloride conducts freely, and is electrolysed by an electromotive force of but little more than a volt.

The theory put forward by Clausius in 1857 in explanation of electrolysis (cf. Clerk Maxwell's "Elementary Treatise on Electricity," p. 104), has been widely accepted by physicists; but it appears to me that, on careful consideration of the evidence, and especially of recent exact observations on conditions of chemical change, it must be admitted, as I have elsewhere contended (B. A. Address), that proof is altogether wanting of the existence of a condition such as is postulated by Clausius. Moreover, it has been shown by Hittorf that cuprous and silver sulphides, and by F. Kohlrausch that silver iodide, all undergo electrolysis in the *solid* state: the partisans of the dissociation hypothesis would, I presume, scarcely contend that it is easily applicable to such cases as these. It also does not appear to afford any explanation of the *abrupt* change in conductivity which occurs in solid silver iodide and sulphide as the temperature is raised; nor of the peculiar variation in conductivity which is observed on diluting sulphuric acid with water.

Again, I venture to think that the conductivity of a *mixture* of compounds which themselves have little or no conducting power is accounted for in but an unsatisfactory and insufficient manner by the hypothesis put forward by F. Kohlrausch (*Pogg. Ann.*, 1876, clix., p. 233); there appears to be *far too great a difference* in the behaviour of the pure compounds, water and liquid hydrogen chloride for example, and of a mixture—no decomposition apparently of either *compound* being effected by any electromotive force short of that which produces disruptive discharge, although the *mixture* of the two will not withstand an electromotive force of little more than a volt. Influenced by these considerations, I am led to conclude that there is no satisfactory evidence that the constituents of the electrolyte either are free prior to the action of the electromotive force, or are primarily set free by the effect produced by the electromotive force upon either member *separately* of the *composite* electrolyte; but that an additional influence comes into play, viz. that of the one member of the composite electrolyte upon the other while both are under the influence of the electromotive force. This influence, I imagine, is exerted by the negative radicle of the other member. Assuming, for example, that in a solution of hydrogen chloride in water the oxygen atom of the water molecule is straining at the chlorine atom of the hydrogen chloride molecule, if when subjected to the influence of an electromotive force the molecules are caused to flow past each other—the phenomena of electric endosmose may be held to afford evidence that in composite electrolytes the molecules are thus set in motion—it is conceivable that this influence, superadded to that of the electromotive force upon the electrolyte, may bring about the disruption of the molecule and conduction: in short, that a state may be induced such as Clausius considers is the state prior to the action of the electromotive force.

A large amount of most valuable information on the connexion of dilution and electrical conduction in aqueous solutions has been recently published by Arrhenius, Bouty, F. Kohlrausch, and Ostwald. In his most recent paper, Ostwald (*Journal für praktische Chemie*, 1885, xxxii., p. 300) has given the results of his determinations of the *molecular conductivity* in the case of no less than about 120 different acids; and it appears to me that many—indeed all—of his observations afford most distinct evidence in favour of the view I have expressed above. The general result of his investigation is that the molecular conductivity increases with dilution: in other words, that the dissolved substance exercises a greater specific effect, finally attaining a maximum; it then diminishes, but he believes this to be due to impurities in the water, especially to neutralisation of the acid by traces of ammonium carbonate. The maximum, he appears to think, would be the same for all acids if the dilution could only be pushed far enough: in the case of monobasic acids it is about 90 (arbitrary units); it is twice this in the case of dibasic, thrice in the case of tribasic, and so on.

I will quote first his results in the case of solutions of hydrogen chloride, bromide, iodide, fluoride, and silicon fluoride. v is the volume in litres which contains a weight in grammes corresponding to the formula of the dissolved substance—36·4 grammes of hydrogen chloride, for example.

v	HCl	HBr	HI	HF	H_2SiF_6
2	77·9	80·4	80·4	...	47·81
4	80·9	83·4	83·2	6·54	57·29
8	83·6	85·1	84·9	7·59	62·20
16	85·4	86·6	86·4	10·00	67·08
32	87·0	87·9	87·6	13·14	71·52
64	88·1	88·9	88·7	17·38	75·61
128	88·7	89·4	89·4	23·11	79·22
256	89·2	89·6	89·7	30·30	83·39
512	89·6	89·7	89·7	39·11	91·62
1024	89·5	89·5	89·3	49·49	109·5
2048	89·5	88·9	89·0	59·56	144·0
4096	88·6	87·6	87·8	69·42	187·1
8192	...	...	...	...	226·6
16384	...	...	...	...	258·6
32768	...	...	...	...	282·6

It will be observed that hydrogen chloride, bromide, and iodide practically behave alike; the numbers for the chloride are, however, slightly lower than those for the bromide and iodide, and the maximum is not reached quite so soon in the case of the chloride. Hydrogen fluoride is altogether different; its molecular conductivity is exceedingly low to begin with, and is considerably below the maximum even when $v = 4096$. But I would call special attention to the numbers for hydrogen silicon fluoride, which is commonly regarded as a dibasic acid: at first, as Ostwald says, it behaves as a monobasic acid of moderate strength—iodic acid, for example; but the maximum for monobasic acids being exceeded, the molecular conductivity increases more and more rapidly, ultimately exceeding the treble value, 270. It must be supposed that it undergoes decomposition in accordance with the equation—

$$H_2SiF_6 + 2H_2O = SiO_2 + 6HF.$$

The noteworthy point is *the large excess of water* required to initiate this change: when $v = 16$ the solution contains less than 1 per cent. H_2SiF_6, and at this point, according to Ostwald, decomposition probably begins; but that it is far from complete even when a very much larger excess is present is evident from the fact that the maximum when $v = 32,768$ is 282 and not above 400.

Now it is well known that hydrogen chloride, bromide, and iodide are, practically speaking, perfect gases under ordinary circumstances: in other words, masses of these gases would mainly consist of molecules such as are represented by the formulæ HCl, HBr, and HI. It has been proved, however, by Mallet, that hydrogen fluoride at temperatures near to its boiling-point mainly consists of molecules of the formula H_2F_2. In the aqueous solution the molecules would be brought more closely together, and therefore it is probable that, even in the case of hydrogen chloride, bromide, and iodide, a certain proportion of more complex molecules would result: the relatively high boiling-point of hydrogen fluoride (19°·4) renders it probable that in the liquid state this compound would at least partially consist of molecules more complex even than is represented by the formula H_2F_2. On the hypothesis put forward in this paper, the influence exercised by the one member of the composite electrolyte upon the other member during electrolysis is at all events mainly exercised by their respective negative radicles, and the extent of the influence thus mutually exerted by these radicles would depend on the extent to which they are still possessed of "residual affinity." If the hydrogen chloride, bromide, and iodide are present chiefly as simple molecules, they should exert, *ab initio*, almost the full effect which they are capable of exerting; and the chief effect of dilution being to decompose the more complex molecules, conductivity should increase to but a slight extent if the extent to which simplification can take place be but small. On the other hand, if owing to the formation of molecular aggregates the residual affinity be more or less exhausted, the initial conductivity will be low, and it will increase on dilution only in proportion as these aggregates become broken up.

It appears to me that the behaviour of the four hydrides under discussion is absolutely in accordance with these requirements of the hypothesis. Evidence of the same kind is afforded by all of Ostwald's results.

The behaviour of solutions of neutral metallic salts on dilution is very similar to that of acids; abundant proof of this is afforded especially by F. Kohlrausch's refined measurements, of which an account has recently been published (*Wied. Ann.*, 1886, xxvi., p. 162). I venture to think that a similar explanation to that above given for oxides will apply to salts; and also that the low molecular conductivities of salts as compared with corresponding acids may be regarded as confirmatory of my hypothesis. I think we must admit that the metals generally have less affinity than hydrogen for negative radicles; if this be granted, we have at once an explanation of the fact that metallic salts are mostly fixed solids, few of which are more than moderately soluble in water while many are very difficultly soluble or insoluble, whereas the corresponding acids are mostly volatile and readily soluble in water, if not miscible with it in all proportions. The affinity of the negative radicles being less exhausted by union with metals than with hydrogen, the fundamental molecules of salts are more prone to unite together to form complex aggregates.

Arrhenius, who has studied the electrical behaviour of solutions of a number of salts, attributes the change observed in molecular conductivity on dilution—as I have done—to molecular changes; but his deductions are all based on the acceptance of the Williamson-Clausius hypothesis of dissociation.

My hypothesis would also account for the increase in conductivity in composite electrolytes with rise of temperature. It is true that as temperature rises the influence which individual molecules exert upon each other would be lessened; but, on the other hand, the complex aggregates would become more and more completely resolved into their fundamental molecules, the velocity of molecular motion would increase, and the tendency of the constituent atoms to remain united would be lessened. From this point of view the determination of the coefficient of change of conductivity with temperature in the case of substances whose molecular conductivity increases considerably on dilution in comparison with allied compounds which exhibit only a slight variation in molecular conductivity on dilution affords an interesting subject for investigation. F. Kohlrausch has already pointed out (*Pogg. Ann.*, 1875, cliv., p. 236) that in the case of all neutral salts, "der Einfluss der Temperatur auf das Leitungsvermögen mit wachsender Verdünnung sich Anfangswerthen nähert, die zwischen engen Gränzen liegen;" and the experiments of F. Kohlrausch and Nippoldt on solutions of sulphuric acid (*ibid.*, 1869, cxxxviii., p. 286) show that the resistance diminishes to a much greater extent for equal increments of temperature in concentrated than in dilute solutions.

As concentrated solutions would be richer in complex aggregates than dilute solutions, these results are in entire accordance with my hypothesis: it does not appear to me that they can be satisfactorily interpreted in terms of the dissociation hypothesis.

In cases where the influence of the one member of the composite electrolyte upon the other is but slight, it may happen that the effect of temperature in diminishing this influence will outweigh that due to molecular simplification, and that, in consequence, conductivity will diminish with rise of temperature; a mixture of alcohol and ether would appear to furnish an example of this kind: according to Pfeiffer's recent observations (*Wied. Ann.*, 1886, xxvi., p. 216), such a mixture behaves as a metallic conductor of very high resistance.

The increase in conductivity of graphite and gas-retort carbon on heating, and the effect of light on the conductivity of (? impure) selenium and some other substances (Shelford Bidwell, Phys. Soc. Proc., pp. 122, 256), appear to me to be also explicable on the assumption that in all these cases we are dealing with composite electrolytes.

If any further proof be needed of an intimate connexion between molecular composition and electrolytic conduction, it is most conclusively afforded, I think, by the observations of W. Kohlrausch on chloride, bromide, and iodide of silver (*Wied. Ann.*, 1882, xvii., p 642). In the fused state, these compounds are better conductors than the most highly-conducting mixture of sulphuric acid and water, which of all liquids is the best conductor at ordinary temperatures, but when the change from the fused to the solid state sets in the resistance of both silver chloride and bromide suddenly increases. No such change takes place, however, in the case of silver iodide. This iodide fuses at 557° according to Rodwell, but at about 540° according to Kohlrausch; its electrical resistance increases only gradually after it has become solid, and remains almost a linear function of the temperature during an interval of 400°, until suddenly at near 150° it increases enormously, this change taking place at the moment when, according to Rodwell (Phil. Trans., 1882, p. 1153), it passes from the transparent, plastic, amorphous solid to the opaque, crystalline state, the volume increasing considerably. Kohlrausch has proved most conclusively that the solid iodide may undergo electrolysis. It would seem that almost immediately after solidification in the case of silver chloride and bromide practically the whole mass consists of complex aggregates so constituted as to be exceedingly bad conductors, but that such aggregates are formed much less readily by silver iodide.

(To be continued.)

THE MAZAPIL METEORIC IRON[1]

AMONG the large number of meteoric irons which have been described, only eight[2] are recorded as having been seen to fall. It is my privilege to be able to add a ninth fall to this short list, and one which may prove to be of exceptional scientific importance. This mass of meteoric iron I received in August last as a gift from my friend, Prof. José A. y Bonilla, Director of the Astronomical Observatory at Zacatecas, Mexico. He stated that it was *seen to fall* at about 9 p.m. on November 27, 1885, during the periodical star-shower of the "Bielids." Such is the unique interest of this meteorite, as shown by its history, that I have delayed announcing it until the evidence of its fall had been substantiated as thoroughly as possible.

The general freshness of surface, which shows very perfectly the flow of the melted crust; the presence of unusually large nodules of a very compact graphite; the very slight superficial oxidation, and its dissimilarity to other meteorites of the region, are all interesting features of this iron, and serve to confirm the statement of its recent fall. When received it weighed about 3950 grammes. Its present weight is 3864 grammes, or 10 pounds $4\frac{1}{4}$ ounces, troy. Its greatest length is 175 millimetres as measured diagonally across the mass. In its thickest part it measures about 60 millimetres. It could be described as a flat irregular mass, covered with deep depressions, having a smooth surface (see Fig. 1).

The evidence of the fall is set forth in the following communication from Prof. Bonilla.

(Translation).—"It is with great pleasure that I send to you the uranolite which fell near Mazapil, during the night of November 27, 1885. That you may the better appreciate the great scientific interest which this uranolite possesses, I will state that everything points to the belief that it belongs to a fragment of the comet of Biela-Gambart, lost since 1852. I here give you the history of this celestial wanderer. On December 2 (1885) I received, to my great delight, from Eulogio Mijares, who lives on the Conception Ranch, 13 kilometres to the east of the town of Mazapil, a uranolite, which he saw fall from the heavens, at nine o'clock on the evening of November 27, 1885. The fall, simply related, he tells as follows, in his own words:—

"'It was about nine in the evening when I went to the corral to feed certain horses, when suddenly I heard a loud hissing noise, exactly as though something red-hot was being plunged into cold water, and almost instantly there followed a somewhat loud thud. At once the corral was covered with a phosphorescent light and suspended in the air were small luminous sparks as though from a rocket. I had not recovered from my surprise when I saw this luminous air disappear and there remained on the ground only such a light as is made when a match is rubbed. A number of people from the neighbouring houses came running toward me and they assisted me to quiet the horses which had become very much excited. We all asked each other what could be the matter, and we were afraid to walk in the corral for fear of getting burned. When, in a few moments, we had recovered from our surprise, we saw the phosphorescent light disappear, little by little, and when we had brought lights to look for the cause, we found a hole in the ground and in it a ball of fire. We retired to a distance, fearing it would explode

[1] From the March number of the *American Journal of Science*, vol. xxxiii. pp. 221–26.

[2] Agram, Croatia, May 26, 1751; Charlotte, Dickson Co., Tenn., August 1, 1835; Braunau, Bohemia, July 14, 1847; Tabarz, Saxony, October 18, 1854; Victoria West, Africa, in 1862; Nejed, Arabia, spring of 1865; Nedagolla, India, January 23, 1870; Rowton, Shropshire, England, April 20, 1876. See the Catalogue o the Meteorites in the Mineral Department of the British Museum, by L. Fletcher, p. 42.

and harm us. Looking up to the sky we saw from time to time exhalations or stars, which soon went out, but without noise. We returned after a little and found in the hole a hot stone, which we could barely handle, which on the next day we saw looked like a piece of iron; all night it rained stars, but we saw none fall to the ground as they seemed to be extinguished while still very high up.'

"The above is the simple recital of the ranchman, and the uranolite which fell is the one I send to you. From the numerous questions I have asked Sr. Mijares, I am convinced that there was no explosion or breaking up on falling. Others who saw the phosphorescence, &c., were Luz Sifuentes, Pascual Saeuz, Miguel Martinez, Justo Lopez, and some whose names I have not obtained. Upon visiting the place of the fall I was particular to examine the earth in and around the hole, and by careful search and washing the earth I found a few small bits of iron, which must have become detached from the uranolite when it penetrated the earth.

"The hole was 30 centimetres deep. Probably the light which was seen came from the volatilisation of the surface of the celestial body due to the high temperature acquired by friction with the atmosphere, and of this volatilised matter falling to the earth as an incandescent powder."

The above communication was followed by an account of the observation of the Biela meteors at Zacatecas by Prof. Bonilla and his assistants. (See Annals N.Y. Acad. Sci. 1887.)

The locality of the fall is situated in latitude 24° 35′ N. and in longitude 101° 56′ 45″ West of Greenwich.

That no explosion was heard when this iron fell, is paralleled by the account of the fall of the fifty-six pound aërolite near Wold Cottage, Yorkshire, England, on December 13, 1795. "This stone fell within 10 yards of where a labourer was at work. No thunder, lightning, or luminous meteor accompanied the fall; but in two of the adjacent villages the sounds were so distinct of something passing through the air towards Wold Cottage that several people went to see if anything extraordinary had happened to the house or the grounds" (L. Fletcher, "An Introduction to the Study of Meteorites," 1886, p. 22). Concerning the aërolites which fell at 11.50 a m., on June 28, 1876, at Ställdalen, in Sweden, "it is remarkable that no meteor was visible at the place where the stones fell, though it was seen over nearly all Sweden."

FIG. 1.—Mazapil Meteoric Iron. Weight 10 lbs. 4¼ oz. troy (⅔ natural size.)

The surface of the Mazapil iron is of great interest. The deeply hollowed depressions entirely cover the mass (see Fig. 1). A thin black crust coats the surface, and exhibits well the striæ of flow, as seen on meteorites whose fall has been observed. In eleven places nodules of graphite are noticed extruding from the surface (the engraving shows some of these), one of them is nearly an inch in diameter. The graphite is very hard and apparently amorphous; troilite and schreibersite were noticed on a section cut off for analysis and for the development of the figures of Widmanstätten. The crystalline structure (see Fig. 2) is well shown in the engraving (Ives' process) which is of natural size. The lines are somewhat similar to that of the Rowton iron in their width and distribution, and are very unlike the known Mexican irons from Toluca, &c.

In its surface and general flatness the mass bears a remarkable resemblance to the Hraschina, Agram, iron[1] which fell May 26, 1751. In its weight it is nearly like the irons of Rowton (7¾ lbs.), Charlotte (9½ lbs.), Victoria West (6 lbs. 6 ozs.), and Nedagolla (9¾ lbs.), which were all seen to fall.

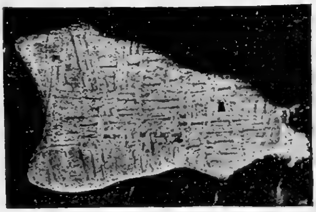

FIG. 2.—Section of Mazapil Meteoric Iron (natural size.

[1] See "Beiträge zur Geschichte und Kenntniss meteorischer Stein-und Metalmassen," by Dr. Carl von Schreibers, Wien, 1820, plate viii.

Mr. J. B. Mackintosh has kindly analysed a small fragment with the following results, which, for comparison with other irons seen to fall, I have placed in tabular form:—

	Mazapil.	Rowton. Flight.	Charlotte. Smith.	Estherville.[1] Smith.
Iron	91·260	91·250	91·15	92·000
Nickel	7·845	8·582	8·05	7·100
Cobalt	0·653	0·371	0·72	0·690
Phosphorus	0·300	......	0·06	0·112
	100·058	100·203	99·98	99·902

Carbon is distributed all through the iron between the crystalline plates, and it is noteworthy that this element was observed with the spectroscope as present, in the "Bielids" of November 27, 1885. Chlorine is also present and shows itself by a slight superficial deliquescence. Of this latter I will state that most of the surface oxidation of the ferrous chloride has occurred since August last. As yet no tests have been made to ascertain the amount of occluded gases, or to analyse the graphite nodules, and it is probable that this might only lead to results similar to those already obtained. Over the mass, where the crust has been accidentally removed, the lines of crystallisation (Widmanstätten figures) can readily be traced without etching the surface. The abrasion due to impact was very slight.

In conclusion, we cannot, from the very circumstantial account of the fall, and the corroborative evidence of the iron itself, which in several particulars contains heretofore unrecorded observances, decline to receive this meteorite as the ninth recorded fall of an iron mass to the earth; and perhaps at another period of the November "Bielids" this fall will be confirmed in all its interesting details. The interest connected with this meteorite, because of its beautifully marked and fresh surface, is enhanced by the concurrence of the time of its fall with the shower of the Biela meteors.

I wish to express here my deep obligation to Prof. Bonilla for the interesting data concerning this meteorite and for the gift of the meteorite itself, and to Mr. Mackintosh also for his kind interest in making the chemical analysis.

William Earl Hidden

SOCIETIES AND ACADEMIES

London

Royal Society, March 24.—"On Ellipsoidal Current Sheets." By Horace Lamb, M.A., F.R.S.

The paper treats of the induction of electric currents in an ellipsoidal sheet of conducting matter whose conductivity per unit area varies as the perpendicular from the centre on the tangent plane, or (say) in a thin shell of uniform material bounded by similiar and coaxial ellipsoids. The method followed is to determine in the first instance the normal types of free currents.

When the normal types and their persistencies have been found, it is an easy matter to find the currents induced by given varying electromotive forces. Supposing that we have an external magnetic system whose potential varies as e^{ipt}, we can determine a fictitious distribution of current over the shell, which shall produce the same field in the interior. If $\bar{\phi}$ denote the current-function for that part of the distribution which is of any specified normal type, ϕ that of the induced currents of this type, it is shown that

$$\phi = -\frac{ip\tau}{1 + ip\tau}\bar{\phi},$$

where τ is the corresponding persistency of free currents. When $p\tau$ is very great this becomes

$$\phi = -\bar{\phi},$$

in accordance with a well-known principle.

This method can be applied to find the currents induced by rotation of the shell in a constant field, it being known from Maxwell's "Electricity," § 600, that the induced currents are the same if we suppose the conductor to be fixed, and the field to rotate in the opposite direction. When the conductor is symmetrical above the axis of rotation, the current-function of any normal type contains as a factor cos $s\omega$ or sin $s\omega$, where ω is the azimuth, and s is integral (or zero). When we apply Maxwell's artifice, the corresponding time-factor is e^{ispt}, where p is the angular velocity of the rotation; and we easily find that the system of induced currents of any normal type is fixed in space, but is displaced relatively to the field through an angle,

$$\frac{1}{s} \text{ arc tan } ps\tau$$

in azimuth, in the direction of the rotation.

In the most important normal types the distribution of current over the ellipsoid is one which has been indicated by Maxwell ("Electricity," § 675) as giving a uniform magnetic field throughout the interior.

In the higher types the current-function ϕ is a Lamé's function, degenerating into a spherical harmonic when two of the axes of the ellipsoidal shell are equal. Of the special forms which the conductor may assume, the most interesting is that in which the third axis (that of symmetry) is infinitesimal, so that we have practically a circular *disk*, whose resistance ρ' varies according to the law

$$\rho' = \rho_0' \sqrt{\{1 - r^2/a^2\}},$$

where ρ_0' is the conductivity at the centre, a is the radius, and r denotes the distance of any point from the centre. In the most persistent type

$$\tau = \frac{\pi^2 a}{2\rho_0'}.$$

This result is of some interest, as showing that the electrical time-constant for a disk of *uniform* resistance ρ_0' must at all events be considerably less than $4·93\ a/\rho_0'$.[1]

The problem of induced currents is then discussed, more particularly in the case of a circular disk, of the kind indicated, rotating in any constant magnetic field. In view of the physical interest attaching to the question, it would be interesting to have a solution for the case of a *uniform* disk; but in the absence of this, the solution for the more special kind of disk here considered may not be uninstructive.

In the most important types of induced currents, the magnetic potential $\bar{\Omega}$ due to the field $\propto xz$, so that the lines of force at the disk are normal to it, but the direction of the force is reversed as we cross the axis of z. The current-function relatively to axes displaced through the proper angle η in the direction of rotation, varies as

$$y\sqrt{\{1 - r^2/a^2\}}.$$

In the next type $\bar{\Omega} \propto z(x^2 - y^2)$, and the current-function, relatively to displaced axes as before, varies as $xy\sqrt{1 - r^2/a^2}$.

"Note to a Memoir on the Theory of Mathematical Form" (Phil. Trans. 1886, vol. clxxvii. p. 1). By A. B. Kempe, M.A., F.R.S.

The object of this note is to make some slight but important amendments of certain sections of the original memoir (viz. secs. 5, 7, 73 to 77, and 167), relating to the definition and use of what the author terms "aspects" of collections of things. An "aspect" of a collection of n things is that which is under consideration when to each individual thing of the collection we mentally affix a distinctive degree of prominence or other mark. These n marks may be regarded as interchangeable with each other, and we thus get $\underline{|n}$ aspects of the collection, of which some are undistinguishable from each other. If the interchanges corresponding to a complete system of undistinguishable aspects of the collection are given we know the "form" of the collection.

March 31.—"On Clausius's Characteristic Equation for Substances applied to Messrs. Ramsay and Young's Experiments on Alcohol." By Prof. Fitzgerald, Trinity College, Dublin.

This paper is an investigation of how far Clausius's equation

$$\frac{P}{R\tau} = \frac{1}{v - \alpha} - \frac{1}{\Theta(v + \beta)^2}$$

represents accurately Messrs. Ramsay and Young's experimental results. It is shown that, considering the enormous range of values to be represented, it represents the results remarkably accurately, except that from the volume of the liquid, where alone the value of α is of much consequence, it follows that α is not constant, but is a function of both the temperature and pressure.

The paper contains a short discussion of the geometrical forms of the curves—a particular case of which is represented by this equation.

[1] I find by methods similar to those employed by Lord Rayleigh for the approximate determination of various acoustical constants, that the true value lies between $\pi a/\rho'$ and $2·26\ a/\rho'$. For a disk of copper (ρ=1600 C.G.S.), whose radius is a decimetre and thickness a millimetre, the lower limit is 0·0014 sec. For disks of other dimensions the result will vary as the radius and the thickness conjointly.

It concludes with a hope that the velocity of sound in a substance near the critical point may be investigated, in order that we may know the two specific heats under these exceptional circumstances.

Physical Society, March 26.—Prof. Balfour Stewart, President, in the chair.—The following paper was read:—On the production, preparation, and properties of the finest fibres, by Mr. C. V. Boys. The inquiry into the production and properties of fibres was suggested by the experiments of Messrs. Gibson and Gregory on the tenacity of spun glass, described before the Society on February 12, and the necessity of using such fibres in experiments on which Prof. Rücker and the author are engaged. The various methods of producing organic fibres such as silk, cobweb, &c., and the mineral fibres, volcanic glass, slag wool, and spun glass, were referred to, and experiments shown in which masses of fibres of sealing-wax or Canada balsam were produced by electrifying the melted substance. In producing very fine glass fibres, the author finds it best to use very small quantities at high temperatures, and the velocity of separation should be as great as possible. The oxyhydrogen jet is used to attain the high temperature, and several methods of obtaining a great velocity have been devised. The best results obtained are given by a cross-bow and straw arrow, to the tail of which a thin rod of the substance to be drawn is cemented. Pine is used for the bow, because the ratio of its elasticity to its density (on which the velocity attainable depends) is great. The free end of the rod is held between the fingers, and when the middle part has been heated to the required temperature the string of the cross-bow is suddenly released, thus projecting the arrow with great velocity and drawing out a long fine fibre. By this means fibres of glass less than 1/10,000 of an inch in diameter can be made. The author has also experimented on many minerals, such as quartz, sapphire, ruby, garnet, feldspar, fluor-spar, augite, emerald, &c., with more or less success. Ruby, sapphire, and fluor-spar cannot well be drawn into fibres by this process, but quartz, augite, and feldspar give very satisfactory results. Garnet, when treated at low temperatures, yields fibres exhibiting the most beautiful colours. Some very interesting results have been obtained with quartz, from which fibres less than 1/100,000 of an inch in diameter have been obtained. It cannot be drawn directly from the crystal, but has to be slowly heated, fused, and cast in a thin rod, which rod is attached to the arrow as previously described. Quartz fibre exhibits remarkable properties, as it seems to be free from torsional fatigue, so evident in glass and metallic fibres, and on this account is most valuable for instruments requiring torsional control. The tenacity of such fibres is about fifty tons on the square inch. In the experiments on the fatigue of fibres great difficulty was experienced in obtaining a cement magnetically neutral, and sealing-wax was found the most suitable. An experiment was performed illustrating the fatigue of glass fibres under torsion, and diagrams exhibited showing that the effect of annealing them is to reduce the sub-permanent deformation to about 1/10 its original amount under similar conditions. Annealing quartz fibres does not improve their torsional properties, and renders them rotten. Besides the use of quartz for torsional measurements, the author believes that quartz thermometers would be free from the change of zero so annoying in glass ones. He exhibited an annealed glass spiral capable of weighing a millionth of a grain fairly accurately, and also a diffraction grating made by placing the fine fibres side by side in the threads of a fine screws. Gratings so made give banded spectra of white light. The author regretted that his paper was so incomplete, but thought the results already obtained would be of interest to the Society. Prof. W. G. Adams congratulated the author on his most interesting paper, and considered the results to be of great importance. He believed the banded spectra exhibited by the grating were probably due to internal reflection within the fibres. Mr. Cunyngham asked whether the glass mirror used in the torsional experiments was magnetic, to which the author replied that this was probable, but even this assumption did not explain all the peculiarities observed.—A paper by Prof. Pickering was postponed till the next meeting, on April 23.

Edinburgh

Scottish Meteorological Society, March 30.—Half-Yearly Meeting.—Mr. John Murray in the chair.—It was reported that four new stations had been recently added, viz., Aberlour, Oban, and Ailsa Craig and Oxcar Lighthouses; and an arrangement had been entered into with the Meteorological Council by which daily observations of temperature and rainfall are transmitted for the Weekly Weather Report issued by the Council for agricultural and sanitary purposes from the Society's stations at Lairg, Glencarron, Fort Augustus, Braemar, Ochtertyre, Marchmont, and Glenlee. Messrs. R. M. Smith, John Murray, and J. Y. Buchanan were re-elected members of the Council. The work of collecting and discussing the sea temperatures round the Scottish coast, for which a grant of 50*l.* has been obtained from the Government Grant Committee, has been transferred to Mr. H. N. Dickson. The report from the Council enters somewhat in detail into the physical and biological work carried on at the Scottish Marine Station. Six trips have been made since July by the *Medusa* in the Firth of Clyde and connected lochs, during which observations of sea temperatures were taken at all depths from the surface to the bottom, special attention being directed to the further investigation of the remarkable and unexpected distribution of temperature occurring in this part of the ocean at certain seasons, as disclosed during previous trips of the *Medusa.* Dredging was also vigorously prosecuted, and all the specimens obtained have been determined, their anatomy investigated, and the results prepared for publication by the staff of the Scottish Marine Station. This Station continues to be largely taken advantage of by biologists, for whom tables are provided in the laboratory free of charge, for prosecuting their zoological researches. As regards the Ben Nevis Observatory, it was reported that the subscriptions raised since the commencement of the present year for clearing off the debt and founding a low-level station of the first order at Fort William now amounted to 822*l.*, thus bringing up the amount contributed by the public since the establishment of the Observatory in 1883 to nearly 8000*l.*—An address was then delivered by the Hon. Ralph Abercromby, at the request of the Council, on modern developments of cloud knowledge, with lime-light illustrations of clouds from all parts of the world. It was shown that clouds were everywhere the same, and that the different forms of clouds which he had exhibited from all regions of the globe could be seen in Scotland. A modification of the present classification of clouds which has been proposed by Prof. Hildebrandsson, of Upsala, and himself, was explained and illustrated. He then dealt successively with the structure of clouds and their height, the atmospheric conditions concerned in the formation of the different kinds of clouds, the remarkable results to which cloud-motions led as regards the nature of cyclones and anticyclones, the forecasting value of clouds, and finally the necessity of attending, in all efforts to interpret the indications of clouds, not merely to their forms, but also to their surroundings. In moving a vote of thanks to the lecturer, Prof. Chrystal took occasion to refer to the great beauty of the photographs shown by the lime-light, which were highly appreciated by a large and influential audience.

Paris

Academy of Sciences, April 4.—M. Janssen, President, in the chair.—Researches on certain phenomena connected with the aberration of light, by M. Fizeau. The paper deals chiefly with the nature of the phenomena that may be produced in the reflection of a pencil of light on the surface of a mirror, assuming this mirror to be endowed with a velocity comparable to that of light.—Stroboscopic method for comparing the duration of vibration of two diapasons, or that of the oscillation of two pendulums, by M. Lippmann. A description is given of a very accurate process of making these comparisons derived from the stroboscopic method.—On the central calm in cyclonic storms, by M. H. Faye. This central stillness is found to be present in all tropical cyclones, persisting even beyond the 50° latitude, but becoming modified according as the storm approaches the Pole without ever disappearing altogether.—On various effects of irritation in the throat, and especially on loss of sensibility and sudden death, by M. Brown-Séquard. Numerous experiments tend to show that the skin of the throat possesses, like the larynx, but to a less degree, the power of arresting sensibility; also that the larynx, the trachea, and also, perhaps, the cuticle covering them, possess the power of causing death under a mechanical irritation in the same way as the rachidian bulb.—On the seismic phenomena of February 1887, by M. Ch. V. Zenger. A parallelism is suggested between these disturbances and atmospheric, electric, and magnetic phenomena and volcanic eruptions so often occurring simultaneously.—Rectification of right, unicursal, circular cubics by means of the elliptical integrals, by M. G. de Longchamps. In supplement to his recent note, the author here establishes the important generalisation that all these cubics may be rectified by means of the elliptical integrals.—On the voltaic arc, by M. G. Maneuvrier. A new process is described, by means of which the voltaic arc may be excited without previous contact of the two electrodes.—Law of distribution of the rays and bands common to several spectra of bands, by M. Deslandres. Having already shown that the rays composing the same band may be divided into a series of identical rays, such that in each series the intervals between one ray and the following run pretty well in arithmetical progression, the author here extends this simple law of distribution to the bands of the same spectrum of bands, indicating an analogy with the law of succession of sounds in a solid body.—Fatal accidents in electric workshops, by M. A. d'Arsonval. Some remarks are presented on the causes of these accidents, on their physiological effects, and on the means of preventing them.—Quantitative analysis of vanadic acid, by M. A. Ditte. It is shown that by observing certain precautions the method indicated by Berzelius, based on the insolubility of the vanadate of ammonia in sal ammoniac may be applied to the analysis of vanadium in the form of vanadic acid with satisfactory results.—On some ammoniacal combinations of the sulphate and nitrate of cadmium, by M. G. André. Some details are given for the preparation of the ammoniacal sulphates and nitrates of cadmium, with indications of their possible relations to the corresponding salts of zinc and copper.—On the extraction and analysis of the vanadium occurring in rocks and mineral ores, by M. L. L'Hôte. The method here described involves two operations: the extraction of the vanadium in the form of vanadic solution, and its analysis by means of titrated liquors, or by weighing.—On the preparation of the propylamines and iso-amylamines, by M. H. Malbot. The observations recently made by the author on the isobutylamines are here extended to the amines derived from various alcohols.—On the power of multiplication of the ciliated Infusoria, by M. E. Maupas. This power is shown to depend on three factors: the quality and abundance of nourishment; temperature; and the biological adaptation of each species from the alimentary standpoint.—Results obtained by the preventive inoculation of the attenuated virus of yellow fever at Rio de Janeiro, by MM. Domingos Freire, Paul Gibier, and C. Rebourgeon. Of the 1675 cases terminating fatally between January 1885 and September 1886, only 8 had been vaccinated, and these at a time when the treatment was still imperfectly understood. In general, the mortality is now 1 per 1000 for the vaccinated, and 1 per 100 for all others.

BERLIN

Physiological Society, March 25.—Prof. du Bois-Reymond, President, in the chair.—Prof. Falk spoke on the influence of extremes of temperature on the colour of blood. In persons either burnt or frozen to death the *post-mortem* patches present a strikingly bright red colour. The speaker has found, as the result of an experimental investigation, that temperatures of 0° C., and below, lead to the colour of the blood becoming bright red by causing the oxygen of the air to be more readily fixed and more stably retained by the corpuscles than is the case at ordinary temperatures. If, however, the blood has stood exposed to the air until putrefactive changes have set in, in this case the action of cold no longer makes the blood brighter in colour. Other experiments have shown that in animals killed by low temperatures the blood is bright red, not only in the peripheral parts but also in the heart and great vessels. Also in human beings frozen to death the blood even in the heart is sometimes observed to be bright red, although in most cases only the blood of the peripheral parts presents this appearance; probably death has ensued from freezing only in cases presenting the first of these two appearances.—The President read a communication from Prof. Fredericq, of Louvain, on Traube-Hering curves. As is well known, a blood-pressure tracing recorded by a mercurial manometer, shows three distinct kinds of curves:—(1) Curves of the first order, which are caused by the systole of the heart. (2) Curves of the second order, which make their appearance at lengthy intervals and are synchronous with the respiratory movements: these curves represent the influence of the respiration on the blood-pressure. (3) Curves of the third order, which make their appearance at still longer intervals and were first described by Siegmund Meyer: these have usually been regarded as due to a rhythmic increase and diminution in the activity of the vaso-motor centre. The curves described by Traube and Hering have until now been regarded as belonging to the above-mentioned third order of curves. Prof. Fredericq, however, regards this as an incorrect view; he regards them as belonging to the second order, corresponding to and produced by the respiratory movements.—Dr. Wurster stated that he has treated the caseine-like substance (see NATURE, vol. xxxv. p. 455) obtained by the addition of hydrogen-peroxide to white of eggs with ammonia, and finds that a portion of this substance is thereby dissolved. Another portion, however, is converted into a ropy mass, which on being dried yields a horny substance, with a very marked affinity for colouring matters, and which exhibits nearly all the characteristics of horn. He has further found that these two bodies undergo no change by the action of nitrite of soda on the white of eggs. By the addition of lactic or acetic acid he has obtained a yellow precipitate which turned intensely red on exposure to the air: the same reagents applied to blood produced a black coloration.—Prof. Zuntz gave a short communication on the course of experiments which he has made in conjunction with Profs. Virchow and Senator on Cetti during his fast lasting over eleven days. The results of the investigation have not yet been completely put together, but will be communicated at an early sitting of the Physiological Society.

GOEBEL'S OUTLINES OF THE CLASSIFICATION OF PLANTS

Outlines of Classification and Special Morphology of Plants. By Dr. K. Goebel. A New Edition of Sachs's "Text-book of Botany," Book II. Authorised English Translation by Henry E. F. Garnsey, M.A. Revised by Prof. I. Bayley Balfour, M.A., M.D., F.R.S. (Oxford: Clarendon Press, 1887.)

ALL botanists who have been familiar, since 1882, with the original of this admirable work, will welcome the present translation, while it will be of even greater value to the large class of students who were unable to make use of the German edition. The full importance of Prof. Goebel's work will only be realised by those who have some acquaintance with the immense progress made in the morphology of plants since 1874, when the last German edition of Sachs's "Text-book" was published. Not a few of the most important of these discoveries are due to Goebel himself, and this fact, no doubt, partly explains the remarkable success with which he accomplished the difficult task of re-writing Sachs's Second Book. Goebel's work is, to all intents and purposes, a new one; but, at the same time, Sachs's own words have been incorporated in the new text in every case where the progress of the science did not actually demand a change.

Important additions to our knowledge have of course been made since the first appearance of this work in Germany. These have been duly recorded, in the English edition, by Prof. Balfour, who has wisely limited the additions to foot-notes. In one or two cases it might, perhaps, have been wished that these notes had been a little fuller.

It will not be without interest to enumerate some of the more striking differences between this work and the corresponding portion of Sachs's treatise. It must not be forgotten that Dr. Vines's revised edition of the latter work had already brought many of these points before English readers.

The same fourfold division of the vegetable kingdom which was adopted by Sachs is maintained here, though it is pointed out that a division into three (Thallophytes, Archegoniatæ, and Angiosperms) would be equally justified. The practical advantages of the former arrangement are obvious. In the classification of the Thallophytes we at once recognise a great advance. The artificial "sexual system," as it has been called, is quite given up, and an arrangement adopted which is based, as far as possible, on the entire life-cycle of the plants in question. Most teachers of botany will already have long abandoned the groups of "Protophyta, Zygosporeæ, Oosporeæ, and Carposporeæ," but it will be an immense gain to students to have a more natural system embodied in a text-book. In Goebel's system we have five main groups. Of these, the first two (Myxomycetes and Diatoms) are kept separate from the rest, on the ground of their uncertain relationships. Then we have the Schizophytes, including the Cyanophyceæ or blue-green Algæ on the one hand, and the Schizomycetes or Bacteria on the other. Then come the two main lines of the Algæ and the Fungi, which are thus again recognised as constituting natural classes, after the separation of the lower groups above mentioned.

The present arrangement is essentially that of De Bary, and no one will doubt that it approximates as nearly to a natural classification as our existing knowledge admits of. The fact that the conditions on which Sachs based his division have been repeatedly shown to vary among the most nearly related plants, is sufficient proof of the necessity for a return to less artificial views. It is to be regretted that no satisfactory place for the Diatoms has yet been found in classification. As regards the Myxomycetes, it will scarcely be doubted that they have no near relationship to any of the higher groups of plants. The fact that the fusion of the plasmodia is not accompanied by a union of their nuclei shows that this process cannot be regarded as a sexual one.

It will be observed that the Yeast-Fungi no longer appear side by side with the Bacteria, but are treated, in accordance with De Bary's views, as reduced Ascomycetes.

In the Algal series, attention may be called to the interesting section on the Volvocineæ, among which the transition from zygosporous to oosporous reproduction can be traced with special clearness. The discoveries relating to Acetabularia, Dasycladus, &c., show that a similar advance has taken place within the very distinct group of the Siphoneæ, while even among the simpler Protococcaceæ indications of an external differentiation between the sexual cells are not wanting. The account of the Phæophyceæ is of special interest from the same point of view, the series from Ectocarpus through Cutleria to Fucus showing the passage from simple conjugation of motile gametes to typical fertilisation of an oosphere by a spermatozoid.

The treatment of the red sea-weeds shows, on the whole, a great advance, though we anticipate still greater changes when the next edition comes to be written. We may venture to express a doubt as to the view here adopted, that the Bangiaceæ are simple forms of the Florideæ. Schmitz has already shown how slight are the grounds on which this arrangement is based. It seems to us probable that a relationship of the Bangiaceæ to the Ulvaceæ may again be recognised in the future, as has already been suggested by Mr. Bennett.

The account of the Characeæ is little modified from that in Sachs, but it will be noticed that they are here treated as oosporous Chlorophyceæ. The question of their systematic position will probably long remain insoluble, but there can be no doubt that they have little in common with any of the carposporous forms of Algæ.

Among the Fungi many changes will be found, of which only one or two can be referred to here. The gradual progress of apogamous degeneration among the Peronospore and Saprolegnieæ, so important for the whole question of sexuality in Fungi, is fully described in the light of De Bary's researches.

Among other points, we may mention the advances in our knowledge of the Lichens, especially of their reproduction, and also the view here adopted, that the Basidiomycetes are wholly asexual forms, their so-called fruit representing a complex gonidiophore.

Leaving the Thallophytes, many signs of advance will be found in the description of the Muscineæ. Attention may especially be called to the very clear account now given of the embryology both of the Liverworts and of the true Mosses. In a future edition a fuller account of the vegetative anatomy of the latter class may perhaps be looked for.

In the group of the Vascular Cryptogams the changes have been very numerous. Goebel's view of the essential distinction between the forms in which the sporangium arises from a single cell, and those in which a whole group of cells takes part in its formation, gives the clue to the arrangement here followed. Indeed, there is no part of the book in which the author's own researches have given rise to more important results. The whole subject of the development of the sporangia, both among vascular cryptogams and flowering plants, is one which Goebel has especially made his own.

As regards other points, we may mention that the important subject of apogamy in Ferns is treated at length in the text, while the converse phenomenon of apospory, more recently investigated by Prof. Bower, is dealt with in an editorial note. The embryology of the whole group is treated much more completely than before, and illustrated by new figures. The brilliant discoveries of Treub in the Lycopodiaceæ are shortly recorded in a note, but his most recent work did not appear in time to be noticed.

Going on to the Gymnosperms, we find that the researches of Treub have here led to important advances in our knowledge of the Cycadeæ. The Coniferæ are treated very fully, and here it is more especially to thef labours of Strasburger that the most important progress is due. To him are to be attributed most of the recent discoveries on the development of the macrosporangium and of the prothallus and embryo. It need scarcely be pointed out that these results, in conjunction with the investigations of the author himself, have demonstrated in every detail the homologies between Gymnosperms and Pteridophyta long ago detected by the genius of Hofmeister.

Before leaving the Coniferæ, attention must be called to an error which has, curiously enough, survived through several editions of Sachs's "Text-book," and through both the German and the English versions of the present work. At the middle of p. 337 it is stated that in Juniperus the lowest of the three cells derived from the oospore divides into four cells, each of which gives rise to a rudimentary embryo, so that four rudimentary embryos proceed from one archegonium. At the bottom of the same page we find the following sentence: "But *Picea vulgaris* agrees with *Juniperus*, inasmuch as the lowest of the three primary cells of the suspensor does not divide, but forms only one rudiment." Of these two contradictory statements the former is, of course, the correct one; in the sentence last quoted, *Thuja* should be read for Juniperus.

As regards the Angiosperms, the most considerable changes introduced relate to the development of the stamen on the one hand, and of the ovule and embryo-sac on the other. In the former case it is especially the work of Warming, in the latter that of Strasburger, to which our present knowledge of the facts is due. The treatment of all these subjects by the author of this book is singularly clear. The student will see how the homologies, which were so evident in the case of the Gymnosperms, can also be traced here up to a certain point, while he will also see exactly where our knowledge is still deficient.

The improved account of the embryology of Angiosperms may also be noticed, especially the interesting summary of Strasburger's investigations on polyembryony.

As regards the translation, both Mr. Garnsey and Prof. Balfour may be warmly congratulated on their success. Here and there a slight want of clearness may perhaps be noticed, but this is very rare, and scarcely any errors have been detected. One on p. 17 may, however, be pointed out. It is there stated that in the Myxomycetes "a plasmodium moves away from illuminated spots; if a stronger light is thrown directly upon these spots, a number of plasmodia collect in them." This does not express the fact as stated in the original, which is that, if *the plasmodia* be directly exposed to strong light, they form larger conglomerations. Again, at the top of p. 97, the phrase "*ins Freie*" should scarcely have been translated "into the air," in speaking of a submerged aquatic plant.

The explanation of terms at the end of the book will be of the greatest possible value not only to students but to botanists. We may hope that it will materially contribute to introduce order into the chaos of our terminology. We are glad to see the good old term *spermatozoid* replacing the inaccurate *antherozoid*, and we could wish that ovum could constantly be used for oosphere. Where clear homologies with the animal kingdom can be traced, it seems a distinct loss to ignore them.

On the other hand, we cannot feel satisfied with the word "sporophyte" for the asexual generation in the higher plants. "Sporophyte" is the correlative of "spermaphyte," and has actually been used by Luerssen and others in the sense of a Cryptogam, as distinguished from the seed-bearing Phanerogam. We should have thought that the older terms "sporophore" and "oophore" would answer every purpose.

In conclusion, we can only say that the appearance of this book marks the most important addition to our morphological literature since 1875. D. H. S.

MINERAL PHYSIOLOGY AND PHYSIOGRAPHY

Mineral Physiology and Physiography. A Second Series of Chemical and Geological Essays, with a General Introduction. By Thomas Sterry Hunt, M.A., LL.D. Pp. 688. (Boston: Samuel E. Cassino, 1886.)

THIS work, as its sub-title implies, is a continuation of the series of essays first published by Dr. Sterry Hunt in 1874, of which a second and revised edition appeared in 1878. The essays which make up the present volume have with one exception, that on "The Genetic History of Crystalline Rocks," already appeared in various scientific journals.

The principal title of the work is explained and justified by its author in the two first essays. Dr. Sterry Hunt advocates a return to the older and wider meaning of the term "physiology" as it was employed two centuries ago; he maintains that all the natural sciences fall into two great divisions, the descriptive or physiographical, and the philosophical or physiological. It seems scarcely necessary to point out that the term physiology is now so universally restricted to the study of the actions of organised beings that any attempt to make it include physics and chemistry, with a large part of geology and astronomy, as the author proposes, can scarcely be expected to meet with much success. In scientific terminology a struggle for existence is continually going on, and it is hopeless to fight against the results of selection: to endeavour at the present day to revive the older and wider meaning of the term "physiology," and to use it as a synonym for "natural philosophy" side by side with the modern and more restricted sense, must almost infallibly lead to confusion. Still more hopeless would it be to try and abolish the use of the term in its present accepted sense.

In the third essay, on "The Chemical and Geological Relations of the Atmosphere," Dr. Sterry Hunt states and defends his well-known speculation concerning the replacement of the carbonic dioxide which is being continually removed from the atmosphere by the processes of kaolinisation and of coal-formation. Rejecting the too obvious suggestion advanced by Stanislas Meunier and others, that the equivalent of the carbonic dioxide abstracted from the atmosphere by the processes in question may be returned to it from subterranean sources, the author insists that such supplies can only come from outside the earth's atmosphere, and must be cosmical in their origin. The fourth essay, following up some of the ideas hinted at in the third, deals with "Celestial Chemistry from the Time of Newton," and is principally occupied with a discussion of the nature of interstellary matter.

The two essays dealing with "The Origin of Crystalline Rocks" and "The Genetic History of the Crystalline Rocks" are devoted to a destructive criticism of various theories which have been propounded to account for the origin of the crystalline schists and gneisses, and the attempt to supply a new one. As is well known, Dr. Sterry Hunt is one of those who maintain that all rocks of this class are necessarily of Archæan age; unlike some of his contemporaries who share the same views, however, he does not shrink from what he believes to be the logical conclusion from these premises, and maintains that the formation of such rocks must result from actions of a very different kind from any now going on upon the globe. According to Dr. Sterry Hunt's idea, which he calls the "crenitic hypothesis," "the crystalline stratiform rocks, as well as many erupted rocks, are supposed to be derived from a primary superficial layer, regarded as the last portion of the globe solidified in cooling from a state of igneous fluidity." After the wonderful speculative flights of these two essays, Dr. Sterry Hunt returns to the ground of sober scientific thought in several essays where ordinary chemists and geologists will not find themselves altogether out of their depth.

The solid contributions made to mineralogical science by the author of these essays may perhaps warrant an attempt on his part to deal with the difficult and involved question of mineralogical classification. This subject he has treated in his essay, "A Natural System of Mineralogy," an elaboration of which is promised in a treatise on mineralogy now in preparation. Dr. Sterry Hunt adopts, as might be anticipated, a purely chemical classification; but his results, which differ in many important particulars from those both of Rammelsberg and Tschermak, do not attract us by their simplicity, and seem perhaps needlessly obscured by the adoption of a very cumbrous terminology.

The essay on "The Geological History of Serpentines" is one in which all the author's peculiar originality and boldness are displayed in their highest perfection. That in the face of the results obtained by the study of rocks with the microscope, anyone could be found to maintain at the present day the *aqueous origin* of many, if not all, serpentines, may seem startling to those who have not read the author's previous writings on the subject. The dexterous gliding over difficult and dangerous places, and the elaborate "figure-cutting" on a few strips of apparently solid ice, constitute one of the most remarkable displays of courage and skill ever exhibited—even by the great mental athlete of Canada himself!

The "Taconic" rocks have formed in North America the battle-ground for two rival schools of geological thought, exactly comparable to that afforded by the Alps to European geologists, and the Scottish Highlands to those of Britain. In the ninth and eleventh essays of the present volume, Dr. Sterry Hunt maintains and stoutly defends his well-known views concerning the origin and succession of the Archæan rocks. For him the most highly foliated schists and gneisses exhibit a stratification clearly due to some kind of sedimentation; in the mineralogical constitution of these rocks he finds evidences of geological age more trustworthy even than those of the organic remains in the later aqueous deposits, and relying implicitly upon this kind of evidence, he has evolved a universal classification for the Archæan deposits which he can apply equally to the rocks of Southern Europe and of British North America. At some of these results persons of less robust faith in Dr. Sterry Hunt's methods can only give way to "admiration," as, for example, when igneous rocks which have been demonstrated to be intrusive in Secondary deposits, are boldly claimed, on account of their mineral characters, as members of some Archæan "system"!

Throughout the present volume, as in the former one, Dr. Sterry Hunt keeps prominently in view his claims to priority, and jealously defends the originality of many of the ideas he puts forward. We cannot but think ourselves that the claim to originality is one which he need take the smallest care to insist upon. If no name had appeared upon the title-page of this remarkable work, every chemist and geologist glancing at its pages would have felt assured that its author could be no other than Dr. Sterry Hunt.

OUR BOOK SHELF

Through the Fields with Linnæus. By Mrs. Florence Caddy. Two Vols. (London: Longmans, Green, and Co., 1887.)

THIS enthusiastic book is the fruit of the author's visit to the land of Linnæus, and her journeys in his track. Its purpose is to tell the story of the life and labours of Linnæus with the local colour so far as it may be restored from contemporary and other records, and from the author's own experiences of travel. We find Linnæus here presented to us sometimes, as in the story of his early struggles while a student at Upsala, and again at the period of his courtship and his absence from the object of his affections, with the air of the hero of a romance rather than the subject of sober biography. It was to be expected that such periods in his life-history would properly take forcible hold of the sympathies of a lady biographer. It may be said at once that the author has carefully consulted the proper authorities—Stoever, Pulteney, Smith, Jackson, &c., and duly acknowledged her indebtedness to them ; and occasionally, with more jubilation than mere complacency, her disregard for them when they fail by disagreement among themselves, or otherwise, to satisfy her. One can hardly say fairer than that. The first impression of the book is unfavourable ; in fact, it is felt that one cannot take it seriously. That it is not meant to be so taken altogether is manifest from such statements as that "by Hök rather than by Krök Carl's name was enrolled," &c. Apart from this kind of thing, however, there is often a temptation to smile at the wrong places. The author's observations on men and things in general are frequent and fearless. For example, in discussing an architectural matter she wonders at "the usually perceptive Fergusson" not recognising the significance of a feature well known to ordinary writers on Swedish architecture. Doubtless Mr. Fergusson would have valued this gentle way of describing him, so unlike the manner of those "cock-a-hoop and overbearing young scientific men" whom the author prophesies will be "charming at forty." There is a superabundance too of quotations in the book beyond the legitimate quotations from Linnæus himself and writers of his life. Indeed, to put it in the fashion of that biographer of Linnæus whom she calls "dear old Stoever," she can rarely keep her course clear of the Scylla of her own wisdom and the Charybdis of miscellaneous quotations from Carlyle and a great variety of other writers.

The ancestors of Linnæus, his life from boyhood and school-days, throughout his University career, are discussed with picturesque descriptions of the land and the people. We then come to his *début* in the treatise on the sexes of plants, in answer to Wahlin's "Nuptiæ Arborum Dissertatio." "This," we are told, "was a blooming new idea in the summer of 1730." He is then followed throughout his travels in Lapland, Dalecarlia, his fruitful visits to Holland, England, and France, his return to Sweden and career at home, including his subsequent journeys—to the end. The following passage will give a fair illustration of the style of the more extravagant passages in the book:—

"Linnæus broke down: he dropped like the begonia at the last—the flower that had always interested him so much, with its male and female flowers so graceful and so differing. The common begonia, that most interesting and elegant of plants, is jointed all the way up, and as it withers the joints become separated and in shape like the bones of the human limbs ; they drop apart, and fall like dry bones upon the ground. This family is a botanical study in itself. 'Many begonias are remarkable for the production of adventitious buds,'" &c.

In spite of this amazing style it must be owned that apart from such small matters as spelling Linnean, in the name of the Society, "Linnæan," the book is wonderfully correct in the main features of the life of Linnæus, and once the reader is accustomed to absurdities such as we have noted, it becomes a readable narrative. The worst of it is that one is hurried off to somewhere between China and Peru for an illustration of some sober fact, and this without sufficient warning to the unwary reader.

Sur une nouvelle Méthode de faire des Mesures absolues de la Chaleur rayonnante. Par Knut Angström. (Upsal: Berling, 1886.)

IN this quarto pamphlet of seventeen pages (with a plate) the author claims to give a simple method for determining the absolute measure of radiant heat, and describes a self-registering apparatus which gives the intensity of solar radiation at any instant, as also the total heat received by the absorbing surface in a given time. Two circular copper disks are alternately exposed to the source of heat and screened from it, and a thermo-electric couple and galvanometer give the differences of their temperature. The method consists in finding accurately the average *time* for the *temperature-difference* of the two plates to be a given (small) amount, positive and negative in turns. By the aid of Newton's law of cooling, which is applicable in this case, the author proves that the intensity of the radiation is proportional to the temperature-difference directly, and the time inversely, and that it is quite independent of the constant of cooling. To verify the last conclusion, the author measured with an instrument of this kind the radiation of a constant source of heat under varying conditions of cooling, and he found that the influence of cooling was completely eliminated.

In the construction of the self-registering actinometer founded on this principle, the absorbing surfaces are those of a differential thermometer, and the temperature-differences are marked by the movement of a thread of mercury in the communicating glass tube. When the thread has moved a certain distance, corresponding to a known temperature-difference in the two bulbs, an electric circuit is completed, and an electro-magnet turns the instrument through 180°, thus reversing the positions of the screened and unscreened bulbs. By the usual clock-driven pencil and revolving cylinder, a curve is drawn of which the abscissa is proportional to the time, and the ordinate to the number of turns which the instrument has made in the time. It is then shown that at any instant the intensity of the radiation is proportional to the tangent of the angle which the curve makes with the axis of abscissæ, and that the total heat received in a given time is proportional to the difference of the ordinates corresponding to the beginning and end of the time. The constants by which these variables are to be multiplied must be found by comparison with an absolute instrument like that already mentioned, and the necessity for this comparison may prove an obstacle to the general use of the instrument. Notwithstanding this drawback, the author claims for his invention that it gives results in accordance with those of the absolute instrument, and that it works as satisfactorily on stormy days as on calm ones. There is no doubt that the instrument is deserving of a fair trial, and a comparison of the results obtained from it and from some other recent forms of actinometer, would be of great value.

The paper is carefully written and printed, and we have noticed only two unimportant slips: one on p. 9, last line but one, where 40°·0 should be 41°·0 ; and another on p. 16, line 9, where *plus* should be *moins*. T. H. C.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Vitality and its Definition

WHILE warmly congratulating Prof. Judd upon the ability with which he has brought "out into clear relief the analogies between the science dealing with the mineral kingdom and those concerned with the animal and vegetable kingdoms," I cannot but think he has a little understated the difference between organic and inorganic matter. As this has arisen from a misconception of Mr. Spencer's definition of life—a misconception which has previously come before my notice in cases where other minds have looked at this same question—I venture to think you will allow me a few lines to show from what it arises, in the hope of expounding a subject which, popularly understood, must undoubtedly appear a little complex.

If, instead of taking the "concrete equivalent" of the definition, which the Professor has taken, though it is only used in the original "for our present purpose," we take "the broadest and most complete definition of life," . . . "*the continuous adjustment of internal relations to external relations*" ("Principles of Biology," vol. i. p. 80), we shall find that the changes undergone by minerals, even the physiological changes, will not obviously come within it; for it appears to me that, in the illustrations named in last week's NATURE, the minerals only display a continuous adjustment of internal *changes* to external *changes*. A change in the incident forces produces a change in the internal molecular arrangement of the mineral; a further change in the forces is *followed* by a further molecular, or molar, rearrangement in the mineral, and so on. There is no *anticipatory*, or *induced, change*—this is the point—in the mineral, which will correspond with the change which usually is connected with, and is sequent upon, the first environmental change, as is the case with living organisms. A quotation from the "Principles of Biology" (vol. i. p. 79) in conclusion will, I hope, now make my meaning clear. "If a creature's rate of assimilation is increased in consequence of a decrease of temperature in the environment; it is that the *relation* between the food consumed and heat produced, is so re-adjusted by multiplying both its members, that the altered *relation* in the surrounding medium between the quantity of heat absorbed from, and radiated to, bodies of a given temperature, is counterbalanced. If a sound or a scent wafted to it on the breeze, prompts the stag to dart away from the deer-stalker; it is that there exists in its neighbourhood a *relation* between a certain sensible property and certain actions dangerous to the stag, while in its organism there exists an adapted *relation* between the impression this sensible property produces, and the actions by which danger is escaped." The importance attaching to the word *relation* in this quotation has led me to emphasise it by italics.

Churchfield, Edgbaston F. HOWARD COLLINS

Oldhamia

PROF. SOLLAS's ingenious suggestion as to the origin of *Oldhamia* (NATURE, p. 515; Proc. R.D.S. p. 355) undoubtedly deserves very careful consideration; but it appears to me to leave some serious difficulties unexplained. For instance, the following occur to me after reading his paper and after examining two very fine specimens—one of *O. antiqua*, the other of *O. radiata*—recently placed in my hands by Mr. R. H. Scott, F.R.S.:—(1) The "puckerings," which are supposed to simulate the organism, are more definite in their boundaries than is usually the case with the ridgy or wavy "rucking up" which often occurs in phyllites as a first stage in the production of *Ausweichungsclivage*. (2) While I can trace down into the mass of the slate a certain puckering, I am at present unable to connect it with the *Oldhamia* visible on the upper surface. (3) As Prof. Sollas himself remarks, it is difficult to account for the peculiar branching form of *Oldhamia*. As it happens, during the last two or three years I have seen many examples of puckered phyllites, but never met with anything like *Oldhamia*. This difficulty in the case of *O. antiqua* seems to me almost insuperable. (4) In some cases I can detect two sets of markings crossing one another, so that the surface of the stone shows a reticulate structure, one set of lines being less definite than the other. This looks very much as if one branch of an organism were lying on the top of another; but I cannot account for it by mechanical movements alone. (5) The constancy of character in the markings is also a difficulty. One would expect every stage of development from the least to the most imitative. Now, though the *Oldhamia* is often indistinct, it certainly seems to me more like bad preservation than imperfect development of a structure.

Of course I do not in the least question the accuracy of the observations made by Mr. Teall and Prof. Sollas on the structure of the Bray Head rock; I only doubt whether the relation of this to *Oldhamia* can be regarded as proved. However, I am having some slides prepared from the above-named specimens, and hope that they may help in solving my difficulties.

Disappearance of Bishop's Ring in Colorado

THE reddish ring about the sun first distinctly appeared here (at the base of Pike's Peak) on November 22, 1883. For several days before that date, a faint discoloration of the region about the sun had attracted my attention. This gradually grew more intense, and, on the day mentioned, became unmistakable. The subsequent history of Bishop's ring as seen at this place is, in brief, as follows:—

The colour was most intense during the winter of 1883-84, and diminished in brightness from that time until its disappearance. At first it was visible almost all the time. Later, it appeared only at the time of cold storms, which were accompanied by great vertical movement of the air, or when, for any reason, the clouds reached to a great height. It was, on the average, brighter during the winters than in the summers; also, it was brighter when the sun was near the horizon. Many times in cold weather there has been not a trace of the ring, although the air was so clear that peaks a hundred miles distant were distinctly visible from the heights behind this city. At other times the ring has been very bright when the air was so hazy that the mountains only ten miles away were hardly visible. During the later months of 1885 it was invisible most of the time, but suddenly flamed out in wonderful intensity at the time of the great norther of January 9-11, 1886. Then for about two months it frequently appeared in the morning, or towards evening. During the warm months of 1886 it was not seen. On October 15 it appeared distinctly. About a week later it appeared very faintly a few times, and since then I have not been able to see a trace of it. My observations have been made at elevations of from 6000 to about 13,000 feet, and there was but little apparent difference in intensity at the different elevations. It is well known that the atmosphere here is, in general, very dry and transparent.

The diffraction-ring was often more coppery, almost rosy, in tint at the time of the northers, and in the thickening haze in the upper air preparatory to hailstorms. The great intensity of the colour at such times, and its peculiar tint, and that, too, irrespective of the amount of haze in the lower atmosphere, makes it probable that the ring was in part due to diffraction on ice-particles. If so, the ice-particles may themselves have been due to precipitation on dust-particles. The fact that no diffraction-ring has been seen around the sun during the past winter is not conclusive, for we have had no great northers, the season being unusually mild. But the disappearance of Bishop's ring for so long a time makes it certain that, even if there can be a circumsolar glow due to diffraction on ice-particles, yet the proper conditions for such a ring are realised only rarely, except when there is a great amount of volcanic dust in the air.

Iridescent Clouds

SEVERAL brilliant displays of iridescent clouds have appeared here during the past winter. One, on January 19, lasted for more than two hours during a "Chinook" wind. A mass of closely-connected cirro-cumulus clouds formed at a great elevation directly over the eastern base of the Rocky Mountains, and thence extended eastward as far as the eye could reach. The western sky was clear. As the clouds drifted slowly eastward, new clouds formed along their western border. The western limit of the clouds was for several hours nearly stationary, then slowly advanced westward opposite the direction of cloud-motion. Along the western border of the clouds were many projecting tongues of cloud. At one time I counted seven complete spectra at the thinner parts of the clouds—all showing bands of red, green, and violet. There were also about twenty-five spectra showing only one or two of the colours. The larger of these iridescent spots were about 10° in diameter, and they varied in distance from 5° to more than 45° from the sun. Their tints were intensely brilliant. There were also great numbers of minute iridescent spots where the colours were in great confusion—a phenomenon which is very common here. They sometimes are so numerous as to simulate Bishop's ring.

A Claim of Priority

IN connexion with the letter of M. Ventosa headed as above in your issue of March 31 (p. 513), I should be glad if you would let me refer to a note which was appended to my paper on "Continuous Calculating Machines," in the Philosophical Transactions of the Royal Society, part ii., 1885.

This note, whilst giving due priority to M. Ventosa in the matter of *one* of the two features of the sphere and roller integrator, described in the above paper, a feature at which I need scarcely say I arrived quite independently, points to the fact that this forms but a part of the integrator in question. When combined with the other portion, that integrator is a calculating machine in the widest sense of the term. I have shown that in addition to giving the value of

$$\int y dx,$$

where y is any linear function of x, other varieties of the mechanism obtain the value of such expressions as

$$\int F_1(x)F_2(x) \ . \ . \ . \ F_n(x)dx,$$

and

$$\int\int \phi(x, y)dydx,$$

and also by a converse process give approximately the value at any instant of R where

$$R = \frac{dy}{dx}.$$

I had not before to day seen the paper of Mr. F. J. Smith in the *Phil. Mag.* (August 1886), referred to by M. Ventosa. On pp. 381 and 382 of my paper above alluded to will be found a description of an integrator which is practically identical with that of Mr. Smith, as I have no doubt he will admit when he reads that description. With that integrator *hollow* brass balls were employed for the very purpose suggested by Mr. Smith. The instrument was, however, abandoned in favour of more convenient forms, one of which was actually employed by that gentleman upon his "ergometer" at the Inventions Exhibition, together with some very ingenious integrators of his own design. There is, I would say, one point of difference between the integrator described by Mr. Smith, and that by myself. The movable arm in the former appears to be guided by a pin in a straight slot. Now in the "sine" form, of which this integrator is an example, this pin should move in the arc of a circle, and it would be interesting to know if approximately correct results have been obtained with what is in some respects a more convenient practical device.

The Vitality of Mummy Seeds

I read with much surprise in Nature of March 31 (in Prof. Judd's defence of his statement as to the longevity of seeds) that "competent botanists have cited the case of the germination of seeds taken from ancient Egyptian tombs as authentic." Many experiments have been made as to the length of time seeds may retain their power of germinating, by Robert Brown, Henslow, and others, with interesting results as to the longevity of some; but my impression is, and I venture to make it public, that competent botanists have universally condemned as utterly worthless the evidence given in support of alleged instances of the germination of mummy seeds. No scientifically responsible person has, so far as I am aware, put the fact on record. In these circumstances, therefore, the results of the successful experiments referred to farther on by Prof. Judd as having recently been made, possess the greatest interest, and botanists will look forward eagerly to the details which it is to be hoped will soon be made public. Hitherto the fruitful source of error has been the deception at the outset of the credulous experimenter by the Arab. In fact, the mummy wheat of one well-known traveller grew up in the form of *oats*—a plant not cultivated by the ancient Egyptians, but now grown in the land they inhabited—though this did not shake his faith in the genuine source of his supply. In the present case, however, the statement made in faith by so high an authority as Prof. Judd leads us to anticipate that the undertaking has been hedged in with all the safeguards demanded by a pure cultivation of undoubtedly genuine material.

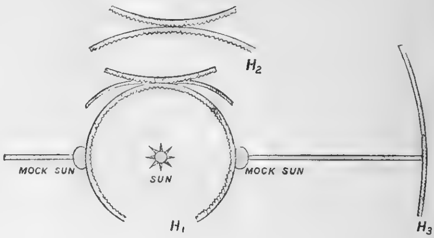
Solar Halos

In the forenoon of March 6 the sun was surrounded by a series of halos of the form shown in the diagram. The side of each arc, marked with a wavy or saw-toothed outline, was red, and the opposite edge blue; but no colour at all was visible in the horizontal belt nor in the farthest-out halo (H_3). This sketch shows the appearance at about 9 a.m.; as the sun rose higher, the horizontal belt got a curve upwards at each side—*i.e.* it continued to be parallel to the horizon—and was prolonged inside H_1 till it almost touched the sun. The two mock-suns



were distinctly on the outside of H_1, and were coloured red next the sun, and blue outside, their reds about coinciding with the blue of H_1. The following are some of the measurements:—

	° ′
Sun to western mock-sun	23 46
,, eastern ,, ...	23 42
,, H_3 (two measurements)...	79 56 81 23

The halo H_3 has, I believe, been very seldom seen, and there are only three estimates of its radius on record: two of these make it 90°, and the third makes it 85° to 90°. It will be seen that our measurements—both about 81°—are considerably less than any of the former ones.

On the Character of the Beds of Chert in the Carboniferous Limestone of Yorkshire

It may be of interest to geologists to know that I have lately ascertained that the beds of chert which occur in the limestones of the Yoredale series of Yorkshire are distinctly of organic origin, and that, in fact, they are composed of the heterogeneously-mingled spicules of disintegrated siliceous sponges. The beds vary from 3 inches to 18 feet in thickness, and the limestones in which they are interbedded are nearly exclusively composed of the broken-up remains of crinoids, thus showing a well-marked alternation of periods in which sponges and crinoids succeeded each other. The spicules can only be studied in thin microscopic sections of the rock; in some cases they are very perfectly preserved and their axial canals are clearly shown; in other examples only very faint outlines can be made out. They appear to belong for the most part to the same group of Hexactinellid sponges as the recent genus *Hyalonema*, but Monactinellid spicules, like those of the existing genus *Reniera*, are also very numerous in some of the beds. Such an enormous accumulation of the debris of siliceous sponges proves that these organisms were as abundant in the Carboniferous as in the Cretaceous seas

The beds of chert referred to are exposed near Harrogate, and at Richmond, Yorkshire, and they are remarkably developed at Arkendale, about fourteen miles above Richmond. I am indebted to Mr. J. G. Goodchild, of the Geological Survey, for directing my attention to this last-named locality. Owing to their resistant character, fragments of the beds are also widely distributed in the boulder-clays to the south of their outcrops, and I have met with them in these clays near York.

It has been known for some time that the remains of siliceous sponges are of common occurrence in the Carboniferous chert beds of Ayrshire and of certain parts of Ireland, but they do not appear to have been noticed hitherto in the corresponding beds of Yorkshire. I hope shortly to give a more detailed description of their principal characters.

Croydon, April 2

The Zirconia Oxy-hydrogen Light

I HAVE been interested in the brief note you gave upon Prof. Linnemann's zirconia light, and as I have for several years been endeavouring to obtain the alleged advantages of this earth as a luminant, and with very different comparative results, if you will allow me briefly to state these, it may possibly be of service. Zirconia has been stated by Du Motay to be the "most luminous" as well as most refractory of earths, and if it indeed be so, its advantages would be very great. I have made many fruitless attempts to procure one of Du Motay's own pencils as prepared and sold many years ago, but none seem now obtainable; if any reader possesses, and can lend me, one for trial (all the better if he can share in or witness it), I shall be exceedingly obliged, in the interests of improved optical projection.

With the assistance of Mr. Chadwick, of Manchester, Mr. H. G. Madan, of Eton College, and a third gentleman, of Leeds, my own experiments have been made with small cylinders about 9 millimetres diameter, compressed from three different samples of zirconia. The incandescent surface was the flat end of such a cylinder.

The first sample was sold as "pure" by Hopkin and Williams, and many cylinders were tried of it. It was very largely contaminated with soda, which might in time have volatilised; but a more hopeless impurity was the large quantity of silica, which quickly fused into a thick yellow glaze. The light was most inferior, but the reddish tinge presently noticed was *not* conspicuous in this sample, which was worthless as an illuminant.

The second sample was prepared by my Leeds colleague, largely by blow-pipe processes. It stood the flame much better, and contained far less soda, which rapidly lessened under the flame. It contained, however, considerable silica, which could be observed through dark glasses to seethe and melt into ridges. When this took place, the light rapidly diminished, and was never near that of a lime cylinder, though at one time respectable. Also, fissures appeared in the face. But the peculiar physical properties of the earth were conspicuous, and chiefly its extraordinary *non-conducting* power. With a powerful jet (capable of yielding 700 candle-power on a lime cylinder) playing upon the small surface described, the full incandescence barely reached the edge of the disk, and the bright portion only extended about $2\frac{1}{2}$ millimetres up the cylinder, bounded by a definite line. At this line a crack all round began to appear, which gradually deepened, until at length the incandescent layer separated and fell off. The glow was of a most pronounced *reddish* character.

The third sample was procured by Mr. Madan from Herr Schuchardt, of Görlitz; it is stated to be prepared "especially" for the oxy-hydrogen light, and is sold at the rate of 18 marks for 10 grammes, of which about half is required to form a cylinder. This sample shrank enormously when heated, both in powder and when first compressed—showing that it was very largely hydrated—and had to be re-crushed and compressed again before anything could be done with it. It was much more free from silica, and half an hour of a powerful jet only produced a slight glaze or polish on the face. The *reddish* glow was very prominent in it also. The most serious fault, or difficulty, was that the circular crack formed and deepened much more rapidly than in the preceding, and the layer separated in less than half an hour. I fear this unequal shrinkage and its effects will alone be a great obstacle, unless—which I much regret we did not test experimentally—the thin layer itself, as detached, should prove sufficient, held in a platinum loop. Possibly it might crack no further.

But the light was again *poor* compared with a good lime. Mr. Madan had the plug crushed and re-made, and tested the light photometrically in his own laboratory at Eton. Compared with a good quarry lime, the zirconia taken as unity was only 1 : 2·88, with the same jet. That is a very startling difference. It is true that the incandescent surfaces are probably in about the same proportion, so that the brilliancy *per unit of surface* may be about the same. But then the incandescent surface of the zirconia cannot be increased, owing to the non-conducting properties already alluded to; so that the fact remains, so far as illumination is concerned, that we can only get with zirconia, or with such samples as I was able to obtain, about *one-third* of the light we can get from a good lime.

This result is so different from that stated by Prof. Linnemann, and years ago by Du Motay, that some explanation seems necessary. I think it lies in the fact that Continental operators do not use nearly such powerful jets as are often used in England, where we obtain 600 to 700 candle-power. Several Continental jets have come into my hands, none of which would give a good light, as a first-class "magic-lantern" lecturer understands it, *i.e.* sufficient to illuminate a disk 25 feet in diameter. Prof. Linnemann's own jet, of which I have seen the drawings, though it has the useful property of condensing the heat into a very small spot, is only a form of the "blow-through," as usually called; and when he remarks upon the "unsteadiness" of the mixing jet, he shows that he is not practically acquainted with it in a good form. Again, I was given by Mr. W. G. Lettsom some time ago a sample of an "improved" composition sold in Germany instead of limes, and stated to be "much better" for oxy-hydrogen purposes; my jets simply burnt holes clean through it (a prism of about 18 mm. diameter) in less than a minute. Now it is noticeable that with a blow-through jet, of about 200 candle-power, the zirconia does compare much more favourably, and is about as bright as the lime.

I write this, however, with a last hope of getting "more light" on the subject. If we could only get the whole light of a good lime-cylinder into the small disk (which is all that can be heated) of zirconia, the advantage would be very great: the parallel or other beam from the lantern from such a radiant is *as sharp* as from an arc light, and every Professor knows what that means. 700 candle-power without trouble—who does not long for it? It will be observed that each of the three samples described behaved differently, and it is in this fact lies my chief hope of any success yet; otherwise it is the decided opinion of all who have shared in these experiments, that the vaunted zirconia light is a sheer delusion. If any reader of these columns knows of purer samples to be procured commercially (I know Draper's process, but am no practical chemist, and have neither time nor means to prepare samples myself); or can tell me if the peculiar *red glow* noticed is characteristic of the earth itself or of some impurity; or has tested lanthana or any other of the more refractory earths; or can in any way assist me in what is, in its way, a matter of some importance to the science lecture-room, I shall feel much obliged for any communication from him, either here, or to LEWIS WRIGHT

7 Beaumont Road, Hornsey Rise, N.

The Production of Newton's Rings by Plane Soap-Films

LORD RAYLEIGH, in his recent lecture at the Royal Institution on "The Colours of Thin Plates," introduced Sir D. Brewster's experiment, in which circular rings instead of the usual straight bands are produced in a vertical soap-film by causing a jet of air to impinge very obliquely upon the film near its edge. The particles are thus thrown into a vortex-motion, and the centrifugal tendency causes the film to become thinner at the centre than at the edge, so as to produce very fair rings of colour.

Perhaps it may be worth mentioning that the same effect may be produced with greater regularity and less risk to the film, by giving the ring to which it is attached a rapid movement of rotation in its own plane. A shallow brass cup, about 8 or 9 cm. in diameter, the edge of which is turned inwards and rounded so as to give it the following section,

is mounted on a horizontal spindle so that it can be turned rapidly in a vertical plane (any ordinary smooth-running multiplying-wheel arrangement will answer, but a small electromotor is by far the most convenient). The edge of the cup is just dipped below the surface of the soap-solution, and then the socket at the back is fitted on the spindle and rotation commenced. At first the straight horizontal bands of colour maintain their form and position, for the reason which Lord Rayleigh well explained; but, as the speed increases, the adhesion of the film to the edge of the cup, and the cohesion of its particles, cause it to take up gradually the motion of the cup; and, as the mass accumulates at the circumference, very perfect circular rings are formed, which can be projected with brilliancy on a screen by the lime-light. Barnard's Second Comet

THERE would appear to be some danger that the observation of the above comet may be relinquished rather prematurely, as it is still sufficiently bright for observation when viewed with our larger telescopes; and, as far as I am aware, there are no published ephemerides later than March 27. To remedy this want, I subjoin places calculated from the elements of Dr. Palisa for Greenwich mean midnight for the period during which the moon will be absent.

Sunspots

IN the summary in regard to solar activity in 1886, published in NATURE for March 10, p. 445, it is stated that, during the period from October 31 to December 12, "on six days only out of the forty-two could there be discovered on the sun any trace even of a spot, and on those days only one tiny spot could be seen." As observed in this locality, there were formed, in the midst of the faculæ which came into view on November 14, one spot on November 15 and two spots on November 16; all having disappeared on November 18, when observation again became possible. On December 8 the first of a group of spots which made a complete transit across the sun's surface appeared. On December 9 this group consisted of three spots, which persisted until the 13th at least, gradually increasing in size. A period of sunspot minimum is best adapted in certain regards to the study of the relations of solar outbursts to magnetic and auroral phenomena; hence precision at such times, in reference to details of the character here indicated, is not unimportant.

Ozone

MY attention has been drawn to a letter in your issue of January 13 (p. 248), respecting the production of ozonised air for respiration in pulmonary complaints. I beg to inform "W. H." that there is at present no convenient electrical apparatus devised for use in a room, that would electrify the air with sufficient power to be of much service. A simple plan for obtaining ozone in small quantities is to mix very gradually three parts of strong sulphuric acid with two parts of permanganate of potash in a jam-pot, and place the vessel under the bed. Ozone will be given off from this mixture for some weeks.

I should be glad to hear the experiences of "W. H." inhaling ozonised air "just sensible to the smell," as I am of opinion that this strength of ozone is rather too great.

Your correspondent is misled in supposing that the Engadine hotels possess appliances for ozonising the air of corridors, &c. It is only the Maloja Kursaal which has adopted my device for this purpose. The electric current used is taken off from one of the dynamos used for lighting. A short description of the plan is given in the third edition of my "Alpine Winter," p. 84.

Upper Engadine A. TUCKER WISE

Electrical Discharges in the Doldrums

I QUITE agree with the Hon. Ralph Abercromby as to the continuous electrical discharges in the doldrums; so is there a continuous discharge of rain. I do not, however, agree with him in thinking that the electrical discharges are in any way directly connected with earth-currents. I should say they are due to electrical discharges on the top of the shower clouds, unaccompanied by thunder. It would be interesting to know if travellers in the centres of Africa and South America have observed this phenomenon there.

DAVID WILSON-BARKER

Green Light at Sunrise and Sunset

MR. R. T. OMOND, of the Ben Nevis Observatory, in NATURE of February 24, p. 391, asks whether the cause of the green colour at sunset at sea is the sun shining *through* the water? This cannot be the cause, for I have many times observed this colour at sunrise behind the mountains Madonie or Copo Zaferano, which, from the Observatory, appear higher on the sea horizon than the sun's disk. That is to say, the phenomenon occurs when, for the observer, the sun is entirely above the marine horizon, and no part of the disk can shine through the water. A. RICCÒ

Palermo Observatory

[This is a well known and obvious effect of atmospheric refraction.—ED.]

A Sparrow chasing Pigeons

"E. A. C." inquires in NATURE of last week (p. 536), whether any of your readers have observed the sparrow chasing pigeons. This habit of the sparrow is very common; I have myself often observed it, and I apprehend that few who keep pigeons have not frequently seen such attacks. The pugnacity of the sparrow did not appear to me to be the result of any previous quarrel with the pigeon, as I never saw the former attack the latter except on the wing, and always from underneath.

A Question for Chemists

Is it known that a mixture of glycerine and permanganate of potassium will take fire spontaneously immediately after being mixed? If so, I should be glad of any reference to the fact.

Bradford WM. WEST

THE PARIS ASTRONOMICAL CONGRESS

THE International Congress called together by the French Government to take steps to obtain a photographic chart of the heavens was opened on Saturday at the Observatory of Paris, and, from the information which has reached us so far, it would seem that its labours are likely to have a result of the highest importance for the science of this and succeeding centuries. The following Directors of Observatories are already in Paris, or are expected: if half of them really come, there will be such a meeting of astronomers as has rarely been seen:—

Baillaud, Toulouse Observatory
Bakhuyzen, Leiden
Beuf, La Plata
Christie, Greenwich
Cruls, Rio de Janeiro
Donner, Helsingfors
Dunér, Lund
Folie, Brussels
Gill, Cape Town
Gyldèn, Stockholm
Krueger, Kiel
Oom, Lisbon
Perry, Stonyhurst
Peters, Clinton (U.S.A.)
Pujazon, San Fernando
Rayet, Bordeaux
Russell, Sydney
Schoenfeld, Bonn
Struve, Pulkowa
Tacchini, Rome
Thiele, Copenhagen
Trépied, Algiers
Vogel, Potsdam
Weiss, Vienna

Besides these Directors of Observatories, and of course all the astronomical members of the Institute, there are other astronomers, such as Messrs. Common and Roberts from our own country, and Messrs. Lohse (from Germany), Winterhalter (from Washington), and Hasselberg (from Pulkowa), whose presence is most important.

The French Government, the Academy of Sciences (with Dr. Janssen as President), and Admiral Mouchez (the Director of the National Observatory of Paris), seem to have done all in their power to facilitate the labours, and even to provide for the comfort, of the various delegates and others representing the various nationalities; and at the opening ceremony the manner in which the Institute and Government are doing all they can was evidenced by the fact that the address which was delivered by M. Bertrand, the eminent mathematician, on behalf of the Academy of Sciences, was followed by another, made by M. Flourens, the Minister of Foreign Affairs.

They certainly manage these things better in France! Fancy a scientific meeting at Greenwich Observatory, addressed by the head of the English Foreign Office!

What M. Flourens said had better be given in his own words:—

Messieurs,—

J'ai l'honneur de vous souhaiter la bienvenue au nom de la France, qui vous offre ici sa cordiale hospitalité.

Je me félicite que cette mission me soit échue de vous complimenter au nom du gouvernement de la République, de vous remercier d'avoir accepté les invitations qui vous ont été adressées par l'éminent et sympathique directeur de notre Observatoire.

C'est une grande œuvre que celle que vous allez entreprendre, et, grâce aux lumières que vous nous apportez de tous les points du globe, mener à bonne fin. Dans la poursuite de cette œuvre, vous aurez, je n'en doute pas, l'appui de tous les gouvernements, qui sont animés aujourd'hui d'une noble émulation pour le développement de la science. En tout cas, le concours du gouvernement de la République française, au nom de laquelle j'ai l'honneur de parler, vous est dès à présent acquis.

Vous allez, dans une féconde et cordiale entente, jeter les bases de l'exécution d'une carte du ciel dont la précision dépassera de beaucoup non seulement tout ce que l'on avait réalisé, mais encore tout ce que l'on avait osé rêver jusqu'à ce jour. Par une merveilleuse application de la photographie, de cet art si riche en résultats imprévus, vous allez diriger l'œil humain dans des profondeurs où, à l'aide des plus puissants télescopes, on n'avait pas cru possible de le faire pénétrer. Le nombre des étoiles inconnues jusqu'ici, dont l'existence sera ainsi révélée, est incalculable.

Ce sera pour votre nom, messieurs, une gloire éternelle d'avoir apporté votre précieuse collaboration à l'inauguration de cette grande entreprise, et le jour de l'ouverture de ce congrès marquera dans les annales de la science humaine.

Une ère nouvelle s'ouvre pour l'astronomie physique comme pour l'astronomie mathématique, qui vont avoir à leur disposition un moyen d'investigation, de contrôle, de précision qui étendra dans une proportion indéfinie la fécondité de leurs recherches. Vous allez écrire la première page authentique des transformations et des modifications de la matière cosmique, c'est-à-dire l'histoire de l'univers lui-même.

Je voudrais complimenter, par leurs noms et par leurs œuvres, chacun des savants illustres qui sont réunis dans cette enceinte. Mais j'abuserais des précieux et trop courts instants de notre réunion. Nos hôtes trouveront bon que je les honore tous en la personne de leur doyen, de l'illustre M. Struve, dont le nom est si sympathique à la France et dont on fêtait naguère le vingt-cinquième anniversaire comme directeur du célèbre observatoire de Poulkova.

Agréez, messieurs, avec mes vœux les plus sincères pour la réussite de vos efforts, la nouvelle assurance du concours du gouvernement de la République.

Prof. O. von Struve replied to this address in a short and impressive speech, and the Conference proceeded to elect officers.

Admiral Mouchez, the Director of the Observatory, was elected Honorary President, and Prof. O. von Struve Acting President. As Vice-Presidents, Messrs. Auwers, Christie, and Fizeau were elected; as Secretaries, Messrs. Tisserand and Bakhuyzen, assisted by Dunér and Trépied.

The Conference then proceeded to pass the following resolutions:—

(1) The progress realised in astronomical photography renders it absolutely necessary that the astronomers of the present century should undertake a conjoint photographic record of the heavens.

(2) This work shall be undertaken at certain stations to be selected, and with instruments identical in all essential points.

(3) The principal objects sought to be attained shall be:—

(*a*) To record the general state of the heavens at the present time by obtaining data which will enable us to determine the position and brilliancy of all the stars down to a certain magnitude, to be hereafter agreed on, with the greatest precision possible; the magnitudes to be expressed according to some photographic standard to be hereafter determined.

(*b*) To fix upon the best means to utilise at the present time the various data furnished by photographic processes.

After these resolutions were passed, the Conference proceeded to appoint a Committee of nineteen members to consider the kind of instrument to be employed, and the lowest magnitude of star it will be necessary to register. The Committee appointed consists of the following astronomers:—MM. Auwers, Bakhuyzen, Christie, Common, Dunér, Fizeau, Gill, Paul Henry, Janssen, Kapteyn, Lœwy, Rayet, Roberts, Peters, O. von Struve, Tacchini, Thiele, Vogel, and Weiss. When this Committee has brought up its Report, the other questions will be considered by a number of Sections, to be appointed to consider and report upon them to the Conference.

Hospitality is not lacking to make the labours of the Conference as light as possible. Admiral Mouchez, who gave a *soirée* on the evening of the 19th, gives a banquet on the 24th. The astronomers are to be received by the President of the Republic, and also at the Théâtre Français by the members of the Institute, on Saturday. There is also to be a ball at the Hôtel Continental, given by Le Comité des Amis de Science.

We warmly congratulate French men of science upon the magnificent results obtained by their countrymen the Brothers Henry, which have been among the causes that have brought the Conference together. If all goes well, the work of the Conference will mark an epoch in the history of astronomy.

HOMERIC ASTRONOMY

I.

THE Homeric ideas regarding the heavenly bodies were of the simplest description. They stood, in fact, very much on the same level with those entertained by the North American Indians, when first brought into European contact. What knowledge there was in them was of that "broken" kind which (in Bacon's phrase) is made up of wonder. Fragments of observation had not even begun to be pieced in one with the other, and so fitted, ill or well, into a whole. In other words, there was no faintest dawning of a celestial science.

But surely, it may be urged, a poet is not bound to be an astronomer. Why should it be assumed that the author (or authors) of the "Iliad" and "Odyssey" possessed information co-extensive on all points with that of his fellow-countrymen? His profession was not science, but song. The argument, however, implies a reflecting backward of the present upon the past. Among unsophisticated peoples, specialists, unless in the matter of drugs or spells, do not exist. The scanty stock of gathered knowledge is held, it might be said, in common. The property of one is the property of all.

More especially of the poet. His power over his hearers depends upon his presenting vividly what they already perceive dimly. It was part of the poetical faculty of the Ithacan bard Phemius that he "knew the works of gods and men" ("Od.," i. 338). His special function was to render them famous by his song. What he had heard concerning them he repeated; adding, of his own, the marshalling skill, the vital touch, by which they were perpetuated. He was no inventor: the actual life of men, with its transfiguring traditions and baffled aspirations, was the material he had to work with. But the life of men was very different then from what it is now. It was lived in closer contact with Nature; it was simpler, more typical, consequently more susceptible of artistic treatment.

It was accordingly looked at and portrayed as a whole; and it is this very *wholeness* which is one of the principal charms of primitive poetry. An irrecoverable charm; for civilisation renders existence a labyrinth of which it too often rejects the clue. In olden times, however, its ways were comparatively straight, and its range limited. It was accordingly capable of being embraced with approximate entirety. Hence the encyclopædic character of the early epics. *Humani nihil alienum.* Whatever men thought, and knew, and did, in that morning of the world when they spontaneously arose, found a place in them.

Now, some scheme of the heavens must always accompany and guide human existence. There is literally no choice for man but to observe the movements, real or apparent, of celestial objects, and to regulate his actions by the measure of time they mete out to him. Nor had he at first any other means of directing his wanderings upon the earth save by regarding theirs in the sky. They are thus to him standards of reference and measurement as regards both the fundamental conditions of his being—time and space.

This intimate connexion, and, still more, the idealising influence of the remote and populous skies, has not been lost upon the poets in any age. It might even be possible to construct a tolerably accurate outline-sketch of the history of astronomy in Europe without travelling outside the limits of their works. But our present concern is with Homer.

To begin with his mode of reckoning time. This was by years, months, days, and hours ("Od.," x. 469, xi. 294). The week of seven days was unknown to him; but in its place we find (in the "Odyssey," xix. 307) the triplicate division of the month used by Hesiod and the later Attics, implying a month of thirty, and a year of 360 days, corrected, doubtless, by some rude process of intercalation. A corresponding apportionment of the hours of night into three watches (as amongst the Jews before the Captivity), and of the hours of day into three periods or stages, prevails in both the "Iliad" and "Odyssey." The seasons of the year, too, were three—spring, summer, and winter—like those of the ancient Egyptians and of our Anglo-Saxon forefathers;[1] for the Homeric *Opora* was not, properly speaking, an autumnal season, but merely an aggravation of summer heat and drought, heralded by the rising of Sirius towards the close of July. It, in fact, strictly matched our "dog-days," the *dies caniculares* of the Romans. This rising of the dog-star is the only indication in the Homeric poems of the use of a stellar calendar such as we meet full-grown in Hesiod's "Works and Days." The same event was the harbinger of the Nile-flood to the Egyptians, serving to mark the opening of their year as well as to correct the estimates of its length.

The annual risings of stars had formerly, in the absence of more accurate means of observation, an importance they no longer possess. Mariners and husbandmen, accustomed to watch, because at the mercy of the heavens, could hardly fail no less to be struck with the successive effacements by, and re-emergences from, the solar beams, of certain well-known stars, as the sun pursued his yearly course amongst them, than to note the epochs of such events. Four stages in these periodical fluctuations of visibility were especially marked by primitive observers. The first perceptible appearance of a star in the dawn was known as its "heliacal rising." This brief glimpse extended gradually as the star increased its seeming distance from the sun, the interval of precedence in rising lengthening by nearly four minutes each morning. At the end of close upon six months occurred its "acronychal rising," or last visible ascent from the eastern horizon after sunset. Its conspicuousness was then at the maximum, the whole of the dark hours being available for its shining. To these two epochs of rising succeeded and corresponded two epochs of setting—the "cosmical" and the "heliacal." A star set cosmically when, for the first time each year, it reached the horizon long enough before break of day to be still distinguishable; it set heliacally on the last evening when its rays still detached themselves from the background of illuminated western sky, before getting finally immersed in twilight. The round began again when the star had arrived sufficiently far on the other side of the sun to show in the morning—in other words, to rise heliacally.

Wide plains and clear skies gave opportunities for closely and continually observing these successive moments in the revolving relations of sun and stars, which were soon found to afford a very accurate index to the changes of the seasons. By them, for the most part, Hesiod's prescriptions for navigation and agriculture are timed; and although Homer, in conformity with the nature of his subject, is less precise, he was still fully aware of the association.

His sun is a god—Helios—as yet unidentified with Apollo, who wears his solar attributes unconsciously. Helios is also known as Hyperion, "he who walks on high," and Elector, the "shining one." Voluntarily he pursues his daily course in the sky, and voluntarily he sinks to rest in the ocean-stream. Subject, however, at times to a higher compulsion. For, just after the rescue of the body of Patroclus, Here favours her Achaian clients by precipitating at a critical juncture the descent of a still unwearied and unwilling luminary ("Iliad," xviii. 239). On another occasion, however, Helios memorably asserts his independence, when, incensed at the slaughter of his sacred cattle by the self-doomed companions of Ulysses, he threatens to "descend into Hades, and shine among the dead" ("Od.," xii. 383). And Zeus, in promising the required satisfaction, virtually admits his power to abdicate his office as illuminator of gods and men.

Once only, the solstice is alluded to in Homeric verse. The swineherd Eumæus, in describing the situation of his native place, the Island of Syrie, states that it is over against Ortygia (Delos), "where are the turning-places of the sun" ("Od.," xv. 404). The phrase probably indicates the direction in which Delos lay from Ithaca, being just so much south of east as the sun lies at rising on the shortest day of winter. To those early students of Nature, the travelling to and fro of the points of sunrise and sunset, furnished the most obvious clue to the yearly solar revolution; so that an expression, to us somewhat recondite, conveyed a direct and unmistakable meaning to hearers whose narrow acquaintance with the phenomena of the heavens was vivified by immediate personal experience of them.

Selene first takes rank as a divine personage in the Homeric hymns. No moon-goddess is recognised in the "Iliad" or "Odyssey." Nor does the orbed ruler of "ambrosial night," regarded as a mere light-giver or time-measurer, receive all the attention that might have been expected. A full moon is, however, represented with the other "heavenly signs" on the shield of Achilles, and figures somewhat superfluously in the magnificent passage where the Trojan watch-fires are compared to the stars in a cloudless sky:

"Even as when in heaven the stars about the bright moon shine clear to see, when the air is windless, and all the peaks appear and the tall headlands and glades, and

[1] Lewis, "Astr. of the Ancients," p. 11. Tacitus says of the Germans: "Autumni perinde nomen ac bona ignorantur" ("Germania," cap. xxvi).

from heaven breaketh open the infinite air, and all stars are seen, and the shepherd's heart is glad; even in like multitude between the ships and the streams of Xanthos appeared the watch-fires that the Trojans kindled in front of Ilios."[1]

Here, as elsewhere, the simile no sooner presents itself than the poet's imagination seizes upon and develops it without overmuch regard to the illustrative fitness of its details. The multitudinous effect of a thousand fires blazing together on the plain inevitably suggested the stars. But with the stars came the complete nocturnal scene in its profound and breathless tranquillity. The "rejoicing shepherd," meantime, who was part of it, would have been ill-pleased with the darkness required for the innumerable stellar display first thought of. And since, to the untutored sense, landscape is delightful only so far as it gives promise of utility, brilliant moonlight was added, for his satisfaction and the safety of his flock, as well as for the perfecting of that scenic beauty felt to be deficient where human needs were left uncared for. Just in proportion, however, as rocks, and peaks, and wooded glens appeared distinct, the lesser lights of heaven, and with them the fundamental idea of the comparison, must have become effaced; and the poet, accordingly, as if with a misgiving that the fervour of his fancy had led him to stray from the rigid line of his purpose, volunteered the assurance that "all the stars were visible"—as, to his mind and eye, they doubtless were.

Of the "vivid planets" thrown in by Pope there is no trace in the original. Nor could there be; since Homer was totally ignorant that such a class of bodies existed. This curious fact affords (if it were needed) conclusive proof of the high antiquity of the Homeric poems. Not the faintest suspicion manifests itself in them that Hesperus, "fairest of all stars set in heaven," is but another aspect of Phosphorus, herald of light upon the earth, "the star that saffron-mantled Dawn cometh after, and spreadeth over the salt sea" ("Iliad," xxiii. 226–27). The identification is said by Diogenes Laertius to have been first made by Pythagoras; and it may at any rate be assumed with some confidence that this elementary piece of astronomical knowledge came to the Greeks from the East, with others of a like nature, in the course of the sixth or seventh century B.C. Astonishing as it seems that they should not have made the discovery for themselves, there is no evidence that they did so. Hesiod appears equally unconscious with Homer of the distinction between "fixed" and "wandering" stars. According to his genealogical information, Phosphorus, like the rest of the stellar multitude, sprang from the union of Astræus with the Dawn ("Theogony," 381), but no hint is given of any generic difference between them.

There is a single passage in the "Iliad," and a parallel one in the "Odyssey," in which the constellations are formally enumerated by name. Hephæstus, we are told, made for the son of Thetis a shield great and strong, whereon, by his exceeding skill, a multitude of objects were figured.

"There wrought he the earth, and the heavens, and the sea, and the unwearying sun, and the moon waxing to the full, and the signs every one wherewith the heavens are crowned, Pleiads, and Hyads, and Orion's might, and the Bear that men call also the Wain, her that turneth in her place, and watcheth Orion, and alone hath no part in the baths of Ocean" ("Iliad," xviii. 483–89).

The corresponding lines in the "Odyssey" occur in the course of describing Ulysses' voyage from the isle of Calypso to the land of the Phæacians. Alone, on the raft he had constructed of Ogygian pine-wood, he sat during seventeen days, "and cunningly guided the craft with the helm; nor did sleep fall upon his eyelids, as he viewed the Pleiads and Boötes, that setteth late, and the Bear, which they likewise call the Wain, which turneth ever in one place, and keepeth watch upon Orion, and alone hath no part in the baths of Ocean" ("Odyssey," v 271–75).

The sailing-directions of the goddess were to keep the Bear always on the left—that is, to steer due east.

It is clear that one of these passages is an adaptation from the other; nor is there reason for hesitation in deciding which was the model. Independently of extrinsic evidence, the verses in the "Iliad" have the strong spontaneous ring of originality, while the Odyssean lines betray excision and interpolation. The "Hyads and Orion's might" are suppressed for the sake of introducing Boötes. Variety was doubtless aimed at in the change; and the conjecture is at least a plausible one, that the added constellation may have been known to the poet of the "Odyssey" (admitting the hypothesis of a divided authorship), though not to the poet of the "Iliad." Known, that is, in the sense that the stars comprising the figure of the celestial Husbandman had not yet, at the time and place of origin of the "Iliad," become separated from the anonymous throng circling in the "murk of night."

The constellation Boötes was invented to drive the Wain, as Arctophylax to guard the Bear, the same group in each case going by a double name. For the brightest of the stars thus designated we still preserve the appellation Arcturus (from *arktos*, bear, *oũros*, guardian), first used by Hesiod, who fixed upon its acronychal rising, sixty days after the winter solstice, as the signal for pruning the vines ("Works and Days," 564–70). It is not unlikely that the star received its name long before the constellation was thought of, forming the nucleus of a subsequently formed group. This was undoubtedly the course of events elsewhere; the Great and Little Dogs, for instance, the Twins, and the Eagle (the last with two minute companions) having been individualised as stars previous to their recognition as asterisms.

There is reason to believe that the stars enumerated in the "Iliad" and "Odyssey" constituted the whole of those known by name to the early Greeks. This view is strongly favoured by the identity of the Homeric and Hesiodic stars. It is difficult to believe that, had there been room for choice, the same list *precisely* would have been picked out for presentation in poems so widely diverse in scope and origin as the "Iliad" and "Odyssey" on the one side, and the "Works and Days" on the other. As regards the polar constellations, we have positive proof that none besides Ursa Major had been distinguished. For the statement repeated in both the Homeric epics, that the Bear *alone* was without part in the baths of Ocean, implies, not that the poet veritably ignored the unnumbered stars revolving within the circle traced out round the pole by the seven of the Plough, but that they still remained a nameless crowd, unassociated with any terrestrial object, and therefore attracting no popular observation.

The Greeks, according to a well-attested tradition, made acquaintance with the Lesser Bear through Phœnician communication, of which Thales was the medium Hence the designation of the group as *Phoinike*. Aratus (who versified the prose of Eudoxus) has accordingly two Bears, lying (in sailors' phrase) "heads and points" on the sphere; while he expressly states that the Greeks still (about 270 B.C.) continued to steer by *Helike* (the Twister, Ursa Major), while the expert Phœnicians directed their course by the less mobile *Kynosoura* (Ursa Minor). The absence of any mention of a Pole-star seems at first sight surprising. Even the Iroquois Indians directed their wanderings from of old by the one celestial luminary of which the position remained sensibly invariable (Lafitau, "Mœurs des Sauvages Américains,"

[1] "Iliad," viii. 551–57. Mr. Andrew Lang's admirable prose-versions are employed throughout this article.

p. 240). Yet not the gods themselves, in Homer's time, were aware of such a guide. It must be remembered, however, that the axis of the earth's rotation pointed, 2800 years ago, towards a considerably different part of the heavens from that now met by its imaginary prolongation. The precession of the equinoxes has been at work in the interval, slowly but unremittingly shifting the situation of this point among the stars. Some 600 years before the Great Pyramid was built, it was marked by the close vicinity of the brightest star in the Dragon. But this in the course of ages was left behind by the onward-travelling pole, and further ages elapsed before the star at the tip of the Little Bear's tail approached its present position. Thus the entire millennium before the Christian era may count for an interregnum as regards Pole-stars. Alpha Draconis had ceased to exercise that office; Alruccabah had not yet assumed it.

The most ancient of all the constellations is probably that which Homer distinguishes as never-setting (it then lay much nearer to the pole than it now does). In his time, as in ours, it went by two appellations—the Bear and the Wain. Homer's Bear, however, included the same seven bright stars constituting the Wain, and no more; whereas our Great Bear stretches over a sky-space of which the Wain is only a small part, three of the striding monster's far-apart paws being marked by the three pairs of stars known to the Arabs as the "gazelle's springs." How this extension came about, we can only conjecture; but there is evidence that it was fairly well established when Aratus wrote his description of the constellations. Aratus, however, copied Eudoxus, and Eudoxus used observations made—doubtless by Accad or Chaldean astrologers—above 2000 B.C.[1] We infer, then, that the Babylonian Bear was no other than the modern Ursa Major.

But the primitive asterism—the Seven Rishis of the old Hindus, the Septem Triones of the Latins, the Arktos of Homer—included no more than seven stars. And this is important as regards the origin of the name. For it is impossible to suppose a likeness to any animal suggested by the more restricted group. Scarcely the acquiescent fancy of Polonius could find it "backed like a weasel," or "very like a whale." Yet a weasel or a whale would match the figure equally well with, or better than, a bear. Probably the growing sense of incongruity between the name and the object it signified may have induced the attempt to soften it down by gathering a number of additional stars into a group presenting a distant resemblance to a four-legged monster.

The name of the Bear, this initial difficulty notwithstanding, is prehistoric and quasi-universal. It was traditional amongst the American-Indian tribes, who, however, sensible of the absurdity of attributing a conspicuous protruding tail to an animal almost destitute of such an appendage, turned the three stars composing it into three pursuing hunters.

The same constellation figures, under a divinified aspect, with the title *Otawa*, in the great Finnish epic, the "Kalevala." Now, although there is no certainty as to the original meaning of this word, which has no longer a current application to any terrestrial object, it is impossible not to be struck with its resemblance to the Iroquois term *Okowari*, signifying "bear," both zoologically and astronomically (Lafitau, *op. cit.*, p. 236). The inference seems justified that *Otawa* held the same two meanings, and that the Finns knew the great northern constellation by the name of the old Teutonic king of beasts.

It was (as we have seen) similarly designated on the banks of the Euphrates; and a celestial she-bear, doubtfully referred to in the Rig-Veda, becomes the starting-point of an explanatory legend in the Râmâyana (De Gubernatis, "Zoological Mythology," vol. ii. p. 109).

[1] According to Mr. Proctor's calculation. See R. Brown, "Eridanus: River and Constellation," p. 3.

Thus, circling the globe from the valley of the Ganges to the great lakes of the New World, we find ourselves confronted with the same sign in the northern skies, the relic of some primæval association of ideas, long since extinct.

Extinct even in Homer's time. For the myth of Callisto (first recorded in a lost work by Hesiod) was a subsequent invention—an effect, not a cause—a mere embroidery of Hellenic fancy over a linguistic fact, the true origin of which was lost in the mists of antiquity.

There is, on the other hand, no difficulty in understanding how the Seven Stars obtained their second title of the Wain, or Plough, or Bier. Here we have a plain case of imitative name-giving—a suggestion by resemblance almost as direct as that which established in our skies a Triangle and a Northern Crown. Curiously enough, the individual appellations still current for the stars of the Plough, include a reminiscence of each system of nomenclature—the legendary and the imitative. The brightest of the seven, α Ursæ Majoris, the Pointer nearest the Pole, is designated *Dubhe*, signifying, in Arabic, "bear"; while the title *Benetnasch*—equivalent to *Benât-en-Nasch*, "daughters of the bier"—of the furthest star in the plough-handle, perpetuates the lugubrious fancy, native in Arabia, by which the group figures as a corpse attended by three mourners. A. M. CLERKE

(*To be continued.*)

RAINBAND OBSERVATIONS AT THE BEN NEVIS OBSERVATORY

RAINBAND spectroscopy is one of the extra subjects taken up at the Ben Nevis Observatory, along with the usual meteorological routine. At every hour, when there is sufficient light, the intensity of the rainband is observed and recorded, and now, the mean daily rainband forms one of the items in the Ben Nevis weather report in the daily newspapers. The scale in use is practically the same as that used by Dr. Mill, of the Granton Marine Station, and described by him in a paper to the Royal Society of Edinburgh (Proc. R.S.E., 1882-84). This scale is in the spectrum itself—a great convenience—being the Fraunhofer lines E, *b*, and F of the solar spectrum. After a preliminary set of observations had been made, in various types of weather, for the purpose of determining the relative intensity of these lines, a numerical value was given to each, namely, to E, 2; to *b*, 4; and to F, 7. After a little practice, it is quite easy to estimate the values less than 2, which often occur, and the values above 7, which very seldom occur. With this scale, the intensity or darkness of the rainband and D line taken together is compared, and the numerical value of its scale-equivalent entered in the register. The instrument used is one of Hilger's rainband pocket spectroscopes, and the part of the sky always observed is between 30° and 40° above the south-western horizon.

The results obtained in 1885 were communicated to the Scottish Meteorological Society, and are published in their Journal for 1886 (see NATURE, vol. xxxiii. p. 622). In 1886, over 3000 observations were made, and the relative frequency with which each number of the scale was observed will convey an idea of the intensity of the rainband on Ben Nevis. The percentage of observations of each number is as follows:—

Rainband	0	1	2	3	4	5	6	7
Percentage ...	24	31	27	8	7	1	1	1

The mean of all the observations gives a rainband of 1·7. Now at sea-level, according to Dr. Mill, the rainband is seldom or never less than E, that is, than 2 on our scale. Hence the mean rainband on the Ben is about equal to the minimum at sea-level. About 80 per cent. of these observations were made when the Ben was enveloped in fog or mist. The only effect fog or mist has upon the rainband is that its intensity is the same in every possible direction, whereas in clear weather, as is well known, it is generally greatest at the horizon and least at the zenith. But as the rainband in fog or mist has been found to be equal to that which is observed in clear weather at an altitude of 30° or 40°—the altitude of that part of sky always observed—the presence or absence of fog and mist has been ignored in working up the observations.

In forecasting the weather for the surrounding low-levels, the rainband observed here, together with similar observations at Fort William, would probably be of great value, but its forecasting power for the summit alone is limited. The lower values generally show indications of rain several hours before it comes on, but the higher values simply indicate a continuation of the heavy rainfall by which they are invariably accompanied. To show that the rainfall increases with the successive numbers of the scale, the mean hourly rainfall has been computed, for each scale value, from the rainfall of the three hours and twelve hours after noon. For the observations of 1885, the mean daily rainband was used. In 1886, each individual observation was taken into account, and, for each number of the scale, the mean rainfall was computed from the rainfall of the three hours after each observation. As the results differ in some respects, they are here given for each year separately :—

Rainband		0	1	2	3	4	5 and upwards
Rainfall (inches)	1885...	·000	·006	·016	·029	·050	·106
	1886...	·002	·006	·012	·016	·027	·076

Owing to the fewness of observations of the numbers 5, 6, and 7, they have been grouped together. The higher values are followed by a rainfall which is proportionally far too high, owing, no doubt, to the fact that these higher values are only observed during the passage of cyclonic disturbances laden with moisture from the Atlantic, when a great amount of this moisture only comes into the spectroscopic field in a condensed state, when it is forced to ascend so as to pass the summit, and consequently does not affect the rainband, but causes a very heavy rainfall. The moisture that ascends the mountain, not being detected below by the spectroscope here, is a constant source of disparities in the agreement of rainband and subsequent rainfall. The fact that our mean rainband is not greater than 1·7, and that the amounts of rainfall were, for 1885, 146·497 inches, and for 1886, 107·847 inches, clearly indicates that a great part of our rainfall is due to the condensation of the moisture that is forced up from below the level of the summit.

In comparing rainband with subsequent rainfall, the temperature of the air at the time of observation, as well as the variation in the temperature, must be taken into account. With the view of ascertaining the relations between rainband, subsequent rainfall, and temperature, the mean hourly rainfall for the three hours after an observation, for each number of the rainband scale, and for every 5° of temperature from 15° to 50°, has been calculated, and the results for rainbands of values 1, 2, and 3. are as follows :—

Temperature		15°	20°	25°	30°	35°	40°	45°	50°
Rainband	1 ...	·003	·005	·010	·006	·006	·004	·000	·000
	2 ...	·005	·010	·024	·015	012	·006	·003	·000
	3 ...	·007	·013	·026	·019	·016	·015	·009	·003

The means for temperatures of 25° and upwards show that for any one rainband, when the temperature rises the rainfall decreases, and when the temperature falls the rainfall increases. The results being as yet only tentative, it cannot be definitely stated by how much the mean hourly rainfall increases or decreases per degree of fall or rise in the temperature, for any one value of the rainband. The means for temperatures below 25° seem to indicate that a fall in the temperature causes a decrease in the rainfall, which is not at all probable. If it be the case that low temperatures do not affect the absorbing powers of aqueous vapour, which is not likely, the smal amount of rainfall at these low temperatures may be due to the necessarily unsatisfactory measurements of precipitation obtained from the rain-gauge when the temperature is below 32°. In truth, snowfall and rainfall as measured by the rain-gauge, can hardly be compared with each other. For a full account of these and other questions of rainfall here, see Mr. Omond's articles and also Mr. Buchan's "Meteorology of Ben Nevis" in the Journal of the Scottish Meteorological Society for the last two years.

The mean rainbands at the different temperatures are :—

Temperature	15°	20°	25°	30°	35°	40°	45°	50°
Rainband ...	0·4	1·1	1·1	1·5	1·9	2·4	2·5	2·3

The greatest number of observations at any one temperature was 724 at 30°, and the least 35 at 50°.

The reason why so many observations were made in 1886 was to find whether there was any daily variation in the rainband. That there is a slight variation will be seen from the following results, which are for the summer months only, viz. :—

Hour	6	7	8	9	10	11	12 noon
Rainband	1·4	1·4	1·6	1·5	1·6	1·6	1·7
Temperature	32°·0	32°·3	32°·7	33°·2	33°·5	34°·0	34°·4
Hour	13	14	15	16	17	18	
Rainband	1·7	1·7	1·8	1·7	1·8	1·7	
Temperature	34°·8	35°·0	35°·0	34°·9	34°·7	34°·3	

The rise in the rainband from 6 a.m. till 3 p.m. following the temperature, points to the cause of this daily variation as being the expansion of the lower atmosphere by the rising temperature, and the consequent raising of the vapour above the level of the Ben. This is almost the same cause to which Mr. Buchan ascribes the rise in the barometric pressure for the same daily period. Prof. Piazzi Smyth says that the rainband does not increase for a rise of temperature *at sea-level*, because the total quantity of vapour over the place of observation is pretty constant (Journal Scot. Met. Soc., vol. v.). But over this summit the quantity of vapour is not constant, but varies, and the rainband varies with it.

Remarkable variations in the rainband occur in the course of a single day, often amounting to 3, and sometimes to 5 and 6. On March 26, 1886, when a cyclone was passing to the north of the Observatory, the rainband varied from 6 at 10 a.m., to 3 at 12 noon, and to 1 at 5 p.m. The strongest mean for any one day was 8 on January 1, 1886, while a mean of 0 has frequently occurred. On December 18, 1885, a rainband, estimated at 12, was observed on the rising sun—this was one of the noted "fore-glow" mornings. In anticyclonic weather, which is characterised by great dryness of the air, with all the clouds at lower levels, a strong rainband is always obtained from the layer of air close over the clouds, in summer, when not a trace is detected at the usual height of observation ; but in similar weather in winter the rainband is often entirely absent, even over the clouds. It is noteworthy that on days with little or no rainband, when not actually looking at the sun, the spectrum as a whole is darker than usual, and on days with strong rainbands, the parts of the spectrum not occupied by lines are brighter than usual. In a certain type of weather, when the rain-gauge completely fails to record the precipitation, the rainband always indicates the presence in the air of the vapour which gives it. This occurs when snow-crystals are deposited with low temperatures and strong winds, as described in NATURE (vol. xxxi. p. 532). The importance of rainband observations will be greatly increased when similar series can be undertaken at the sea-level simultaneously with those on the summit of Ben Nevis.

A. RANKIN

DO SCORPIONS COMMIT SUICIDE?

CORRESPONDENTS of NATURE have repeatedly raised the question whether there is any truth in the old legend that a scorpion, when placed within a ring of red-hot embers, will, after making futile efforts to pass the fiery circle, deliberately kill itself by inflicting a wound with a sting in its own head. Surgeon-General Bidie, of Madras (vol. xi. p. 29), Dr. Allen Thomson (vol. xx. p. 577), and Mr. Gillman (vol. xx. p. 629), have answered the question in the affirmative. The other side has been taken by Mr. Hutchinson (vol. xxi. p. 226), Mr. Curran (vol. xxi. p. 325), and Mr. Lloyd Morgan (vol. xxvii. p. 313). Mr. Hutchinson maintained that the animals experimented on by Mr. Gillman had died from excessive heat. To this Mr. Gillman replied, that the temperature in the centre of such a circle of glowing charcoal as he used does not exceed 50° C.

The subject has lately been thoroughly investigated by Mr. Alfred G. Bourne, Professor of Biology in the Presidency College, Madras; and the results of his observations have been set forth in a paper communicated to the Royal Society by Prof. Ray Lankester. Some of the details of his experiments are not very pleasant reading, but it must be remembered that the question is one of considerable importance, because, if it could be proved that the scorpion commits suicide, its impulse to do so would be, as Mr. Romanes has pointed out, "a unique case of an instinct detrimental alike to the individual and to the species."

One of the arguments used to disprove the existence of the supposed instinct is, that it is physically impossible for a scorpion to sting itself in a vulnerable place. Mr. Bourne shows that this statement is inaccurate. If, he says, a dead scorpion be taken which is quite limp and not in a state of rigour, it will be easily seen that the last four segments of the tail are about the only portions of the body, whether on the dorsal or ventral surface, where a scorpion could *not* sting itself. Further, if two fighting scorpions be watched, it will be seen that the extent to which the sting can be moved about is perfectly wonderful. Moreover, he has noticed that, when the scorpion is placed in very unpleasant circumstances, it not unfrequently lashes its tail about and causes actual penetration of the sting. If, for instance, the rays of a burning-glass be concentrated on any part of the body, the scorpion brings its sting there, and tries to strike away the source of irritation. Occasionally its efforts become more and more frantic, and the point of the sting catches somewhere. The scorpion, however, does not die unless the heat is concentrated on the back. In that case it soon succumbs, even if the sting has been tied down or previously removed.

The most important of Mr. Bourne's propositions is that the poison of a scorpion is quite powerless to kill the same individual, or another individual of the same species, or even scorpions of other species. If this proposition is established, there can, of course, be no further controversy about the matter. *A priori*, it is not improbable, for Sir Joseph Fayrer has shown that the cobra poison will not affect a cobra. Mr. Bourne frequently took a scorpion in his hand, and, holding the sting between a pair of forceps, pricked the scorpion with the sting and squeezed out its poison. There was a little bleeding from the wound, but in every case the scorpion lived for days. He also tried stinging one scorpion with another, using in the first instance specimens of the same species, then specimens of different species. Occasionally, he thinks, the stung individual became a trifle sluggish, but it never died from the sting. In order to make sure that his method of squeezing out the poison was perfectly effective, Mr. Bourne, after stinging a scorpion, sometimes continued to hold the sting, and, taking a cockroach, squeezed out into it some more of the poison. The cockroach invariably became very sluggish at once, and died in an hour or so. He also used a large cricket, stinging it in the femur of the large hind-leg; that leg became paralysed. When the animal was stung in the same place on both sides, both the hind-legs became useless, and it crawled away on the two anterior pairs of legs. Stung in the thorax it became quite torpid; when placed on its back it was not able to turn over. After considerable search, Mr. Bourne procured some specimens of *Thelyphonus*, which he chose as being the nearest relatives of the scorpions. He stung these in his usual method, and in each case they died within six seconds. He then tried some spiders, and they died in a few minutes when well stung. The slower general action in cockroaches and crickets is probably, he supposes, to be explained by the very inefficient circulation of the blood in insects as compared with Arachnida.

In all cases of artificial stinging Mr. Bourne took especial care to avoid mechanical injury to the nerve ganglia. And he tried puncture without the introduction of scorpion poison. Using large insects for this purpose, he obtained complete freedom from ill effects when using simple puncture, whereas the same species of insects when punctured with introduction of scorpion poison were instantly paralysed, and died in half an hour. He also procured two small shore crabs. One he punctured between two joints of the great chela of one side; several drops of blood exuded, but they coagulated, and the crab remained well. The second he stung in the same place with scorpion's sting, squeezing it to insure poisoning. The claw was immediately paralysed, and the crab gradually became torpid, and died in less than an hour.

When a number of scorpions are kept together in captivity, it is not difficult to induce a couple to fight. Mr. Bourne isolated such a couple, and they fought on and off for two days, during which time each repeatedly stung the other. On another occasion he separated two scorpions which had been fighting, and which had repeatedly stung one another. They lived perfectly well.

Apropos of Mr. Gillman's remarks about the actual temperature to which the scorpion is subjected in the "fiery circle," Mr. Bourne tried this experiment. He placed a scorpion and a cockroach (for comparison) in an incubator with glass sides, and gave them a piece of wood to walk about upon, and gradually raised the temperature. At 40° C. both seemed uncomfortable, and the cockroach performed a sort of licking action on all its legs and antennæ. At 45° C. the scorpion became very sluggish, and at 50° C. it was nearly dead. A large furious scorpion before the experiment, it now lay on its back and did not attempt to get up. Mr. Bourne took it out and gave it a cold bath, and put it in a cool earthenware vessel, and in the course of two hours it recovered. The cockroach was left in the incubator till the temperature reached 52° C. When nearly dead, it was taken out, and very gradually recovered. To try the effect of a wet heat, a scorpion and a cockroach were placed in water at 43° C., and they both died almost immediately, whereas they would both have lived in cold water for hours.

The inference drawn by Mr. Bourne from his experiments is that scorpions do not commit suicide, and that when they die within a ring of fire, heat is the cause of death. After he had reached this conclusion he was told that according to some authorities inclosure in a circle of oil, or inclosure under an inverted tumbler, will cause a scorpion to kill itself. He accordingly placed a scorpion on a plate within a ring of cocoa-nut oil. It calmly walked through. He placed another scorpion on a plate, and round the edge a thick roll of rag dripping with kerosene oil. The animal walked out over the rag. When daubed with oil, it appeared uncomfortable, but did nothing remarkable. The experiment with an inverted tumbler was made, and gave the same negative result.

THE MYTHICAL ZOOLOGY OF THE FAR EAST

A SHORT time ago the British Museum acquired a comprehensive collection of Japanese and Chinese pictures, made by Mr. William Anderson, for some years medical officer to the British Legation in Tokio. This gentleman's magnificent work on the "Pictorial Arts of Japan" has already been noticed in these columns; and he has just placed students of the arts of the Far East under an additional debt of gratitude to him by the preparation of a catalogue of his collection in the British Museum, which has just been published by the Trustees of that institution. With this volume, except for a special purpose, we have nothing to do; but it is impossible to glance through it without being struck by the amount of labour which the author has devoted to his dissertations on the various schools of painting, to his descriptions of characteristic examples of these schools, and to his explanation of the motives which inspired the artists. The word "catalogue" is a modest one to employ in describing the work, for though it contains the numbers and names of the pictures, this is the least part of its contents.

Amongst the motives of the artists of China and Japan, mythical zoology held a very important place; it evidences, says Mr. Anderson, "a courage of invention almost unparalleled in the pseudo-science of Oriental races." It holds, too, a disproportionate place in the folk-lore and superstitions of the people of both countries. Yet it has scarcely received any attention in Europe. In Prof. Angelo de Gubernatis's great work on "Zoological Mythology" there is but a single reference to China, and none at all to Japan, while the myths of Aryan nations occupy the greater part of his volumes. Here and there in books relating to the countries of Eastern Asia scanty references to popular myths respecting animals are found, but, so far as we are aware, Mr. Anderson's is the first work which gives any adequate conception of the marvellous extent of this species of lore amongst the Chinese and Japanese. As the latter owe their art, literature, and religion to China, so they owe also their scientific myths. The Chinese have developed mythical zoology to a greater extent than any other nation. "Their literature teems with strange conceits, some of which appear to be transcripts of local folk-lore, others appertain to Buddhism or Taoistic legends, and others are accepted as sober facts of natural history." These have almost all been adopted and improved in treatment by the Japanese.

Mr. Anderson divides the anthropological myths into three classes:—

(1) Persons born of woman with or without divine agency, who develop magical powers, work miracles, and attain a fabulous longevity.

(2) Those distinguished by physical peculiarities of a fabulous nature. Amongst these are giants; dwarfs; perforated men, who are conveyed about by coolies by means of poles put through holes which conveniently exist in their bodies for this purpose; stomachless men, who, according to popular belief, "dare not laugh for they have no sides to hold"; men with enormously long legs, and those with similarly long arms; men with tails, who carefully dig holes where they sit in order to provide a receptacle for the appendage; and many other extraordinary beings, all of which are truthfully described, from Chinese works of authority and repute, in the great Japanese encyclopædia *Wa-Kan-San-Sai dzu-yé*.

(3) Transitional beings, who combine with human elements parts naturally appertaining to the lower animals: such are feathered men; those with human faces, but the wings and beak of a bird; mermen, who have human heads and arms attached to the body of a fish, and learn the secrets of the deep from the murmuring hollow of the Conchifer. To this section also belongs the vampire bride who lures men to her deadly embraces till she has drained away their life-blood.

Mythical animals are similarly classified:—

(1) Those without any remarkable peculiarities of conformation, but gifted with supernatural attributes. Thus the tiger is classed in Chinese mythology as one of the supernatural animals, the king of beasts, and the representative of the masculine or active principle of Nature. It attains the age of a thousand years, and after passing the half of this term its hair becomes white. It is sometimes seen in association with the dragon, apparently as the emblem of the power of faith; it is also regarded as the type of wisdom, and in illustration of this attribute Mr. Anderson gives a story (p. 51) which has a familiar analogy in European folk-lore. The fox, again, is the demon of mischief, with the power of changing his shape at will, but ever with some evil design on the comfort of mankind. When he reaches the age of fifty, Mr. Anderson tells us, he is able to accomplish at will his most favourite and baneful metamorphosis into the resemblance of womankind; at a hundred he can take the shape either of a young and beautiful girl, or of a wizard strong in all the powers of magic; and when he reaches the term of a thousand years he becomes a Celestial Fox, characterised by a golden colour and nine tails, and may be admitted to heaven. But it appears he does not always avail himself of this privilege, for the possession of the extra tails only gives him an augmented cunning and capacity for wickedness. The tortoise also attains a marvellous longevity, and is variously represented as the embodiment of a star in Ursa Major, and as a descendant of the first dragon. In Hindoo mythology the tortoise supports the elephant which supports the world; in Japanese art it is represented as bearing on its back the mountain abode of the immortals. The horse is also associated with longevity, and it is still a popular belief that the female is delivered of its progeny through the mouth. The crane is one of the commonest figures in Japanese art; in Chinese mythical zoology there are four varieties, distinguished by their colours; they all live to a fabulous age, and after completing six hundred years are superior to the necessity of other sustenance than water. Many other notices of animals belonging to this class are scattered throughout Mr. Anderson's book in connection with pictures in which they are represented.

(2) Animals differing from their fellows only in size, or in alterations of the due number of parts. Such are serpents eight hundred feet long, which devour elephants; nine-tailed foxes; the four-eared monkey which heralds the deluge; the fish with ten bodies and one head, whose flesh is a sure preventive of boils; and many others.

(3) Creatures made up by the amalgamation of parts of various animals. Amongst these composite monsters the principal is the dragon, which, according to the Japanese encyclopædia already mentioned, has the head of a camel, the horns of a deer, the eyes of a demon, the ears of an ox, the body of a serpent, the scales of a carp, and the claws of an eagle. It is not necessary to say more by way of description, for it is the most familiar object in the art of China and Japan. It is treated by writers of the last century as really existing. It becomes at will, according to a Chinese author of the seventh century B.C., reduced to the size of a silkworm, or swollen till it fills the space of heaven and earth. "In Chinese Buddhism it plays an important part, either as a force auxiliary to the law, or as a malevolent creature to be converted or quelled." It is a guardian of the faith, an attribute of saintly or divine personages, an enemy of mankind, an emblem of majesty, the presiding genius of rainfall, and a symbol of time and place, giving its name to certain days and years, and to a point of the compass. Many more details about this extraordinary creature will be found scattered through Mr. Anderson's book, especially on pp. 48 *et seq.* The *kilin* or *kirin*, "the noblest form of the animal creation,

and an emblem of perfect good," also belongs to this class. It has the body of a deer, the tail of an ox, and a single horn, so that it resembles the unicorn. The phœnix is another animal of this kind, with the head of a pheasant, the beak of a swallow, the neck of a tortoise, and the outward resemblance of a dragon. It is regarded as an omen of good, and heralds the advent of a beneficent reign. "In works of art it is a nondescript bird of gorgeous plumage, intermediate between that of the peacock and bird of paradise, and bears flame-like appendages where the neck joins the body."

All the creatures referred to here, and many more belonging to one or other of the classes of zoological myths, are represented pictorially in the *Wa-Kan-San-Sai dzu-yé*, already mentioned, and in the *Mangwa* of Hokusai, a book to which access can be obtained without difficulty in most of the capitals of Europe.

To the mythical animals already mentioned, which are common to China and Japan, the Japanese have added some of their own invention. Such are serpents, giant centipedes, monster devil-fishes; earth-spiders, probably representing the troglodytes of old Japan; the raccoon-faced dog, which possesses in a minor degree the evil powers and tendencies of the fox; the wolf-like animal which produces thunder; the "whirling neck," or being which has the power of so elongating the neck that the head appears in places remote from the body; the man-devouring *kappa*, which frequents rivers and ponds, and politely challenges wayfarers to single combat; and many other equally strange creatures. An outline sketch of Japanese demonology will be found at p. 59, and a striking myth of a demon spider at p. 109.

Enough, however, has been said to show that if Mr. Anderson, in his catalogue and larger work on the "Pictoral Arts of Japan," has revealed to British readers a new and most important branch of art, he has incidentally indicated to his readers a new world of myth, which has hitherto found no place in the consideration of students of comparative mythology in Europe, but which can now be no longer neglected. Mr. Anderson of course treats it almost solely in its relation to art, but he informs the reader in every case where further and more detailed information may be obtained. The task of tracing these myths to their source and of finding analogies elsewhere is one for the scientific inquirer. Mr. Anderson has done the more laborious part of the work in bringing them together. He also suggests that very many of them will be found to have their homes in India, and to have spread with the doctrines of Buddha to China and other far eastern countries. One great advantage which the student of the zoological and other myths of China and Japan will have is that in the exhibition of the Anderson Collection, which is shortly to be opened at the British Museum, he will be able to see in the most graphic form the conceptions of successive generations of artists of the beings to which the myths relate—an advantage which could not be obtained even in the countries themselves without considerable expenditure of money, time, and labour. It only remains to be said that we have adopted Mr. Anderson's classifications, and in many instances have employed his own words in the descriptions of the myths scattered in so much profusion throughout the catalogue.

NOTES

WE regret to have to announce the death, on Good Friday, at the Nice Observatory, of M. Thollon, the eminent spectroscopist. Few men devoted to spectroscopic inquiry have worked so unceasingly and successfully; and in him Science loses one of the most single-minded of her votaries. He has been cut off in the midst of his labours, which, especially since his location at M. Bischoffsheim's magnificent observatory and the completion of the spectroscopic installation there, have borne such rich fruit in the shape of a method of sorting out the telluric from the true solar lines (a method slightly modified by Cornu), and of a map of the solar spectrum as observed by the new form of spectroscope of his own invention, which vastly surpasses in dispersion and purity of image anything that preceded it. Dr. Thollon has not only worked at Nice, but at the Pic du Midi and the Paris Observatory; he was also one of the observers of the total solar eclipse in Egypt in 1882. In all his wanderings, as in his work, he made many friends, and all who knew him will mourn his loss, not only as a man of science, but as one possessing, above the ordinary degree, a true and genial nature.

ON March 5 a drawing-room meeting for the promotion of technical education was held at the house of Mr. E. C. Robins, under the presidency of Prof. Huxley. A Memorandum of the proceedings has now been printed for private circulation. An address on the technical training at the Central Institution at South Kensington was delivered by Prof. Ayrton. The address was followed by a discussion, in which Prof. Silvanus Thompson, Mr. Brewin, Prof. Perry, Prof. Henrici, and others took part. In summing up the debate, Prof. Huxley remarked that something had been said about rivalry between the Central Institution and the Finsbury School. That most excellent and vigorous school which the City and Guilds Institute had established at Finsbury was chiefly intended to give primary technical instruction to workmen and others who could snatch only a few hours a week from their daily labour for the purpose of receiving it. The Central Institution, on the other hand, was chiefly intended for the advanced instruction of persons who could give up their time for one or more years to the higher branches of technology. Exhibitions enabled the promising student of the schools at Finsbury and elsewhere to pass to the Central Institution, and profit by the advantages it offered him. To talk of rivalry between the two was like talking of a rivalry between Eton and Cambridge. No doubt the day would come when a score of such schools as that at Finsbury would be sending their picked scholars to the Central Institution; but, before that day could come, the organisation of the Central Institute must be so far completed that it could receive them and deal with them. A great deal had been said about the 100,000*l.* or 150,000*l.*, or whatever it was, that had already been spent on the Central Institution, and of the 10,000*l.* a year that it cost. He begged leave to repeat that which he had said elsewhere, that if in the course of the next ten years the City and Guilds Institute could succeed in catching and training another Faraday or Whitworth or Armstrong, he would from a mere commercial point of view be worth all the expenditure initial and assured.

A HIGHLY interesting series of experiments has recently been successfully carried out by M. Olszewski. The more permanent gases have not only been liquefied at pressures averaging only 740 mm. by aid of excessively low temperatures, but the boiling-points, melting-points, and densities of these so-called gases have been determined at atmospheric pressure. The glass tube in which the condensation was effected was surrounded by a bath of liquefied ethylene, which could be caused to boil by reduction of its pressure, and, by use of a specially constructed air-pump, was reduced in temperature to $-150°$. When this point was reached, the gas to be liquefied was admitted into the tube from a Natterer cylinder containing the gas at about 40-60 atmospheres pressure, and was readily liquefied. A hydrogen thermometer was used to determine the temperature of the liquid, and the boiling-point of methane at atmospheric pressure was found to be $-164°$ C., that of oxygen $-181°·4$, nitrogen $-194°·4$, carbon monoxide $-190°$, and nitric oxide $-153°·6$. The melting-point of carbon monoxide was also determined to be $-207°$, and that of nitrogen as low as $-214°$. M. Oslzewski's nearest approach to absolute zero was $-225°$ for solid nitrogen. The density of methane at 736 mm. and $-164°$ was found to be 0·415, that of oxygen at 743 mm. and $-181°·4$ was 1·124, while that of nitrogen at 741 mm. and $-194°·4$ was found to be 0·885. The densities were determined by reading off the position of the liquid meniscus in the tube, volatilising a portion by means of an aspirator, and again reading off the height of the column, the volume of the volatilised portion being measured by the amount of water running out of the aspirator. At the fifth experiment with nitrogen, the tube, which had survived two years' experiments, burst, and destroyed the apparatus, so that the densities of carbon monoxide and nitric oxide must be left for future experiments.

ON Saturday next, and the two following Saturdays, Dr. R. von Lendenfeld will deliver a course of lectures at the Royal Institution on recent scientific researches in Australasia.

ON the 4th inst. the first meeting of the Sanitary Legislation Conference was held in the rooms of the Sanitary Assurance Association. The following resolutions were passed: (1) that the sanitary registration of all buildings is desirable in the interest of the public health; (2) that it is desirable that the law should forbid any building being used for public or semi-public purposes, unless and until the arrangements for the water-supply, drainage, and ventilation of such building have been certified as satisfactory by some properly-qualified person; and (3) that the provision of a public sanitary register for the voluntary registration of private houses would be instrumental in promoting sanitary improvement.

AN important topographical and geological Expedition has been organised by the Canadian Government for the exploration of the country watered by the River Yukon. According to Lieut. Schwalk, who went over much of the ground for the U.S. Government in 1883, this river is over 2000 miles in length, and it is believed that in many districts there are valuable deposits of gold. The Expedition will start from Victoria, British Columbia, early in May. The part of the work relating to geology and natural history will be conducted by Dr. Dawson, Assistant-Director of the Canadian Geological Survey; and under him Mr. W. Ogilvy will take charge of the topographical work, and make an accurate survey and measurement of as much of the Yukon as lies within British territory.

IT has been determined to transfer the Observatory of Rio de Janeiro to Santa Cruz, nearly on the same parallel, and a little more to the west. The Observatory is of considerable importance, owing to its position, being nearly on the Tropic of Capricorn, and it has recently been greatly improved by the present Director, Sr. Cruls. It is stated in the *Bollettino mensuale* of the Italian Meteorological Society, that from January of the present year the Observatory will commence the publication of a monthly Bulletin containing *inter alia* the meteorological observations made at fifteen stations in Brazil. Hitherto observations from that country have been very scarce indeed.

AFTER the first International Ornithographical Congress at Vienna in 1884, numerous stations for observing the habits of birds were organised all over the world. Dr. A. B. Meyer, the Director of the Zoological Museum at Dresden, was appointed Director for the erection of all such stations in Saxony. This gentleman, together with Dr. F. Helm, of Arnoldsgrün, has just published the first Annual Summary for the year 1885. It contains the results of about forty-eight series of observations from thirty-six stations, and articles on 180 species of birds.

WE have received four numbers of the "Encyclopædie der Wissenschaften," edited by various eminent German men of science, and issued by Trewendt of Breslau. One of these numbers concludes an elaborate dictionary of mineralogy, geology, and palæontology. Two others form part of an equally elaborate dictionary of chemistry, and the remaining number contains some sections of a treatise on botany.

THE Religious Tract Society are about to publish "Pioneering in New Guinea," by the Rev. James Chalmers, who has lived and travelled in New Guinea during the last eight years. A special chapter contains answers given by natives to 115 questions carefully drawn up by Mr. Chalmers.

"A LIST OF BRITISH BIRDS," revised by Mr. Howard Saunders, will be found of much service both for the labelling of specimens and for reference. It has just been issued by Messrs. Gurney and Jackson.

EARTHQUAKES on April 1, 2, 3, and 4 are reported from Aden. No damage was done.

WE hear that Mr. Murray has resigned the post of Librarian and Curator to the Karachi Museum. During his tenure of office he has written several hand-books on the zoology of Sind, and his Catalogue of the vertebrate fauna of that province is a valuable epitome of the subject. He will be succeeded by Mr. W. D. Cumming, who was for some time stationed at Fao, in the Persian Gulf. While there Mr. Cumming devoted himself with much energy to the study of the avifauna of the neighbourhood, and sent several interesting collections to England, where they have been described by Mr. Bowdler Sharpe. The collections proved to be one of the most important acquisitions of the British Museum during the year 1886.

LARGE cases, showing the nests of the Heron, Hen-harrier, Starling, Sand-Martin, and Common Tern, have been lately added to the Natural History Museum. Prof. Flower has also placed in the great hall a large case illustrating the principal breeds of domestic pigeons derived by man's selection from the common blue Rock-pigeon (*Columba livia*). Popular guides to most of the departments have recently been published by the Trustees, and the Index Museum in the great hall bids fair to supply the student with a complete introduction to the study of zoology and botany. In face of the energetic labours of the staff of this Museum to render the collections under their charge educational for the masses, it is satisfactory to learn that several members of Parliament have announced their intention of questioning the wisdom of reducing the grant to the British Museum, as has been done this year in deference to the rage for economy at present in vogue.

PROF. BARBOZA DU BOCAGE has recently described a Sun-bird and a Grass-warbler from the Island of St. Thomas as *Cinnyris newtonii* and *Prinia molleri*. Zoologists will welcome the return of Prof. Bocage from the realms of politics back to the charge of the Lisbon Museum, which, under his care, rose to a position of first-rate importance.

VOLUME I. of the Journal of the Science College of the Imperial University, Japan, which has been recently published, contains a valuable paper by Mr. Sekei Sekiya, Professor of Seismology in the University, on the comparison of earthquake records given at the same station by different seismographs, the comparison being made as a test of the accuracy of the instruments. Two recent earthquakes are discussed, each of which was recorded in duplicate at the Tokio Observatory, by two somewhat different forms of Ewing's horizontal pendulum seimograph, and the autographic records are reproduced in the paper. Prof. Sekiya compares the corresponding motions as recorded by different instruments, and remarks that when the records are gone through, wave by wave, the corresponding pointers are found to have drawn waves of exactly the same amplitude and period, and even the irregular minor ripples which are superposed on the principal undulations are reproduced faithfully by both. He concludes that this exact coincidence proves conclusively the trustworthiness of the horizontal pendulum seismograph. The diagrams reproduced in the Journal also show the vertical motion of the ground, as recorded by Ewing's vertical motion seismograph. This motion, the author points out, is much less in amplitude than the horizontal motion (usually from $\frac{1}{3}$ to $\frac{1}{7}$), and its average period is only about half that of the horizontal motion. The three components of motion, when combined, give a resultant form of extraordinary complexity for the path pursued by particles on the surface of the ground during an earthquake shock.

THE Association Scientifique de France has discontinued the publication of its weekly Bulletin, and will issue, instead, a *Compte rendu* of the Conferences of the Association in half-yearly volumes. A few advance parts will be published fortnightly, for the use of such of the members as may desire to have them. The Bulletin has been published since 1864.

MR. JAMES WILD, Geographer to the Queen, died at his London residence, at the age of seventy four, on the 17th inst. He was educated at Woolwich for the army, but afterwards devoted himself to the production of scientific and educational works. He soon became a member of various scientific Societies, and his maps and geographical works secured for him the position of Geographer to the Queen. For a good many years he had a seat in Parliament. After his retirement from political life he represented the Ward of Cornhill in the Common Council, and he took a leading part in directing the attention of the Clothworkers' Company, of which he was a member, to the subject of technical education. It was mainly through his efforts that the technical schools of Bristol, Manchester, and Leeds were erected. Among the many honours conferred upon him was the gold medal for scientific merit, granted by the present German Emperor as King of Prussia.

IN a paper entitled "Field Notes from Afghanistan," printed in the new number of Records of the Geological Survey of India, Mr. C. L. Griesbach gives an account of instances of recent glacial action observed by him when crossing the Hindu Kúsh by the Chahárdar Pass in October 1886. The road which leads from Chápdarra camping-ground on the north side of the Hindu Kúsh to the top of the pass ascends a narrow straight valley, bounded on each side by steep cliffs, some of them crowned with perpetual snow. The bottom of the valley itself is greatly choked and partially filled with debris, which might be simply the detritus from the hill-sides. Large cones and fans of fragmentary material descend from each small ravine on both sides. So far only the configuration of the valley, its nearly straight course and absence of larger side streams, would suggest the former presence of glaciers. But on reaching an elevation of 12,000 feet, one suddenly comes to a huge mass of debris, which closely resembles the recent accumulations near the lower end of a glacier. Large blocks, some of them of immense dimensions, are loosely mingled with angular fragments of every size, and the whole is arranged like a dam across the valley. The hill-sides (gneiss) are polished and grooved, and the blackened surfaces glisten and shine in the distance like metal. All the larger blocks show extensive grooving and deep ice-scratches on their polished sides. This mass of debris lies at the base of a terrace filling the valley. The former glacier, of which this is the end moraine, was on the upper and raised portion of the valley. The latter bears the remarkable appearance of an ice-worn trough; it is wider than the valley below, and its base is now partially filled by finer debris, through which a small stream winds its way amidst a series of swampy pools. It is within the area of perpetual snow, and the latter with frozen patches of ice lies on the hill-sides and in sheltered depressions. The valley looks as if the glacier had only quite recently left it. Moraines and glacial silt still lie as they were deposited. The head and catchment area of the valley close to the top of the pass (14,100 feet) is still rather thickly covered with frozen snow. Near the head of a narrow valley leading from the Chahárdar Pass to the Deh-i-Tang, at an elevation of 12,050 feet above sea-level, several small ravines join. Mr. Griesbach noticed that three of these ravines were still filled with glaciers. Although they were very small, the moraine accumulations near their lower ends were enormous.

IN a highly important and interesting paper on the structure of the Nostochineæ, contained in the first volume of the new Italian botanical journal *Malpighia*, Prof. A. Borzi, of Messina, states the very interesting fact that, in *Nostoc ellipsosporum* and other species of the same genus, a distinct communication can be detected between adjacent cells. If the cell is an intercalary one, it has two pores at opposite poles; if apical, only one; and through these pores pass very delicate threads of a substance which sometimes gives the reactions of protoplasm, sometimes of cyanophycin, the substance of which, according to Borzi, both the cell-contents and the investing gelatinous sheath of the Nostocaceæ are composed. This intercommunication between the cells is always interrupted in the formation of heterocysts. During the transformation of ordinary cells into heterocysts, the walls become thicker, the gelatinous substance of which they are composed collecting especially round the pores through which the strands pass, and eventually completely closing them up. In this way is formed a short conical projection pointing towards the interior of the heterocyst. In the vegetative cells of the filament, that is, those which are not destined to become heterocysts, the connecting threads appear always to consist of protoplasm. In the hormogones this connexion between adjacent cells is especially evident. In addition to several species of *Nostoc*, Prof. Borzi has observed this interesting phenomenon in several of the other families of Nostochineæ or filamentous Cyanophyceæ, viz. in the Scytonemaceæ, Stigonemaceæ, and Rivulariaceæ.

PROF. D. KIKUCHI, of Tokio, who graduated at Cambridge in 1877, is editing, at the request of the Education Department of the Japanese Government, text-books of geometry and algebra, those in use at present being very unsatisfactory. He has already translated and published the syllabus of plane geometry drawn up by the Association for the Improvement of Geometrical Teaching, and has also done the same for Clifford's "Common Sense of the Exact Sciences." His principal course of lectures—a two years' one—is on dynamics, commencing with statics, and including sound and liquid waves.

WITH reference to Mr. Hooper's paper on *Gymnema sylvestre*, printed by us last week, Mr. J. C. Shenstone writes to us that the peculiar properties of the plant were described in a communication to the Linnean Society, December 7, 1847, by Capt. Edgeworth. The plant was pointed out to him by the natives, who were aware of its peculiarity. "No doubt," says Mr. Shenstone, "this is the Mr. Edgeworth alluded to by Mr. Hooper in his paper as having first discovered the property of the plant, but a reference to the original communication may interest some of your readers."

AN experimental passenger-train, lighted throughout by electricity, and heated by steam from the engine, is now running between New York and Boston. Each car is illuminated by eighteen 16-candle glow-lamps, the current being derived from storage-batteries beneath the floor-timbers, charged for ten hours by dynamos. Both light and heat are said to be ample, and *Science* believes that danger from fire, in case of accident to the train, is much lessened, if not almost wholly done away with.

MACHINERY for winding silk from cocoons was lately set up at Washington by the Department of Agriculture. Much interest is manifested in the experiments, and the demand for copies of the Bulletin on Silkworm Culture is so great that it has been necessary to issue seven or eight editions. According to officials of the Department of Agriculture, the requests for silkworm eggs have never been so numerous since the Department began their distribution. It is expected, therefore, that large quantities of American-grown silk will be placed upon the market this year.

WHEN crossing the Atlantic, Prof. Dennis, of New York, recently made some observations to test the purity of the ocean-air. He had previously prepared capsules of sterilised gelatine. One which was exposed in a state-room on the main deck of the steamer developed five hundred points of infection in eighteen hours; one exposed in the cabin on the main deck developed only five or six points in ten days; a third, hung over the bow of the ship for ten days, remained uncontaminated.

MR. V. G. EATON, writing to the *Popular Science Monthly*, says that in most of the eastern cities of the Unites States fully 30 per cent. of the men over thirty years of age show unmistakable signs of baldness, while nearly 20 per cent. have spots on their heads that are not only bald, but polished with the gloss that is supposed to belong to extreme old age alone. He has been in most of the churches and theatres in all the large eastern cities, as well as in Chicago, St. Louis, and other places of the West, and has verified his assertion by actual count. He has found that bald-headed men are most plentiful in New York and Boston, and that after these cities come Philadelphia, Washington, and the western towns. The following are a few of his observations taken in Boston:—Trinity Church: 243 men; 71 actually bald, 46 indications of baldness. King's Chapel: 86 men; 38 actually bald, 14 indications of baldness. Hollis Street Theatre, orchestra at performance of the "Mikado": 63 men; 27 actually bald, 10 indications. Boston Theatre, Judic: 126 men; 51 actually bald, 43 indications.

THE additions to the Zoological Society's Gardens during the past week include two Polar Bears (*Ursus maritimus*), from the Polar Regions, presented by Mr. Joseph Monteith; two Brown-throated Conures (*Conurus æruginosus*), from South America, presented by Lieut.-General Newton; a Ring Dove (*Columba palumbarius*), a Turtle Dove (*Turtur communis*), British, presented by Mr. C. L. Sutherland, F.Z.S.; a Secretary Vulture (*Serpentarius reptilivorus*), from South Africa, presented by Mr. J. Newbury; a White-tailed Buzzard (*Buteo albicaudatus*), from America, presented by Mr. John Lloyd; two Common Gulls (*Larus canus*), British, presented by Mr. J. A. Cotton; two —— Ducks (——) from the Falkland Isles, presented by Mr. F. E. Cobb, C.M.Z.S.; two Viscachas (*Lagostomus trichodactylus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE U.S. NAVAL OBSERVATORY.—We learn from *Science*, vol. ix. No. 217, that the new Naval Observatory, for which Congress appropriated 400,000 dollars several years ago, is to be built forthwith. Mr. R. M. Hunt, of New York, has been appointed architect of the building, and operations will shortly begin.

RESEARCHES ON THE SUN'S DIAMETER.—Prof. Di Legge, of the Campidoglio Observatory, Rome, has published in *Atti della R. Accademia dei Lincei*, ser. 4, vol. i., a discussion of the meridian transit observations of the sun's diameter taken at the Observatory during the years 1874–83. From May 1876 the observations were made by projecting the sun's image on a screen, so that two or more persons could observe simultaneously, and thus determine their "personal equations" from observations made under precisely similar circumstances. Altogether, 5796 transits were observed on 2213 days, giving an average of 221 days per annum. The mean resulting horizontal semi-diameters of the sun, collected in biennial groups, show a progressive diminution, which, taking into consideration Auwers' researches on the subject (NATURE, vol. xxxv. p. 496), are most probably due to change in the habits of the observers, as the table of mean annual personal equations given by Prof. Di Legge would also lead us to infer. The mean values of the horizontal semi-diameter at mean distance found from each observer's transits are respectively as follows:—Di Legge, 961″·329 ± 0″·011; Respighi, 960″·760 ± 0″·013; Giacomelli, 961″·307 ± 0″·012; and Prosperi, 961″·356 ± 0″·014; the combined mean value being 961″·188.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *APRIL* 24–30

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on April 24

Sun rises, 4h. 48m.; souths, 11h. 58m. 5·6s.; sets, 19h. 8m.; decl. on meridian, 12° 51′ N.: Sidereal Time at Sunset, 9h. 18m.

Moon (at First Quarter on April 30) rises, 5h. 48m.; souths, 12h. 55m.; sets, 20h. 14m.; decl. on meridian, 12° 11′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′

GEOGRAPHICAL NOTES

THE new volume (xi.) of the *Geographisches Jahrbuch*, edited by Prof. Hermann Wagner, begins a new series, and assumes a new form. It has been elongated from the small square form with which we have been familiar, into a respectable octavo, containing about 500 pages. Moreover the present volume is entirely devoted to what in former years was only a section: an account of progress in the various departments into which scientific geography is divided. The next volume will no doubt contain memoirs on various subjects of geographical interest. The subject of physical geography (or rather geophysics) is treated by Dr. Hergesell and Dr. Rudolph. Prof. Toula deals with the investigations of the last four years in the geognostic structure of the earth's surface in all parts of the world. The progress of oceanography is of course dealt with by the great authority on the subject, Dr. O. Krümmel, while Dr. Hann does a similar service for geographical meteorology, or climate. Botanical geography is treated by Dr. Oscar Drude, and zoological geography by Dr. L. K. Schmarda. Dr. G. Gerland gives the results of research in ethnology during 1884–86 in the various quarters of the globe. Under Dr. Wagner's sole editorship the *Jahrbuch* is becoming more valuable than ever as a book of reference in scientific geography.

THE Rev. George Grenfell, the explorer of the Mobangi and other important tributaries of the Congo, has arrived in London. Unfortunately his health is by no means satisfactory, and it will be necessary for him to rest for some time, therefore his appearance at the Royal Geographical Society must be delayed. He has brought home with him his original maps, which are admirable specimens of such work. They are on a scale of about 5 inches to a mile, and are evidently plotted with the greatest care; his work is therefore likely to take a high place. Dr. Lenz, who has arrived in Vienna, it is hoped will be in London at the end of this month, and as Dr. Junker may be here about the same time, it is just possible that both these eminent explorers may appear together at the first meeting of the Geographical Society in May.

UNDER Colonel Woodthorpe, the work of surveying our new Burmese territory is proceeding apace. Up to the end of January the out-turn of work amounted to 800 square miles on the $\frac{1}{4}$-inch, and 260 miles on the $\frac{1}{8}$-inch scale.

THE narrative of Baron Nordenskjöld's memorable journey into the interior of Greenland in 1883, is now appearing in instalments in the German journal *Globus*, profusely illustrated.

TWO Expeditions are being sent out by the Russian Geographical Society this year: one, under J. P. Kusnetzow, to investigate the flora of the Northern Urals; and another, under Prince Massalsky, to continue his Transcaucasian researches, which include both botany and ethnography.

VALENCY AND RESIDUAL AFFINITY[1]

II.

METALLIC CONDUCTION.—I do not propose in any way to discuss metallic conduction, but merely to call attention to some of the analogies between it and electrolytic conduction.

It is conceivable, and it would appear probable from the fairly regular manner in which the electrical resistance of most pure metals decreases as the temperature falls, the coefficients of change being practically very nearly the same in all cases, that the increase in resistance as temperature rises is mainly due to the increase in molecular inter-distances. As a rule, resistance increases on the passage of a metal from the solid to the liquid state, but there are noteworthy exceptions from which it would appear probable that even in pure metals conductivity to some extent depends on molecular composition: thus the conductivity of bismuth increases at the moment of fusion from 0·43 to 0·73 of that of mercury at 31°, and that of antimony from 0·59 to 0·84 (L. de la Rive, *Comt. rend.*, 1863, lvii., p. 691); it is well known that bismuth contracts considerably on fusion, and this is probably also the case with antimony. Again, according to Bouty and Cailletet (*ibid.*, 1885, c., p. 1188), the resistance of mercury decreases at the point of solidification in the ratio 4·08 : 1; this is a remarkable increase in conductivity, and it is difficult to believe that it is wholly due to mere contraction of volume.

That the behaviour of alloys is worthy of far more attention than it has hitherto received appears most clearly from the few data at disposal. I would specially call attention to the curve given by Prof. Lodge as representing the specific conductivities of the copper-tin alloys (Phys. Soc. Proc., 1879–80, iii., p. 158). The general resemblance of this curve to that given by F. Kohlrausch for mixtures of sulphuric acid and water appears to me to be in the highest degree suggestive.

Valency—Chemical Change.—Notwithstanding the fierce controversy which has been waged between the advocates of the doctrine of fixed valency, our views on the subject are still in an unfortunate degree unsatisfactory and indefinite. Even those—and they probably form a large majority—who regard valency as a variable, dependent both upon the nature of the associated radicles and the conditions—especially as to temperature—under which these are placed, often hesitate to attribute a valency sufficiently high to account for every case of combination; in fact, both parties agree in distinguishing "atomic" from "molecular" compounds, and differ only as to where the line shall be drawn.

It is difficult to over-estimate the importance of the theory of valency: its application has led to an enormous extension of our knowledge of carbon compounds especially, and it has furnished us with a simple and consistent system of classifying the mighty host of these bodies; but, on the other hand, it may be questioned whether it has not led us away from the search into the nature of chemical change, and even if the introduction of the terms saturated and unsaturated has not had a directly pernicious effect. The almost universal disregard of molecular composition as an important factor in chemical change in the case of solids and liquids, and the popular tendency to overlook the fact that our formulæ of such bodies are purely empirical expressions, has undoubtedly exercised a prejudicial influence.

No known compounds *are saturated:* if any were, such would be incapable, I imagine, of directly taking part in any interaction, and in their case decomposition would necessarily be a precedent change. The paraffins are apparently, of all bodies, the most inert and the most nearly saturated,[1] and next to them comes hydrogen—the unsaturated character of which is displayed in interactions such as occur at atmospheric temperatures between it and platinum and palladium, and when it displaces silver from silver nitrate or certain of the platinum metals from their salts. One of the most striking instances, perhaps, of popular error in this respect is water, which is always regarded as a saturated compound, although its entire behaviour, and especially its physical properties, characterise the molecule H_2O, I think, as that of an eminently unsaturated compound: I fail to see how, otherwise, we are to explain the high surface-tension and high specific heat of liquid water, its high heat of vaporisation, and its imperfectly gaseous behaviour up to temperatures considerably above its boiling-point, let alone its great solvent power and its tendency to form hydrates with a multitude of compounds—*especially oxygenated* compounds, be it added.

The theory was brought most prominently under the notice of chemists by Helmholtz in the last Faraday Lecture, that electricity, like matter, is, as it were, atomic, and that each unit of affinity or valency in our compounds is associated with an equivalent of electricity—positive or negative; that the atoms cling to their electric charges, and that these charges cling to each other. Thus barely stated, this theory does not appear to take into account the fact that the *fundamental* molecules, even of so-called atomic compounds, *are never saturated*, but more or less readily unite with other molecules to form molecular compounds—molecular aggregates; and unless the application of the theory to explain the existence of such compounds can be made clear, chemists must, I think, decline to accept it. The impression which the facts make upon the mind of the chemist certainly is (1) that no two different atoms have equivalent affinities; and (2) that affinity is a variable depending on the nature of the associated elements: but, owing to the recognised complexity of nearly all cases of chemical change, it is difficult to draw any very definite conclusion on this point.

If, however, the nature and properties of so-called molecular compounds generally be considered, and if an attempt be made to form any conception of their constitution, one striking fact is

[1] Revision and extension of a paper by Prof. H. E. Armstrong, F.R.S., communicated to the Royal Society last year. Continued from p. 572.

[1] It is probably more correct to place nitrogen first in the list, as being the most inert substance known.

noticeable, viz. that the *metals* in them apparently retain the properties which they exhibited in the parent atomic compounds. Everyone knows the marked difference in properties of ferrous as contrasted with ferric salts: they differ not only in chemical behaviour, but also in their physical properties, and are readily distinguishable by their colour. The properties of the ferrous molecular compounds, however, are those of the simple ferrous compounds: ferrous potassium chloride, for example, $Fe_2Cl_4 . Cl_2K_2$, is a green salt much like ferrous sulphate. Facts such as these have led me to suggest that in such cases the formation of the molecular compound is due to the attraction of the negative element of the one "atomic" compound by the negative element of the other, the metal having no influence except that the amount of affinity of which the negative element is possessed depends on the nature of the metal with which it is associated. It would in fact appear that hydrogen and the metals generally may be regarded as the analogues of the C_nH_{2n+1} and C_nH_{2n-7} hydrocarbon radicles, and that their compounds with negative elements may be likened to unsaturated hydrocarbons of the form $C_nH_{2n+1} . CH . CH_2$. We know that whenever such a compound enters into combination, the C_nH_{2n+1} radicle takes no part in the change, combination of whatever kind being effected by means of the unsaturated radicle, $CH . CH_2$, with which it is associated. I do not mean to contend that the metals are fully neutralised in their compounds, but merely that as a rule they behave as though they were saturated, just as do the C_nH_{2n-7} radicles derived from the benzenes. There can be little doubt that an absolute distinction must be drawn between hydrogen and the metals on the one hand, and the non-metals on the other. Regarding the facts in the light of our knowledge of carbon compounds, it is difficult to resist the conclusion that the differences observed are due to differences in structure of the stuffs of which the elements as we know them are composed, the which differences condition perhaps a different distribution of the electric charge or its equivalent, in the case of each element.

ADDENDUM, *April* 1887.—I will now venture to call attention to the points which after a year's further consideration of the subject appear to me of special importance.

We are as far as we ever were from being able to define a "simple electrolyte" in the chemical sense—that is to say, to define the class or classes of compounds to which simple electrolytes belong. The investigation of the electrical behaviour of *pure* compounds is therefore of the highest importance; it is essential, however, to bear in mind that not only must pure compounds be studied, but scrupulous care must be taken to guard against a possible decomposition of the substance under examination, either by heat alone, or by contact with the electrodes or the containing vessel. I believe that the conclusions which Clark based on his most interesting observations on the electrolysis of mercuric salts are vitiated by some such effect having been overlooked. The experimental difficulties surrounding the problem are therefore very great; and the more hopeful method of attacking it in many cases would appear to be that adopted in Kohlrausch's experiments on the specific resistance of water: in other words, to determine the influence of impurities.

A similar problem relates to the possibility of basing a definition of a non-metal as distinct from a metal on electrical properties. It is well known that no consistent definition can be given, and that we are at present obliged to base our division of the elements into metals and non-metals on general considerations. Now, although metals differ enormously in specific resistance, the metals as a class oppose a comparatively feeble resistance to the passage of electricity, and moreover resistance always increases as the temperature of a metal rises; it is therefore noteworthy that not only is the specific resistance of non-metals, such as carbon, phosphorus, selenium and sulphur, enormously great in comparison with that of metals, but that it diminishes as temperature rises: non-metals therefore behave in this respect as electrolytes, and as no special precautions have hitherto been taken to obtain pure non-metals for the purpose it is well worth while to ascertain if the specific resistance offered by non-metals be not the greater the nearer the approximation to purity.

To determine the valency or atom-fixing power of an element, according to present views, it is necessary to determine the number of atoms which can enter into direct association with an atom of the element considered; and this necessarily involves a discussion of the nature of "atomic" as distinct from "molecular" compounds. The electrical hypothesis that an atom of unit valency carries unit charge, a dyad two such charges, a triad three, involves the more specific determination of the number of charges which are associated with any particular atom; but, again, on this hypothesis we have to determine whether any real distinction can be drawn between atomic and molecular compounds, and whether an atom having, say, unit charge, has the power of combining with more than a single atom. My own view certainly is that atomic and molecular compounds are specifically distinct; and that in the latter the number of atoms associated with what may be regarded as the grouping element or elements in the compound is in excess of the number of unit charges which the particular element or elements of necessity carry. Taking nitrogen as an example, it appears to me that the whole of the evidence to be derived from the study of nitrogen compounds is compatible with the assumption that nitrogen carries at most three charges: that it is a triad, in fact; and I am inclined to regard the ammonium compounds of the type $NH_3 . HX^1$ as molecular compounds in which the residual affinities of N and X^1 serve to unite H_3N with X^1H. The more I study the question the more I incline to the belief that sooner or later we must accept Kekulé's ruling, unfashionable as this has become of late years.

The foregoing may appear to many to be but a restatement of the tenets of the advocates of the doctrine of fixed valency. It appears to me, however, that in the hypothesis of a definite unit charge—in other words, of a definite unit valency—we have a conception which for the first time enables us to frame a consistent doctrine of valency: a given atom may be assumed to carry under all circumstances a certain definite charge, and the problem which the chemist has to determine is, firstly, the number of unit charges associated with any particular atom, and, secondly, the manner in which the charge is, as it were, distributed when the atom is brought into association with other atoms. The following illustration will perhaps serve to make my meaning clear. Let unit charge or unit valency be regarded as a unit "line of affinity" passing through the atom, and let it be supposed that the atom moves upon this line of affinity with a degree of freedom depending on its nature; then it may be supposed that combination between two atoms consists in the overlapping of the lines of affinity. If each atom move out to the end of its line of affinity, no part of the line will overhang; the molecule will consequently be saturated; there will be no residual affinity. On this view the stability of a molecule will depend on the extent to which the lines of affinity of the constituent atoms *overlap*, and its tendency to associate with other molecules will depend on the extent to which the lines of affinity of the constituent atoms *overhang*. For example, it may be supposed that in ordinary chlorine the two atoms of which the molecule consists have moved out near to the end of the lines of affinity, so that there is but little overhang: the molecule is therefore of considerable stability, but forms unstable combinations with other molecules; in iodine, on the other hand, it may be supposed that the atoms are closer together, the lines of affinity overlapping less than those of chlorine; consequently the molecule is less stable than that of chlorine, but may form more stable molecular compounds as the lines of affinity overhang to a greater extent than do those of chlorine. It is possible in this way to understand that an atom which carries but unit charge—a monad, in fact—may enter into association with two distinct atoms. Adhering to the above symbolic language, it may even be suggested that perhaps the difference between a non-metal and a metal may be that the structure of the non-metals is such that they move with difficulty upon their lines of affinity, and probably in a very limited number of directions, and with unequal freedom in different directions; and that the structure of metals is such that they move with comparative freedom upon their lines of affinity, in some cases even with complete freedom, and almost equally so in several directions.

Speculations such as these are of value only if they serve as a guide to further inquiry. I venture to put them forward in the hope of inducing chemists to devote more attention to the study of molecular compounds, for it is in this direction that we are likely to gather most important information as to the valency of elements other than carbon and hydrogen. Of late years such inquiries have been but rarely pursued, and no doubt they are less attractive than those which result in some new synthesis or the determination of the constitution of an organic product; but their future value will be great, and the number of workers is now so large that our sense of proportion demands that attention should no longer be directed almost exclusively to the study of carbon compounds.

There is one other problem to which I would direct attention —the study of liquid diffusion. No interpretation of the remarkable results obtained by Graham has yet been given, and they appear in many cases to be quite at variance with the results of chemical inquiries. But there is a striking parallelism to be observed between Graham's results and those obtained on determining the electrical conductivity of solutions. Applying the view which I hold regarding the electrolysis of composite electrolytes to liquid diffusion, it appears to me not improbable that diffusion may be to a large extent the outcome not so much of the proper motion of the molecules of the dissolved substance as of a propulsive action exercised by the molecules of the solvent. The molecules in a mass of water we know may be assumed to be moving in every direction, and this being the case they would tend to carry other molecules along with them: the extent to which this action would take place would, however, largely depend on the attraction which exists between the molecules of water and those of the dissolved substance. From this point of view it appears of considerable importance to extend the study of liquid diffusion to dilute solutions. It may be added that this hypothesis would probably account for the behaviour of colloids, as these are known to be chemically neutral substances; in fact, they are compounds almost destitute of residual affinity.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

KING'S COLLEGE, LONDON.—Prof. W. Grylls Adams, F.R.S., will deliver a course of lectures on Electro-Magnetism, Magneto-Electricity, the Testing of Motors and Dynamos, Electric Lighting, and Transmission of Power, during the present Term.

A course of practical work in Electrical Testing and Measurement with especial reference to Electrical Engineering will also be carried on under his direction in the Wheatstone Laboratory.

The lectures will be given once a week—on Mondays, at 2 p.m.,—and the Wheatstone Laboratory is open daily from 1 to 4, except on Saturdays.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 31.—"Note on the Development of Voltaic Electricity by Atmospheric Oxidation." By C. R. Alder Wright, D.Sc., F.R.S., Lecturer on Chemistry and Physics, and C. Thompson, F.C.S., Demonstrator of Chemistry, in St. Mary's Hospital Medical School.

Whilst investigating processes for the manufacture of cuprammonium hydroxide (now used commercially on a considerable scale) we noticed that if the air supply be greatly in deficiency relatively to the bulk of the copper, under certain conditions the solution is but little coloured, containing copper dissolved principally as cuprous, and not as cupric, oxide. This might, perhaps, be anticipated *a priori*, inasmuch as it is well known that blue cupric solution in ammonia, when digested with metallic copper in the absence of air, takes up a second equivalent of copper, becoming colourless cuprous solution; but further experiments seem to indicate that the production of cuprous oxide under the oxidising influence of a limited supply of air is the primary action, and not merely a secondary result.

When a sheet of copper is kept out of direct contact with air by being immersed in ammonia solution, oxidation of the metal is gradually effected by virtue of the dissolving of oxygen from the air at the surface of the fluid, and diffusion of the oxygen solution to the vicinity of the copper. This action is an extremely slow one if the copper be covered by some depth of fluid, and if the setting up of convection currents through heating or evaporation be prevented by keeping the vessel perfectly at rest and at an equable temperature, and well closed to prevent escape of ammonia; but if these precautions be neglected it goes on much more rapidly, and the liquid comparatively soon becomes blue; it can, however, be also materially accelerated by arranging horizontally on the surface of the fluid a plate of platinum or other electrically conducting material not chemically acted upon by the fluid, and connecting this by means of a wire, &c., with the copper plate. The upper conductor, or *aëration plate* as it may be conveniently termed, being simultaneously in contact with the atmosphere and fluid, attracts to its surface a film or aura of condensed gases, the oxygen of which becomes gradually transferred to the copper, a voltaic current circulating through the fluid and connecting wire. Cuprous, and not cupric, oxide thus results, dissolved in the ammonia solution in contact with the copper plate, the mechanism of the reaction being conveniently represented by the scheme—

Copper plate Cu_2 | OH_2 | OH_2 | O Aëration plate,

Copper plate | Cu_2O | H_2O | H_2O | Aëration plate,

water being represented as the electrolyte for simplicity's sake. The air film on the aëration plate being constantly renewed by absorption from the atmosphere, the process goes on continuously as long as the two plates are connected together by the wire. This wire may be lengthened at will so as to make the current which passes through it whilst the action goes on relatively stronger or weaker according to the amount of resistance introduced into the circuit; and by including a galvanometer or silver voltameter in the circuit the ordinary phenomena due to the passage of currents are readily recognisable.

The maximum E.M.F. thus capable of development varies considerably with the strength of the ammoniacal solution, being the less the weaker the fluid; addition of common salt or of sal ammoniac to the liquid notably increases the E.M.F. and diminishes the internal resistance of the cell. Spongy platinum in a thin layer as the aëration plate gives higher values than thin platinum foil; the highest numbers thus obtained, using pretty concentrated ammoniacal brine, fell but little short of 0·8 volt; or somewhat less than the E.M.F. corresponding with the heat of formation of cuprous oxide,[1] since, according to Julius Thomsen, Cu_2,O = 40,810 = about 0·88 volt.

It is obvious that this copper atmospheric oxidation cell has a close connexion with the "air-battery" described in 1873 by Gladstone and Tribe (Roy. Soc. Proc., vol. xxi. p. 247) in which what is virtually an "aëration plate," consisting of a tray full of crystals of silver is used, opposed to a copper plate immersed in a solution of copper nitrate. Cuprous oxide is formed in both cases, in virtue of the indirect combination brought about between the oxygen of the air and the copper: but there is this great difference between the two (apart from the cuprous oxide being deposited as such in Gladstone and Tribe's arrangement, and being kept in solution in ours), that in the one the cuprous oxide is formed *at the surface of the copper plate* itself, and in the other *at the surface of the aëration plate.* This essential difference is embodied in the above depicted scheme as compared with the following one which represents the action in Gladstone and Tribe's cell:—

Silver + O | $Cu(NO_3)_2$ $Cu(NO_3)_2$ | $Cu(NO_3)_2$ $Cu(NO_3)_2$ | Cu Cu } Copper.

Silver | O Cu Cu | $(NO_3)_2Cu$ $(NO_3)_2Cu$ | $(NO_3)_2Cu$ $(NO_3)_2Cu$ | Copper.

One result of this difference is that the surface of the aëration plate in the ammonia cell is kept constantly the same, whereas in the nitrate cell it is continually changing its character through deposition of solid cuprous oxide on the silver: in consequence of this deposition, whilst the E.M.F. of the ammonia cell, *cæteris paribus*, is constant, that of the nitrate cell is continually varying. Gladstone and Tribe, moreover, only obtained an E.M.F. of $\frac{8}{83}$ to $\frac{11}{83}$ of a Daniell, or about 0·104 to 0·143 volt, even under the most favourable conditions, viz. when the cell was connected with an electrometer; whilst four or five times this amount is indicated by the cells examined by us.

Following up the ideas suggested by the above observations, we are making a number of experiments with a variety of analogous combinations, in which atmospheric oxidation constitutes the essential chemical action taking place; by varying the nature of the aëration plates, the metals dissolved, and the liquids employed (as also by substituting other gases, *e.g.* chlorine, for air), a large number of combinations are obviously obtainable. Some of those which we have so far examined present points of considerable interest, the oxidising action exerted under favourable conditions being strongly marked: so much so that certain metals, *e.g.* mercury and silver, not ordin-

[1] The actual chemical change going on in the cell is the synthesis of cuproso-ammonium hydroxide, so that the (unknown) heat of solution of cuprous oxide in ammonia should be added to this to obtain the total heat development.

arily prone to atmospheric oxidation, can under suitable conditions be gradually oxidised and dissolved in appropriate liquids, just as the copper is dissolved in the ammonia in the cell above described; these actions, moreover, being accompanied by the development of currents of strength sufficient to cause measurable amounts of electrolytic decomposition outside the cell, *e.g.* in a silver voltameter.

"Action of Caffein and Theine upon Voluntary Muscle." By T. Lauder Brunton, M.D., F.R.S., and J. Theodore Cash, M.D.

Caffein and theine both cause rigor in the voluntary muscles of frogs (*Rana temporaria*). The action is, however, very variable, the rigor being sometimes exceedingly well marked, and at other times not observable. Theine seems to be rather more powerful than caffein, but the quantitative difference between them is slight. There is, however, a marked qualitative difference between them, inasmuch as theine tends to produce rhythmical contractions in the muscle. A variation is observed in the action of the alkaloids on the different muscles of the same frog.

The addition of lactic acid to a solution of theine or caffein causes the rigor to appear sooner, develop more rapidly, and attain a greater maximum, and a somewhat similar effect is produced by calcium chloride. Potash retards and diminishes the action of theine or caffein. One phenomenon which seems deserving of attention is the rhythmic contraction of the muscle produced by theine. This rhythm is so slow that it would escape attention unless a very low rate of speed were used in the recording apparatus; it is sometimes as slow as from three to about one contraction per hour; it may continue for twenty hours. In one instance we observed the remarkable phenomenon to which we have given the name of pseudo-rigor; in this experiment the application of the theine was followed by slight relaxation of the muscle, to this succeeded an equal contraction, and then followed great relaxation below the normal, so great indeed that the negative curve below the abscissa strongly resembled the positive curve of contraction due to rigor in most other experiments.[1]

"Contributions to our Knowledge of the Connexion between Chemical Constitution and Physiological Action. Preliminary Communication on the Action of certain Aromatic Bodies." By T. Lauder Brunton, M.D., F.R.S., and J. Theodore Cash, M.D.

The distinctive action of the lower members of the fatty series is their stimulant and anæsthetic action on the nerve-centres.

The members of the aromatic series also affect the nervous system, but they appear to affect the motor centres more than the sensory, so that instead of producing anæsthesia, like the members of the fatty series, they tend rather to produce tremor, convulsions, and paralysis. Benzene, chlorobenzene, bromobenzene, and iodobenzene are all somewhat similar in their action on frogs; the halogen radicals not modifying the action of the benzene to such an extent as they do in the case of ammonium salts. The voluntary muscles are weakened by them, and there is a slight tendency to paralysis of the motor nerves; but the action is chiefly exerted upon the brain and spinal cord. The brain is first affected, as shown by general lethargy and disinclination to move. Next the cord is affected; motions are imperfectly performed, and there is a tendency to general tremor on movement resembling that observed in disseminated sclerosis; sometimes, however, the tremor is observed independently of movement.

The addition of hydroxyl to the benzene nucleus intensifies the convulsant action, so that oxybenzene (carbolic acid) and dioxybenzene cause convulsions in frogs, and trioxybenzene causes jerkings, though of a slighter character.

Zoological Society, April 5.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's menagerie during the month of March 1887.—Mr. F. Day exhibited and made remarks on a specimen of a Mediterranean fish (*Scorpæna scrofa*), taken by a trawler off Brixham early in March last, and new to the British fauna.—Mr. J. H. Leech exhibited some specimens of new butterflies from Japan and Corea, and gave a short account of his recent journeys to those countries in quest of Lepidoptera.—The Secretary read a letter addressed to him by the Rev. G. H. R Fisk, of the Cape Colony, respecting the killing and eating, by a shrew, of a young venomous snake (*Sepedon hæmachates*).—Prof. Flower, F.R.S., communicated, on behalf of Messrs. John H. Scott and T. Jeffery Parker, of the University of Otago, N.Z., a paper containing an account of a specimen of a young female *Ziphius*, which was cast ashore alive at Warrington, north of Dunedin, New Zealand, in November 1884.—Mr. Richard S. Wray read a paper on the morphology of the wings of birds, in which a description was given of a typical wing, and the main modifications which are found in other forms of wings were pointed out. One of the principal points adverted to was the absence, in nearly half the class of birds, of the fifth cubital remex, its coverts only being developed. The peculiar structure of the wings in the Ratitæ and the *Sphenisci* was also commented upon.—A communication was read from the Rev. H. S. Gorham, on the classification of the Coleoptera of the division Languriides. The author pointed out the characters which, in his opinion, were available for the systematic arrangement of this family of Coleoptera, and for its division into genera. The subject had hitherto not received the attention it deserved, and several errors had gained currency, owing to the hasty and insufficient way in which the structure of these insects had been analysed. He added an analytical table of about forty genera, many of those proposed being new. Further notice of the American genera would soon appear in Messrs. Godman and Salvin's "Biologia Centrali-Americana."

[1] This phenomenon is difficult to explain, but it suggests the possibility of a transverse as well as a longitudinal contraction in muscular fibre.—March 29, 1887.

Mathematical Society, April 7.—Sir J. Cockle, F.R.S., President, in the chair.—The following papers were read, or taken as read:—On the intersections of a circle and a plane curve, by Prof. Genese.—A new theory of harmonic polygons, by the Rev. T. C. Simmons.—On some properties of simplicissima, with especial regard to the related spherical loci, by Mr. W. J. C. Sharp.—On Briot and Bouquet's theory of the differential equation $F\left(u, \frac{du}{dz}\right) = 0$, by Prof. Cayley, F.R.S.—Two points in the plane of a triangle and a cubic through them, by R. Tucker.—A tetrahedral note, by Dr. Wolstenholme.

EDINBURGH

Royal Society, April 4.—Dr. J. Murray, Vice-President, in the chair.—Prof. Tait communicated a note by Prof. Cayley, on a formula for $\Delta^n 0^i/n^i$, when n and i are very large numbers.—Mr. R. Kidston read the first part of a paper on the fossil flora of the Radstock series of the Somerset and Bristol coal-fields (Upper Coal-measures).—Dr. Sang read a paper on the achromatism of the four-lens eye-piece, describing a new arrangement of the lenses. He also read a note on an effective arrangement for observing the passage of the sun's image across the wires of a telescope.—Prof. Turner read a communication by Mr. F. E. Beddard, on the structural characteristics of certain new or little-known earthworms. Five new species found in Australia and New Zealand were treated of.—Prof. J. Geikie discussed the geology and petrology of St. Abb's Head.

PARIS

Academy of Sciences, April 12.—M. Janssen, President, in the chair.—On the relations that exist between cyclones and concurrent storms and hurricanes, by M. H. Faye. From an attentive study of the synoptical storm charts of the United States Signal Service, the author is able to confirm the conclusions already drawn by M. Marié-Davy from the meteorological observations made at the Paris Observatory so far back as the year 1864. It is shown (1) that tornadoes, hurricanes, and hailstorms are simply secondary phenomena directly associated with the central cyclonic movement; (2) that in the United States their trajectories have no general relation either to the isobars or to the normal atmospheric currents; (3) that these relatively short trajectories are parallel to the vast cyclonic trajectories at the moment when these local phenomena arise; (4) that they all lie on the right flank of the cyclone itself, which may thus be regarded as a complex meteorological system accompanied on its right side by whole colonies of destructive tornadoes and hurricanes with their attendant waterspouts, hailstorms, and torrential downpours, all moving together across seas and continents. The whole movement is regulated by the simple law of the mechanics of fluids, which determines the formation of spirals or vortices in the upper atmospheric regions. The surprising variety of the physical effects produced by the movement is simply due to the descending vortex, which, as in our electric machines, suffices to bring into contact and set in violent motion aërial masses lying far apart, with their consequent differences of temperature, and aqueous particles either frozen or in a state of vapour and of positive or negative tension.—On the term "latex" in botany, by M. A. Trécul. In reply to some recent objections made to his comprehensive use of this term, the author here justifies its application both to the contents of the laticiferous vessels and to the product of the secreting ducts. The numerous facts brought together in this communication tend clearly to establish the fundamental resemblance between the physical and physiological properties of the contents of the laticiferous vessels properly so called, and of the secreting tubes, so that these two classes of vessels are properly grouped together under the common designation of vessels of the latex.—On some essays made at sea with Capt. Fleuriais' new collimating gyroscope, by M. de Jonquières. The results are given of the observations made with this instrument by Lieut. Baule, of the steamer *La Gascogne*, during a recent trip from Bordeaux to Brazil. Although this was the first application of the apparatus, the observer was able by its means to record the rolling of the vessel with considerable accuracy.—On earthquakes, by M. Oppermann. The author substantially accepts the general view of seismologists, that these disturbances are mainly due to the pressure exercised on the upper crust by the aqueous vapour formed at great depths below the surface by filtration through fissures or porous rocks.—On the winter egg of Phylloxera, by M. P. de Lafitte. The author replies to some misleading statements recently made by M. Donnadieu, and calculated to affect the issue of the experiments which are now being carried on throughout the wine-growing districts of France.—On a complementary experiment relative to waterspouts, by M. Ch. Weyher. The experiments hitherto described had reference only to the artificial formation of the "*buisson*," that is, of the two inverted cones superimposed at their summits. Here a further process is described, by means of which the author has succeeded in producing the complete waterspout, with its tube of vapour attached on the one hand to the centre of the *buisson* and on the other to the centre of the revolving drum placed 3 metres above the surface of the water. To effect this all that is needed is to project a jet of vapour to the neighbourhood of the axis of the vortex, or, better still, simply to heat the water in the large reservoir sufficiently to cause some vapour to rise.—A study of the alkaline vanadates (continued), by M. A. Ditte. Here are treated the vanadates of soda: VO_5NaO; $2VO_5NaO$; $3VO_5,2NaO$; $3VO_5NaO$; $VO_5,2NaO$; $VO_5,3NaO$; and VO_5NaO.—On the upheaval of the south-west coasts of Finland, by M. Venukoff. The topographic surveys recently carried out in Finland show once more that the shores of the Baltic are continually rising. Since the surveys of 1810–15 several islands have become peninsulas, while many shallows have become islands or beaches. On the south-west coast and in the neighbouring Aland Archipelago many places are pointed out by the inhabitants which a few years ago were under water, but which are now grazing-grounds, market-gardens, or cornfields. The local authorities are now taking steps, by means of which the progress of this geological phenomenon may in future be determined with absolute certainty and accuracy.—The sudden death was announced of M. Thollon in the midst of his labours connected with the construction of a great solar chart, on which the distinction between the telluric and solar rays would have been indicated. M. Thollon's name will always be remembered in connexion with spectroscopic studies, which have been greatly advanced by his improved spectroscope and by the device suggested by him for distinguishing rays of solar origin from those due to the terrestrial atmosphere.

BERLIN

Physical Society, April 1.—Prof. von Helmholtz in the chair.—Dr. Pernet spoke on the comparison of barometers, and drew attention to a number of sources of error which must be avoided when reading off a barometer. The speaker has carried out a series of comparisons with corrected standard barometers, aneroid barometers, and the standard barometers of different stations. He finds that the standard barometers of Berlin and Paris correspond exactly within the limits of errors of observation; aneroids do not yield anything like the same exactness that may be obtained with syphon-barometers.—Dr. Pernet also brought a new form of standard mercurial thermometer before the Society, and explained its construction. It consists essentially of the usual bulb and fine tube, which is widened out above and below into two receptacles each of which is capable of holding a mass of mercury corresponding to a column representing 50°. By means of this arrangement the instrument is easily graduated, and admits of any desired adjustment of the zero and graduation; also by varying the amount of mercury with which it is filled the same exactness in reading which is possible between 0° and 50° can be obtained even up to 200°.—Dr. Kötter spoke on the mean rate of flow of a fluid from a small aperture. This rate, as is well known, depends not only upon pressure, weight, &c., but upon a certain constant which is called the coefficient of efflux, and which has been determined to be 0·62. The speaker gave an account, in their historical order, of a number of researches which have been made with a view to determining this coefficient mathematically, and then proceeded to explain his own methods of calculation, which lead to the value $\frac{\pi}{2+\pi}$ established by Kirchhoff and Rayleigh.—Dr. König exhibited a direct-vision spectroscope constructed by Wernicke, which is contained in a glass tube instead of a wooden one, and thus admits of the internal arrangement of the instrument being seen.

PRACTICAL ELECTRICITY

Practical Electricity. By W. E. Ayrton, F.R.S. (London: Cassell and Co., 1887.)

PROF. AYRTON'S book on Practical Electricity fills a gap, and is well fitted for the purpose for which its author has designed it. The book comprises the substance of the first year's course for students of electrical technology in the City and Guilds Central Institution at South Kensington, with some additional matter, which is chiefly in small type. The subject of Current is treated first, then comes Electromotive Force or Potential Difference, and afterwards Resistance. This is undoubtedly the logical order, though, as Prof. Ayrton points out, this sequence appears complicated to the minds of learners, from the fact that in the definitions of the Paris Congress the volt is made to depend on the ohm and the ampere. The practical units, ampere, ohm, volt, &c., are used throughout, but a little more space might have been given with advantage to the definitions of these units. Take, for instance, the definition of an ampere, 6. After showing by means of a most instructive and well-arranged experiment (Fig. 1) that a current produces magnetic, chemical, and thermal effects, and further, that the chemical changes are the same in two or more voltameters of the same kind, Prof. Ayrton proceeds:—"We shall therefore *define the strength of a current as being directly proportional to the amount of chemical decomposition produced in a given time; and the current that deposits* 0·00111815 *gramme or* 0·017253 *grain of silver per second on one of the plates of a silver voltameter, the liquid employed being a solution of silver nitrate containing from* 15 *to* 30 *per cent. of the salt,* we shall call an *ampere*,' and take it as our unit current." But frequently a beginner will at once wish to know why these special numbers, which will seem to him unnecessarily complex, should have been taken. Why not select ·001 gramme of silver rather than ·00111815? will be an obvious question, to which no answer is given. Surely, too, four significant figures would be sufficient. Besides, this is not the definition of ampere adopted by the Paris Congress, and it involves the experiments of someone on the electro-chemical deposition of silver. The experiments given in the early part of Chapter II. do not need the previous definition of the *unit current*, and from them the fact that a current exerts on a magnet a definite force depending on its strength and (§ 22) on the dimensions and position of its circuit is established. Thence the idea of the current which exerts on a definite magnet a unit force is easily reached, and from this we get the ampere of the Congress definition, which is found, by careful experiment, to deposit so many grammes of silver per second.

So, too, the definition of the "volt" would have been clearer if the excellent illustration of difference of potential given in § 40, Fig. 28, had been carried a little further, and it had been pointed out that, just as the water loses potential energy in falling from one level to another, and that loss is measured by the quantity of water multiplied by the difference in pressure, so the electric current loses energy in passing from one point to another, and that loss is measured by the quantity of electricity multiplied by the difference of electrical potential. But these, perhaps, are points which can be better brought out by a teacher in explaining difficulties to his class.

The book is, we believe, the first in England which accepts distinctly the resolutions of the Paris Congress as a basis. Another novelty to be found in it is the use of the letters P.D. (potential difference) for the old abbreviation E.M.F. This is a change for which, if it can be satisfactorily introduced and accepted, all teachers will be thankful, for it will get rid of the confusion existing between the resultant electrical force at a point, and the electromotive force between two points, which is not a force at all.

The plan of the book has been already indicated. Starting from the definition of an ampere, the various means of measuring currents are described, and full

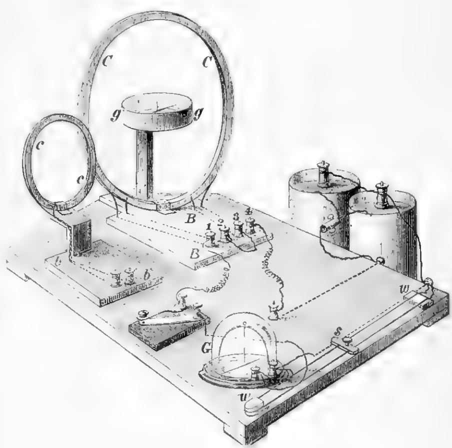

Fig. 15.[1]

details are given of the methods for carrying out the experiments, for recording results graphically and otherwise, and for drawing conclusions from the experiments. The illustrations show clearly the arrangement of apparatus in each case. In Prof. Ayrton's laboratory the apparatus required for any one series of observations is mounted permanently on the same board; the student finds everything ready, and the necessary connexions made when he begins. As to the desirability of this, there will no doubt be some difference of opinion; but with large classes of beginners some such plan is necessary. Thus, Fig. 15 shows the apparatus for investigating the action of a current on a magnet. The large coil C C is so arranged that the current can be made to traverse it eight, twelve, or sixteen times, and its effect on the magnet *g g* observed; or the coil C C can be replaced by *c c* of half the radius, which has four turns on it; or, again, C C can be used simultaneously with *c c*, the current being

[1] We are indebted to Messrs. Cassell for the blocks used to illustrate this article.

sent in opposite directions through the two. *w w* is a resistance by means of which the current may be varied at will, and G a galvanometer.

Chapter III. introduces us to difference of potential, and here the writer describes in a practical form the experiments for the verification of some of the ordinary laws of statical electricity.

Ohm's law and its proof follow in Chapter IV., and it is shown that the resistance of a conductor remains unchanged so long as its other physical conditions are the same. § 80 gives the definition of the "legal ohm." It is not quite accurate to speak of its having been legalised, at any rate in this country; though, as the letter from the B.A. Committee on Electrical Standards, which is printed at the end of the preface, shows, the question of its adoption as a legal standard is now before the Government. Various methods of comparing resistances follow, with full practical details, but the important one due to Prof. G. C. Foster, for comparing two nearly equal resistances, has been omitted from § 97.

Batteries and other forms of current-generators are next considered, with details as to their construction and

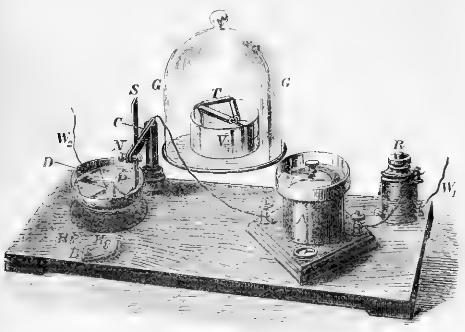

Fig. 157.

use; and an account of the methods of determining thei E.M.F. and resistance is given.

"Insulation" is the title of Chapter VI., and many o the practical hints given under this head are of grea value.

In the next chapter, condensers, and the methods of constructing them and of measuring their capacities, are treated of. We find also a chapter devoted to commercial ammeters and voltmeters, which gives in an easily accessible form particulars as to some of the best known of these instruments, with practical methods of testing and calibrating. In Fig. 157 we have the arrangement of apparatus for comparing an ammeter with a silver voltameter. R is an adjustable resistance of a useful character, made of a number of washers of carbonised cloth which can be pressed into close contact by a screw. Latimer Clark's cell is described in § 214, in the H form. A simpler pattern consists of a test-tube with a platinum wire sealed through the bottom. The end of this is covered with pure mercury, and above this is a layer of mercurous sulphate, with a saturated solution of sulphate of zinc above all. A rod of clean zinc dips into the zinc sulphate passing through the cork which closes the test-tube, and the whole is kept tight with marine glue.

In an appendix Kirchhoff's laws of divided circuits are considered. The method of treating such problems introduced by Maxwell, and which has recently been illustrated at some length by Prof. Fleming, is also referred to.

Another point of importance which calls for notice is the number of examples introduced by way of illustration; some of these are completely worked out, others left as exercises for the student.

The book concludes with some specimens of the instructions for experiments which are given to students at the City and Guilds Institution, with the apparatus with which each experiment is performed. Of these instructions there are four; and many who use the book will wish their number was larger. We will close this notice by quoting the last of them.

To calibrate an ammeter by means of a silver voltameter (the apparatus required has been figured above):—

"Preliminary.—The voltameter consists of a platinum dish containing a 25 per cent. solution of silver nitrate, and in which a silver plate is immersed. An adjustable carbon resistance is provided, by means of which the current passing through the voltameter can be maintained constant during each experiment, and can be varied in the different experiments.

"Experiments.—(1) Carefully clean, dry, and weigh the platinum dish, the *approximate* weight of which is 78 grammes.

"(2) Pour the solution of silver nitrate into the dish, and place it on the three brass pins provided for its reception, and which are electrically connected with the left-hand binding-screw on the board. Immerse the silver plate in the solution, and clamp it in such a position that its edges are equally distant from the sides and bottom of the dish.

"(3) Turn the small milled head at the top of the ammeter so that the pointer of the ammeter comes opposite the zero on the scale, if not there already. Place the copper connecting-wire in the mercury cups marked A and C (which cuts out the voltameter), and adjust the carbon resistance until a convenient current flows round the ammeter. Remove the connecting-wire.

"(4) Quickly insert the connecting-wire in the mercury cups marked A and B, carefully noting the instant at which the circuit was completed. Allow the current to pass for a convenient time (ten to thirty minutes, according to the strength of the current used), and keep the current constant by the adjustable resistance. Note the temperature of the room during the experiment, and, at the end of the interval decided on, quickly break the circuit.

"(5) Empty the solution from the dish into its bottle, and carefully wash the deposited silver with distilled water. Then fill the dish with distilled water, and allow it to stand ten to fifteen minutes Again wash with water, alcohol, and ether, dry over the spirit-lamp, and cool in the desiccator.

"(6) Carefully determine the increase of weight due to the silver deposited on the dish.

"(7) Calculate the strength of current used in the experiment, assuming that one ampere deposits 1·11815 milligrammes of silver per second.

"(8) Repeat the experiment with several different strengths of current.

"(9) Tabulate your results in some convenient form, and write them with your name on the card, on which you will find recorded the results of previous experiments."

SPOLIA ATLANTICA

Spolia Atlantica. (1) Contributions to the Knowledge of the Salpidæ, by M. P. A. Traustedt; (2) Remarks on some of the Oceanic Annulata, by G. M. R. Levinsen; (3) Contributions towards the Morphology and Systematic Arrangement of the Pteropoda, by J. E. V. Boas. (Copenhagen, 1885-86.)

THE three monographs which at the instance, and under the supervision, of the Directors of the Zoological Museum of Copenhagen, have been included in one quarto volume under the title of "Spolia Atlantica," originally appeared in the Transactions of the Danish Royal Society of Natural Sciences. But although bound together, each monograph in this *édition de luxe* is complete in itself, with separate title-page, table of contents, descriptive plates, and all other necessary means of separate reference, while the convenience of readers not acquainted with Danish has been amply considered by the addition of Latin and French translations of the descriptions of the animals, and of many other important parts of the text.

The first of this triplet of monographs, which deals with the so-called "aggregate" and "solitary" forms of the several species of Salpæ, is based on a study of the exceptionally complete collections preserved in the Zoological Museum of Copenhagen, for which that institution is mainly indebted to Prof. Steenstrup, at whose suggestion and under whose direction Herr Traustedt compiled his memoir. The monograph presents a clear and comprehensive description of all the well-established species of Salpæ with their distinctive dual forms, and unqualified praise may be given to the care with which the figures have been drawn, and the admirable manner in which, by means of pale blue outlines, the delicacy and transparency of the bodies of the animals have been represented.

In treating of the Salpidæ, it is impossible to forget how much of our knowledge of these curious animals is due to the observations of Chamisso, the clever author of "Peter Schlemihl," who, while serving as naturalist in the exploring expedition of the Russian commander Kotzebue, first discovered that the "aggregate" or chain Salpa and the "solitary" Salpa were not distinct species, as had been supposed, but only parts of the perfect organism of one species. By the discovery of this fact, which Chamisso ingeniously, but, as subsequent investigations have shown, too fancifully, explained on the hypothesis that these animals were subject to a law of "alternation of generations," new and highly important paths of morphological inquiry were opened. Yet, singularly enough, nearly thirty years passed after the publication, in 1819, of Chamisso's treatise "De Animalibus quibusdam e Classe Vermium Linneana (de Salpis)" before his observations were tested by further scientific investigation. About the middle of the century Meyen and Vogt turned their attention to the curious and interesting phenomena connected with the embryonic development of the Salpæ. These inquiries were soon followed by the still more important researches of Profs. Krohn and Huxley, the latter of whom in a paper entitled "Observations upon the Anatomy and Physiology of Salpa and Pyrosoma," which appeared in the Phil. Trans. 1851, has shown that Chamisso erred in his explanation of the nature of a "chain Salpa," which, to use Mr. Huxley's words, "is nothing more homologically than a highly individualised generative organ."

Herr Traustedt does not enter into the question of the embryonic development of the Salpidæ, and hence his work gives no information regarding the physiology of these animals, nor does he in any way refer to the various hypotheses that have been advanced in explanation of the character of the "aggregate" and "solitary" forms. For such information the student must go elsewhere. As a guide to the anatomical structure of both forms in the eleven species described and drawn by the author, the memoir will, however, be found of great service, while it contains much useful information as to the geographical distribution of these animals not to be found elsewhere.

In the treatise on "Some Oceanic Annulata" Herr Levinsen supplies many interesting details regarding various members of the families Alciopidæ and Typhloscolecidæ, together with descriptions of several species of Sagitta, to which are added lists of their geographical distribution. In this, as in the memoir on the Pteropoda, the illustrations are worthy of all praise.

The memoir by Dr. Boas, which constitutes the last and longest of the series, treats at great length of the morphology, systematic arrangement, and geographical distribution of the Pteropoda. The materials employed by the author were derived in part from the extensive collections in the Zoological Museum of Copenhagen made by, or under the direction of, Prof. Steenstrup, and in part from numerous specimens placed at the writer's disposition by Profs. Dohrn, Möbius, Leche, and Spengel. It is worthy of note that a very large proportion of the specimens referred to as belonging to the Museum of Copenhagen were obtained from amateur collectors; Danish naval officers, captains of merchant ships, and travellers having responded with alacrity to Prof. Steenstrup's appeal for help in obtaining samples of these and other animals from remote regions.

OUR BOOK SHELF

Complete Hand-book on the Management of Accumulators. By Sir David Salomons, Bart. Second Edition, revised and enlarged. (London: Whittaker and Co., 1887.)

THE author has for some years past had an installation at his country residence for the purpose of lighting it and for working motors which drive the machinery in his large and well-equipped workshop. He has used accumulators, as he informs us, ever since they may be said to have been produced in commercial form in 1882. No expense nor trouble have been spared in making this installation a model one, and experiments have been made on many points in connexion with the subject. As the whole installation has been made and worked under his immediate personal superintendence, he has acquired a considerable amount of experience, the result of which, as far as it regards the management of accumulators, he places before the public in this work.

After a general description of cells of the E.P.S. and Elwell-Parker type, he proceeds to give directions for setting up and charging them. The causes of, and remedies for, "buckling" and "scaling" are discussed. The harm caused by too rapid a discharge is pointed out, and methods for preventing it are explained, as well as various devices for regulating the E.M.F. of the charging current and that on the line. The method of cleaning and "re-pasting" the plates is explained, and various hints are given for the management of the battery. In an appendix is a description of the arrangement of his accumulator house, a photograph of the interior of which forms the frontispiece to his book. He also gives a brief account of the history of the installation, from which we learn that the total cost of buildings and installation has been about 6000*l.*, that the number of lamps is about 500 of 20-candle power, but that the greatest number used at any one time has rarely exceeded 200, and that an arc lamp taking 40 or 50 amperes and one or two motors have been used together with them. The expenses—including wages, coal, oil, waste, washers, repairs, lamp renewals, &c.—were, in 1886, 210*l.*, or at the rate of $\frac{1}{4}$*d.* per 20-candle lamp per hour. He does not, however, say anything as to the cost of the accumulators; and as to the length of time which they may be expected to last he only says vaguely that "the cells may last for years in perfect order if all the instructions here given are properly attended to." His present accumulators were only put up in August 1885, those previously erected having proved to be unsatisfactory.

It is a pity that the useful information in this work is not conveyed in better language. In what is intended as a workshop hand-book we do not look for the elegance of an Addison; but we do want plain English. As an example of the language we may quote the following sentence from the preface: "Only cells of the Electrical Power Storage Company, of Messrs. Elwell-Parker, and their type, are dealt with, because at this moment there is probably no other better kind, or largely in use." The meaning of this is clear, though even that is more than may be said of other sentences in the book.

Among minor faults we protest against the coinage of such a hideous word as "acidometer," by which, apparently, is meant the instrument commonly known as a hydrometer; we do not think "s.g." is an improvement on the ordinarily accepted abbreviation for specific gravity; and we object to the plural "dynamos" as against the ordinary rule of our language which gives us "potatoes" and "echoes."

A more serious error is found in the "Index of Terms" on the back of the title-page—

"Watt = volt × ampere = measure of force or energy."

We should recommend the author to get the work revised by some onewho understands the rudiments of science as well as those of the English language.

School Hygiene: The Laws of Health in Relation to School Life. By Arthur Newsholme, M.D. (London: Swan Sonnenschein, Lowrey, & Co., 1887.)

ABOUT the importance of the matters dealt with in this little book there can, of course, be no dispute; and, as Dr. Newsholme points out in his preface, they have engaged the serious attention of many School Boards and Committees, and been made the subject of a good deal of useful legislation. Most school-managers still have something to learn about the principles of school hygiene, and many of them will, no doubt, find in Dr. Newsholme's volume exactly the kind of information they want. He discusses the subject under two heads, "Schools" and "Scholars." Under the first head he presents his ideas on questions connected with the choice of sites for schools, the construction of school buildings, school furniture, lighting of school-rooms, general principles of ventilation, natural ventilation, ventilation and warming, and draining arrangements. In the part relating to "Scholars" he has chapters on mental exercise, excessive mental exercise, age and sex in relation to school work, muscular exercise and recreation, rest and sleep, children's diet, children's dress, baths and bathing, eyesight in relation to school life, communicable diseases in schools, and school accidents. Dr. Newsholme has studied his subject thoroughly, and his conclusions are all the more valuable because they have been to a large extent suggested by his experience as a medical officer of health, and as a medical referee for various schools and training colleges.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Mass, Weight, and Dynamical Units

IF the laws of dynamics were made solely for the use of engineers, as a celebrated engineer declared of rivers that they were intended to feed canals, it might be conceded to Prof. Greenhill that it would not be *necessary* that the more abstract notion of mass should be distinguished from that of weight, and that the fundamental equation of dynamics might conveniently be taken as $P = W\frac{f}{g}$, where W is the weight (or mass) of the body moved expressed in pounds or tons, &c., and P the force producing in it the acceleration f, and reckoned in the same units. But a pound weight as a force is a variable unit, unless it is taken at some particular place (as Greenwich), and then the corresponding value of g must be employed (though the variation of g on the surface of the earth is not so great as often to need to be taken account of by the engineer); and so the astronomer and physicist, as well as the student of abstract dynamics, are right in demanding a less arbitrary measure of force than one founded on the force acting vertically downwards on a body at the earth's surface, as well as an absolute constant belonging to each body (its *mass*) independent of time and place. I conceive, therefore, in spite of Prof. Greenhill's arguments, that, in the interest of clearness of thought, as well as to avoid the practical inconvenience of a variable unit of force, the notions of mass and weight must be kept distinct, and the equation $W = Mg$, as a special case of the general equation $P = Mf$, still insisted on by all teachers of dynamics, at any rate to non-engineering students; while it would be well for engineers also (*me judice*) to have their dynamics cast in the same mould as the rest of the scientific world.

I should not have troubled you with the above very obvious remarks had I not wished to observe, *à propos* of Mr. Geoghegan's suggestion of names for units of velocity and acceleration in NATURE of April 7 (p. 534), that it is highly desirable that a convenient and consistent *notation*, as well as *nomenclature*, should be adopted for the several dynamical units.

With respect to the particular suggestion that *vel* and *cel* (or *velo* and *celo*, as used by Mr. Lock in his forthcoming book, "Dynamics for Beginners") should be employed for the units of speed and acceleration in the foot-second system, I regard it as an almost fatal objection that the accepted C.G.S. system having appropriated the words *dyne* and *erg* for its units of force and work has a prior right to *vel* and *cel* for its units of speed and acceleration; namely, the centimetre per second, and the centimetre per second per second. If so, the units of the foot-second system might be called the *footvel* and the *footcel*.

Names for the dynamical units are, however, I think, of less importance than a convenient and suggestive notation for them. I have endeavoured to devise such a notation (or, rather, to fill up and complete notations which have more or less come into use) in a table, which is now under the consideration of a Committee of the Association for the Improvement of Geometrical Teaching, and which is substantially as follows.

In a perfectly general system, let **L**, **M**, **T** stand respectively for the fundamental units of length, mass, and time, and let **V**, **A**, **U**, **Δ**, **E** stand for the units thence derived of speed, quickening (acceleration), momentum or impulse, force, and energy or work respectively: then the statement that the unit of speed is the speed of the unit of length *per* unit of time is naturally expressed thus, $V = L/T$. On the same principle we should have—

$$A = V/T = L/TT,\ U = MV = ML/T,\ \Delta = MA = ML/TT,\ E = L\Delta = LML/TT.$$

This may be simplified, using the analogy of the fluxional notation, by writing $\dot{L}$ for L/T and L for $\ddot{L}/TT$. Then $\dot{L}$, $\ddot{L}$ may take the place of V and A, and we have—

$$U = M\dot{L},\ \Delta = M\ddot{L},\ E = L\Delta = LM\ddot{L}.$$

Names for the several units are hardly needed in the general system.

In the C.G.S. system the units of length, mass, and time are respectively the centimetre, gramme, and second, denoted by C, G, S. Then if U_G, Δ_G, E_G denote the units of momentum or impulse, force, and energy or work, we have, on the same principle as before, $\dot{C}$, $\ddot{C}$ to denote the speed of a centimetre per second and the acceleration of a centimetre per second per second respectively, and the equations—

$$U_G = G\dot{C},\ \Delta_G = G\ddot{C},\ E_G = C\Delta_G = CG\ddot{C}.$$

If *names* for all these units are required, we may use these: *vel, cel, mom, dyne, erg*; and we may say, a *mom* is a *gramme-vel*, a *dyne* is a *gramme-cel*, and an *erg* a *centimetre-dyne*.

In the F.P.S., or British system, the units of length, mass, and time are respectively the foot, pound, and second, denoted by F, P, S. Then, if U_P, Δ_P, E_P denote the units of momentum or impulse, force, and energy respectively, we have, on the same principles, $\dot{F}$, $\ddot{F}$ to denote the speed of a foot per second and the acceleration of a foot per second per second respectively, and the equations—

$$U_P = P\dot{F},\ \Delta_P = P\ddot{F},\ E_P = F\Delta_P = FP\ddot{F}.$$

I propose as names for these units: *footvel, footcel, poundem, poundal, pounderg*. I should have called the unit of force a *pound-dyne* or *poundyn*, but that *poundal* has already obtained general acceptance.

The foregoing are all absolute units. The corresponding (Greenwich) gravitation-units are the *pound-weight* = 32·19 *poundals*, the *foot-pound* = 32·19 *poundergs*, and the *second-pound* (as it has been proposed by Prof. Unwin to name the gravitation-unit of momentum, or time-integral of a pound-weight through one second) = 32·19 *poundems*; so that to convert absolute F.P.S. units into gravitation-units, or *vice versâ*, it is only necessary to divide or multiply by 32·19, since the acceleration due to gravity at Greenwich = 32·19 $\ddot{F}$.

It is, I think, comparatively unimportant whether the *names* above suggested are, all of them, accepted or not; but the *notation* will, I believe, be found a great aid to the beginner in fixing in his mind the dimensions of the different magnitudes, and an effective safeguard against the too common confusion of units of force, impulse, and work. I doubt whether in speaking much would be gained by saying "*footvel*" instead of "foot per second," or "*footcel*" instead of "foot per second per second," while in *writing*, the symbols $\dot{F}$ and $\ddot{F}$ might be always used and read either way.

ROBT. B. HAYWARD

Harrow, April 12

Units of Weight, Mass, and Force

FAR be it from me to interfere between Mr. Alfred Lodge and Prof. Greenhill; but, whilst leaving Mr. Lodge to his fate and Prof. Greenhill, perhaps, as an engineer, I may be permitted to offer a few remarks on the general question. First, then, it appears to me that Prof. Tait's thoroughgoing condemnation of certain phrases of the engineering vernacular, and of the grave errors of certain writers, has been strained in some quarters to mean a general charge against engineers of inability to think or write clearly on the physical laws which lie at the root of their every-day practice. Such an unqualified charge is on the face of it absurd; for otherwise we must confess that the lives' work of Thomson and Tait has been a total failure as regards its influence on the truly practical men of their generation. Can this be so?

Prof. Greenhill's remarks on the abominable semi-numerical equation $W = Mg$, or $\frac{W}{g} = M$, I most heartily welcome [where W is a mass and g a numeric; the moment writers on dynamics, who use the gravitation system, pass from merely proportional equations to their physical interpretation, then must we face with them this most wretched equation]. But perhaps it will be at once a surprise and a gratification to Prof. Greenhill to know that a whole (academic) generation of Scottish University engineering students has been taught to eschew this same equation as an unclean thing, and to adopt the mode of thought clearly set forth in the last two paragraphs of his letter of February 28. Some five or six years ago I was myself so taught by one who is now, alas! no more. The possibility of thus clearing of cant not only the engineering but the purely mathematical mind seems to me, as indeed Prof. Greenhill indicates, to be a direct consequence of the acceptance by Thomson and Tait of the British Imperial pound as the unit of mass or quantity of matter.

Having fixed, then, for good and all, the unit of mass, and taking the British foot and the second as the units of time and length respectively, the unit of force defines itself in virtue of Newton's Second Law. To this unit—the British unit of force—Prof. James Thomson has given, as nearly everyone knows, the name "poundal." Now the most convenient practical unit of force, for physicists as well as engineers, is not the poundal, but the gravitation at the earth's surface of the unit of mass, a quantity which is not absolutely constant, the inconvenience so arising being, however, practically unimportant, or at most involving a reduction to an arbitrary standard. To pass, then, from a force expressed in poundals to a force expressed in units of gravitation of the Imperial pound at the standard place, one simply wants to know how many poundals go to the gravitation of the Imperial pound at that place—in other words, the change ratio. The answer is simple: the numeric g for the standard place; for a force equal to the gravitation of the Imperial pound at the standard place acting upon a mass of one Imperial pound would generate a momentum per second of g (numeric) pounds mass × feet per sec. per sec.; and the poundal a momentum per second of one pound mass × feet per sec. per sec.; and by Newton's Second Law the ratio of the forces is, therefore, the numeric g. What more does the physicist or engineer want to know? How many poundals go to the gravitation of a ton mass at the standard place? Answer, the numeric 2240 g. Could anything be simpler? The difficulty is to find the difficulty, or to assign the *raison d'être* of the so-called gravitation unit of mass.

When the old unnatural gravitation unit of mass is abandoned, and the transition from the natural unit to the gravitation unit of force made by means of the change ratio, the vicious use of the word mass to denote the result of dividing by the numeric g the mass of a body in standard pounds (viciously on the same system called the weight and denoted by W) ceases; and the dire confusion between weight and mass becomes a thing of the past. The emancipation of the term weight from its bondage to mass would appear to have afforded opportunity for its use wherever it might be of service in suggesting or denoting gravitation. For example, there are three units, each called a pound, viz. the Imperial British unit of mass, the gravitation of the same mass at any the same place on the earth's surface, and the pound sterling. Physicists, like Sir Wm. Thomson and Prof. Tait, use terms such as "pound weight," "gramme weight"; similarly we have "pound mass" coming into use; and probably we shall soon hear of "pound money." Prof. Greenhill, with his strong engineering sympathies, objects to the time-honoured "pounds per square inch" being rendered "pounds weight per square inch"; and if I may presume to offer an opinion, the old phrase is already cumbrous enough. Still, if Prof. Tait and Prof. Greenhill ultimately agree that there is anything to be gained in perspicuity, for the sake of the weaker members perhaps it might be well for us to put in practice, on some occasions, the injunction to sacrifice all rather than cause our brother to offend.

Some one might possibly step in to draw attention to the fact that the pages of even our own great high priest of exact applied science are disfigured by $\frac{W}{g}$; but sure I am that were Rankine now with us he would lead the way with Prof. Greenhill in a crusade against the apologists for the obscurity of which W/g is the symbol. Take, for example, Rankine's bold introduction of the dynamical unit of quantity of heat. Take the opinion of

Clausius, than whom none could be a more unprejudiced witness. "At the same time in the theoretical development of the mechanical theory of heat, in which the relation between heat and work often occurs, the method of expressing heat in mechanical units effects such important simplifications that the author has felt himself bound to drop his former objections to the method on the occasion of the present more connected exposition of that theory." ARCHD. C. ELLIOTT

Edinburgh, April 18

Seismometers

I HAVE long ago learnt not to look for any fair recognition of my work in seismometry on the part of Prof. John Milne, and when he accuses me of appropriating without acknowledgment the work of others it is time to decline further controversy with him. The points raised in his last communication (NATURE, April 14, p. 559) are sufficiently answered in mine of December 11 (p. 172). I there quoted part of a letter written by Prof. Chaplin, now of Harvard University, then of Tokio, and Secretary of the Seismological Society of Japan, under whose eyes the events occurred to which Prof. Milne refers. I did not quote the whole of Prof. Chaplin's letter, because it contained sentences I was unwilling to give except under the strongest provocation. After referring to my seismograph in the words already quoted (p. 172), Prof. Chaplin continues:—

"I do not remember that in the discussions on your machine Mr. Gray ever claimed to have invented a similar machine, and I am surprised to know that he makes that claim now. On this and other points it appears to me that Messrs. Gray and Milne have not treated your inventions and investigations with fairness, and that you have just grounds for complaint. I am willing you should make such use of this note as you see fit."

As to the question of priority, this judgment, from a man at once unprejudiced, most competent to form an opinion, and fully informed of the matter in dispute, must (so far as I am concerned) close a discussion of which your readers cannot but be weary. With your permission I shall give, in a later number of NATURE, an example of the excellent work which Prof. Sekiya is now doing with my instruments in Japan.

University College, Dundee, April 16

April Meteors

THE Lyrids have, this year, offered a somewhat scanty display, though a few brilliant meteors have been seen shooting from the usual radiant-point.

In 1884 April 19, this shower was very rich, the horary number of its meteors for one observer being about 22, but in the following year, 1885, it exhibited a considerable decline, the hourly rate being only 3. In 1886 I obtained no observations, owing to the bright moonlight and in the present year, on April 20, the horary number was slightly more than 2, so that the numerical character of the recent display has fallen far short of some of its apparitions in preceding years.

On the night of April 17, this year, the shower had not visibly opened, for none of its meteors were recorded in a 2½ hours' watch. On each of the nights of the 18th and 19th the sky was closely observed for 4½ hours, but the Lyrid shower was very feeble, and only furnished 1 meteor per hour. On the 20th, in 3 hours I noted 7 Lyrids, and these were brilliant.

The average radiant-point from the three nights was at $269° + 32°$, and there is confirmation that this point advances in R.A. with the time, though not to the marked degree ascribed in NATURE for May 7, 1885, p. 5. But the meteors from this stream have been so scarce at their late recurrence that it has been very difficult to ascertain the exact radiant for each night. Moreover, these Lyrids move with great apparent velocity, flashing out with extreme suddenness and they are gone, together with the faint streaks sometimes accompanying them, before the eye is enabled to catch the directions with satisfactory precision.

On the four nights April 17 to 20 inclusive, I noticed 70 shooting-stars belonging to the minor systems of the Lyrid meteoric epoch, and amongst these the best was that of a radiant of very swift, short meteors at $231° + 17°$, a few degrees west of β Serpentis. This stream is not new, for I saw a well-defined shower of Serpentids from the same point during my observations of the Lyrids in 1885, on April 19–20 (NATURE, May 7, 1885, p. 6).

In this and in previous years I have also recorded some meteors ascending in very long flights from a radiant centre close to θ Libræ, at $235° - 15°$. This is the only observation of this shower at the April period, though Lieut.-Colonel Tupman found a pair of radiants near the position assigned in the first week of March 1869–70.

I subjoin a short list of bright meteors seen here while watching the progress of the Lyrids, and I should be glad to hear that any of these had been observed elsewhere.

Date	Hour	Mag.	Apparent Path From	To	Notes	Radiant
1887	h. m.		° °	° °		
April 19	13 13	♀	269 + 11	269 + 1	Swift, streak	Lyrid
19	13 46	♃	308 + 61½	56 + 65½	Swift, streak	279° + 13°
20	9 48	1	211 + 7	194 − 4	Very swift	Lyrid
20	10 29½	>1	243 + 14	234 + 5	Swift, streak	Lyrid
20	10 47	1	239 + 53	269 + 62¼	Slow, train	206° + 18°
20	12 28	>1	308 + 40	316 + 40¼	Very swift	Lyrid

Bristol, April 22 W. F. DENNING

Vertical Decrement of Temperature and Pressure

IN NATURE of March 10 (p. 437), Mr. Maxwell Hall gives an interesting table of the vertical distribution of temperature and pressure in Jamaica, and, apparently in happy ignorance of the dangers of the process known as extrapolation, goes on to apply the results of observations extending to a maximum height of only 7400 feet to the determination of the probable temperature of meteorites in extra-terrestrial space. As he expresses a desire to know whether any similar results have been found in India, and as I have on several occasions during the past ten years discussed the vertical distribution of temperature and pressure in this country, I gladly take this opportunity of referring him to my papers on the meteorology of the North-West Himalaya, and on the temperature of North-Western India, published in the "Indian Meteorological Memoirs," vols. i. and ii. From the latter I extract the following table on the mean decrement of temperature up to a height of 12,000 feet, computed from the observations of twenty-five stations combined in various ways. For each month an interpolation formula of the form

$$T = T_0 + ah + bh^2 + ch^3,$$

was computed, and by its means the decrements from sea-level to 1000 feet, 1000 to 2000 feet, &c., were calculated. Finally, the average decrement for the twelve months was computed, and is here given in an abridged form. The curves for the several months differ very widely from one another, those for the summer giving the most rapid decrement at sea-level, and the decrement increasing with altitude in winter:—

Height Feet		Mean temperature decrement ° F.
0 to 2000	... ...	6·16
2000 to 4000	... ...	5·87
4000 to 6000	... ...	5·61
6000 to 8000	... ...	5·37
8000 to 10000	... ...	5·16
10000 to 12000	... ...	4·98

The mean height of the barometer at sea-level in the region in question, the centre of which lies a little north of Simla, is about 29·8 inches; the mean at 6000 feet is 24·1 inches, and the mean at 12,000 feet about 19·4 inches. With these data, and adopting Mr. Hall's formula

$$\delta T = \lambda . \delta P + \mu . (\delta P)^2,$$

we find $\lambda = 2°·979$ and $\mu = 0°·02$. These coefficients do not differ widely from Mr. Hall's values, which are 2°·92 and 0°·08 respectively. At the limit of the atmosphere, where $\delta P = 29''·8$, δT would be $-106°·5$, which would give, as the mean temperature of external space, about $-30°$ F., the mean temperature at sea-level being 77° F.

Taking the simplest formula, $\delta T = \lambda . \delta P$, we find $\lambda = 3°·19$, which is almost identical with the value quoted by Mr. Hall from an early volume of NATURE, but which, if it held good to the limit of the atmosphere, would make the temperature of external space about $-18°$ F., since the mean temperature at sea-level is 77° F.

The only conclusion to be drawn from such observations is that the vertical decrement of temperature on mountains varies greatly with locality as well as season, and the results obtained for one locality cannot be fully applied to another, much less extended to determine the temperature at the superior limit of the atmosphere.

An interesting point of resemblance between Mr. Hall's observations and those made on the Himalaya is that the diurnal range of temperature diminishes to a minimum at about 5000 feet, and then increases with increasing elevation.

Allahabad, March 30 S. A. HILL

Royal Society's *Soirée*

MAY I be permitted, through the columns of NATURE, to ask, on behalf of the Sub-Committee appointed to make arrangements for the forthcoming *soirée* of the Royal Society, that Fellows and others who have apparatus or objects of scientific interest suitable for exhibition on that occasion will communicate at once with the Secretaries or myself. HERBERT RIX,

Royal Society, Burlington House Asst. Sec. R.S.

HOMERIC ASTRONOMY[1]

II.

TURNING to the second great constellation mentioned in both Homeric epics, we again meet traces of remote and unconscious tradition. Yet less remote, probably, than that concerned with the Bear. Certainly less inscrutable. For recent inquiries into the lore and language of ancient Babylon have thrown much light on the relationships of the Orion fable.

There seems no reason to question the validity of Mr. Robert Brown's interpretation of the word by the Accadian *Ur-ana*, "light of heaven" ("Myth of Kirke," p. 146). But a proper name is significant only where it originates. Moreover, it is considered certain that the same brilliant star-group known to Homer no less than to us as Orion, was termed by Chaldeo-Assyrian peoples "Tammuz" (Lenormant, *Origines de l'Histoire*, t. i. p. 247), a synonym of Adonis. Nor is it difficult to divine how the association came to be established. For about 2000 B.C., when the Euphratean constellations assumed their definitive forms, the belt of Orion began to be visible before dawn in the month of June, called "Tammuz," because the death of Adonis was then celebrated. It is even conceivable that the heliacal rising of the asterism may originally have given the signal for that celebration. We can at any rate scarcely doubt that it received the name of "Tammuz" because its annual emergence from the solar beams coincided with the period of mystical mourning for the vernal sun.

Orion, too, has solar connexions. In the Fifth "Odyssey" (121-24), Calypso relates to Hermes how the love for him of Aurora excited the jealousy of the gods, extinguished only when he fell a victim to it, slain by the shafts of Artemis in Ortygia. Obviously, a sun-and-dawn myth slightly modified from the common type. The post-Homeric stories, too, of his relations with Œnopion of Chios, and of his death by the bite of a scorpion (emblematical of darkness, like the boar's tusk in the Adonis legend), confirm his position as a luminous hero (R. Brown, *Archæologia*, vol. xlvii. p. 352; "Great Dionysiak Myth," chap. x. § v.). Altogether, the evidence is strongly in favour of considering Orion as a variant of Adonis, imported into Greece from the East at an early date, and there associated with the identical group of stars which commemorated to the Accads of old the fate of Dumuzi (*i.e.* Tammuz), the "Only Son of Heaven."

It is remarkable that Homer knows nothing of stellar mythology. He nowhere attempts to account for the names of the stars. He has no stories at his fingers' ends of translations to the sky as a ready means of exit from terrestrial difficulties. The Orion of his acquaintance—the beloved of the Dawn, the mighty hunter, surpassing in beauty of person even the divinely-born Aloidæ—died and descended to Hades like other mortals, and was there seen by Ulysses, a gigantic shadow "driving the wild beasts together over the mead of asphodel, the very beasts which he himself had slain on the lonely hills, with a strong mace all of bronze in his hand, that is ever unbroken ("Odyssey," xi. 572-75). His stellar connexion is treated as a fact apart. The poet does not appear to feel any need of bringing it into harmony with the Odyssean vision.

The brightest star in the heavens is termed by Homer the "dog of Orion." The name *Seirios* (significant of sparkling), makes its *début* in the verses of Hesiod. To the singer of the "Iliad" the dog-star is a sign of fear, its rising giving presage to "wretched mortals" of the intolerable, feverish blaze of late summer (*opora*). The deadly gleam of its rays hence served the more appropriately to exemplify the lustre of havoc-dealing weapons. Diomed, Hector, Achilles, "all furnish'd, all in arms," are compared in turn, by way of prelude to an "*aristeia*," or culminating epoch of distinction in battle, to the same brilliant but baleful object. Glimmering fitfully across clouds, it not inaptly typifies the evanescent light of the Trojan hero's fortunes, no less than the flashing of his armour, as he moves restlessly to and fro ("Iliad," xi. 62-6). Of Achilles it is said:—

"Him the old man Priam first beheld, as he sped across the plain, blazing as the star that cometh forth at harvest-time, and plain seen his rays shine forth amid the host of stars in the darkness of night, the star whose name men call Orion's Dog. Brightest of all is he, yet for an evil sign is he set, and bringeth much fever upon hapless men. Even so on Achilles' breast the bronze gleamed as he ran" (xxii. 25-32).

In the corresponding passage relating to Diomed (v. 4-7), the *naïve* literalness with which the "baths of Ocean" are thought of is conveyed by the hint that the star shone at rising with increased brilliancy through having newly washed in them.

Abnormal celestial appearances are scarcely noticed in the Homeric poems. There are neither eclipses[1] of sun or moon, nor comets, nor star-showers. The rain of blood, by which Zeus presaged and celebrated the death of Sarpedon ("Iliad," xvi. 459, also xi. 54) might be thought to embody a reminiscence of a crimson aurora, frequently, in early times, chronicled under that form; but the portent indicated is more probably an actual shower of rain tinged red by a microscopic alga. An unmistakable meteor, however, furnishes one of the glowing similes of the "Iliad." By its help the irresistible swiftness and unexpectedness of Athene's descent from Olympus to the Scamandrian plain are illustrated.

"Even as the son of Kronos the crooked counsellor sendeth a star, a portent for mariners or a wide host of men, bright shining, and therefrom are scattered sparks in multitude; even in such guise sped Pallas Athene to earth, and leapt into their midst" ("Iliad," iv. 75-9).

In the Homeric verses the Milky Way—the "path of souls" of prairie-roving Indians, the mediæval "way of pilgrimage"[2]—finds no place. Yet its conspicuousness, as seen across our misty air, gives an imperfect idea of the lustre with which it spans the translucent vault which drew the wondering gaze of the Ionian bard.

The point of most significance about Homer's scanty astronomical notions is that they were of home growth. They are precisely such as would arise among a people in an incipient stage of civilisation, simple, direct, and childlike in their mode of regarding natural phenomena, yet incapable of founding upon them any close or connected reasoning. Of Oriental mysticism there is not a vestige. No occult influences rain from the sky. Not so

[1] Continued from p. 588.

[1] Görlitz finds a prediction of a solar eclipse at "Odyssey," xx. 357; but the expression appears quite indefinite and figurative.

[2] To Compostella. The popular German name for the Milky Way is still *Jakobsstrasse*, while the three stars of Orion's belt are designated, in the same connexion, *Jakobsstab*, staff of St. James.

much as a square inch of foundation is laid for the astrological superstructure. It is true that Sirius is a "baleful star"; but it is in the sense of being a harbinger of hot weather. Possibly, or probably, it is regarded as a concomitant cause, no less than as a sign of the August droughts; indeed the *post hoc* and the *propter hoc* were, in those ages, not easily separable; the effect, however, in any case, was purely physical, and so unfit to become the starting-point of a superstition.

The Homeric names of the stars, too, betray common reminiscences rather than foreign intercourse. They are all either native, or naturalised on Greek soil. The transplanted fable of Orion has taken root and flourished there. The cosmopolitan Bear is known by her familiar Greek name. Boötes is a Greek husbandman, variously identified with Arkas, son of Callisto, or with Ikaros, the luckless mandatory of Dionysos. The Pleiades and the Hyades are intelligibly designated in Greek. The former word is usually derived from *plein*, to sail; the heliacal rising of the "tangled" stars in the middle of May having served, from the time of Hesiod, to mark the opening of the season safe for navigation, and their cosmical setting, at the end of October, its close. But this etymology was most likely an after-thought. Long before rules for navigating the Ægean came to be formulated, the "sailing-stars" must have been designated by name amongst the Achaian tribes. Besides, Homer is ignorant of any such association. Now in Arabic the Pleiades are called *Eth Thuraiyâ*, from *therwa*, copious, abundant. The meaning conveyed is that of many gathered into a small space; and it is quite similar to that of the Biblical *kîmah*, a near connexion of the Assyrian *kimtu*, family (R. Brown, "Phainomena of Aratus," p. 9; Delitzsch, "The Hebrew Language," p. 69). Analogy, then, almost irresistibly points to the interpretation of Pleiades by the Greek *pleîones*, many, or *pleîos*, full; giving to the term, in either case, the obvious signification of a "cluster."

Of the Hyades, similarly, the "rainy" association seems somewhat far-fetched. They rise and set respectively about four days later than the Pleiades; so that, as prognostics of the seasons, it would be difficult to draw a permanent distinction between the two groups; yet one was traditionally held to bring fair, the other foul weather. There can be little doubt that an etymological confusion lay at the bottom of this inconsistency. "To rain," in Greek is *huein*; but *hus* (cognate with "sow") means a "pig." Moreover, in old Latin, the Hyades were called *Suculæ* ("little pigs"); although the misapprehension which he supposed to be betrayed by the term was rebuked by Cicero (*De Nat. Deorum*, lib. ii. cap. 43). Possibly the misapprehension was the other way. It is quite likely that "Suculæ" preserved the original meaning of "Hyades," and that the pluvious derivation was invented at a later time, when the conception of the seven stars in the head of the Bull as a "litter of pigs" had come to appear incongruous and inelegant. It has, nevertheless, just that character of *naïveté* which stamps it as authentic. Witness the popular names of the sister-group—the widely-diffused "hen and chickens," Sancho Panza's "las siete cabrillas," met and discoursed with during his famous aërial voyage on the back of Clavileño, the Sicilian "seven dovelets,"—all designating the Pleiades. Still more to the purpose is the Anglo-Saxon "boar-throng," which, by a haphazard identification, has been translated as Orion, but which Grimm, on better grounds, suggests may really apply to the Hyades (*Teutonic Mythology*, trans. by J. S. Stallybrass, vol. ii. p. 729). It is scarcely credible that any other constellation can be indicated by a term so manifestly reproducing the "Suculæ" of Latin and Sabine husbandmen.

The Homeric scheme of the heavens, then, (such as it is), was produced at home. No stellar lore had as yet been imported from abroad. An original community of ideas is just traceable in the names of some of the stars; that is all. The epoch of instruction by more learned neighbours was still to come. The Signs of the Zodiac were certainly unknown to Homer, yet their shining array had been marshalled from the banks of the Euphrates at least 2000 years before the commencement of the Christian era. Their introduction into Greece is attributed to Cleostratus of Tenedos, near, or shortly after, the end of the sixth century B.C. By that time, too, acquaintance had been made with the "Phœnician" constellation of the Lesser Bear, and with the wanderings of the planets. Astronomical communications, in fact, began to pour into Hellas from Egypt, Babylonia, and Phœnicia about the seventh century B.C. Now, if there were any reasonable doubt that "blind Melesigenes" lived at a period anterior to this, it would be removed by the consideration of what he lets fall about the heavenly bodies. For, though he might have ignored formal astronomy, he could not have remained unconscious of such striking and popular facts as the identity of Hesperus and Phosphorus, the Sidonian pilots' direction of their course by the "Cynosure," or the mapping-out of the sun's path among the stars by a series of luminous figures of beasts and men.

Thus the hypothesis of a late origin for the "Iliad" and "Odyssey" is negatived by the astronomical ignorance betrayed in them. It has, however, gradations; whence some hints as to the relative age of the two epics may be derived. The differences between them in this respect are, it is true, small, and they both stand approximately on the same astronomical level with the poems of Hesiod. Yet an attentive study of what they have to tell us about the stars affords some grounds for placing the "Iliad" the "Odyssey," and the "Works and Days" in a descending series as to time.

In the first place, the division of the month into three periods of ten days each is unknown in the "Iliad," is barely hinted at in the "Odyssey," but is brought into detailed notice in the Hesiodic calendar. Further, the "turning-points of the sun" are unmentioned in the "Iliad," but serve in the "Odyssey," by their position on the horizon, to indicate direction; while the winter solstice figures as a well-marked epoch in the "Works and Days." Hesiod, moreover, designates the dog-star (not expressly mentioned in the "Odyssey") by a name of which the author of the "Iliad" was certainly ignorant. Besides which an additional constellation (Boötes) to those named in the "Iliad" appears in the "Odyssey" and the "Works and Days"; while the title "Hyperion," applied substantively to the sun in the "Odyssey," is used only adjectivally in the "Iliad." Finally, stellar mythology begins with Hesiod; Homer (whether the Ionian or the Ithacan) takes the names of the stars as he finds them, without seeking to connect them with any sublunary occurrences.

To be sure, differences of place and purpose might account for some of these discrepancies, yet their cumulative effect in fixing relative epochs is considerable; and, even apart from chronology, it is something to look towards the skies with the "most high poet," and to retrace, with the aid of our own better knowledge, the simple meanings their glorious aspect held for him.

A. M. CLERKE

ON ICE AND BRINES[1]

I.

THE composition of the ice produced in saline solutions, and more particularly in sea-water, has frequently been the object of investigation and of dispute. It might be thought that to a question of whether ice so formed does or does not contain salt, experiment would at once give a decisive answer. Yet, relying on experiment alone, competent authorities have given contradictory answers. All

[1] Paper read before the Royal Society of Edinburgh, by J. Y. Buchanan on March 27 last.

agree that ice, whether formed artificially in the laboratory by freezing sea-water, or found in nature as one of the various species of sea-water ice, retains, in one form or another, and with great tenacity, the salt existing in solution in the water. The question at issue is whether this salt is to be attributed to the solid matter of the ice or to the liquor mechanically adhering to it, from which it is impossible to free it. Most bodies, and especially those which take a crystalline form, are easily purified and freed from all suspected foreign matter, with a view to analysis, by the simple operation of washing and drying. It is impossible to wash the crystals, formed by freezing a saline solution, with distilled water, because they melt at a temperature below that at which distilled water freezes. The effect of the addition of a small quantity of distilled water to a quantity of saline ice is at first the anomalous one, that what was a wet sludge is transformed into a dry crystalline powder. It is of course impossible to dry the ice by heat, and to do so by more intense freezing would be begging the question. The experimental difficulties therefore account for some of the divergence of opinion on the subject. The mixed character of the substances examined has also much to do with it. As a rule it may be said that those investigators who have confined their observations to the laboratory have concluded that the ice forming when saline solutions of moderate concentration, including sea-water, are frozen, is pure ice, and the salt from which it is impossible to free it entirely belongs to the mother-liquor, while those who have collected and examined sea-water ice in high latitudes have come to the opposite conclusion.

During the Antarctic cruise of the *Challenger* I made a number of observations on the sea-water ice found in those regions, and relying principally on the fact that the melting temperature of the ice was markedly lower than that of fresh-water ice, and that it was impossible by any of the ordinary means familiar to chemists for freeing crystals from adhering mother-liquor to materially reduce its salinity, I came to the conclusion that the ice forming in freezing sea-water is not a mixture of pure ice and brine, but that it contains the salt found in it in the solid state either as a crystalline hydrate or as the anhydrous salt, but most probably as a hydrate. In dealing with this subject, Dr. Otto Pettersson ("Water and Ice," p. 302) quotes my observations, and also rejects the view that "sea-ice is in itself wholly destitute of salts, and only mechanically incloses a certain quantity of unfrozen and concentrated sea-water." He founds his belief on the fact that numerous analyses of specimens of sea-water ice have shown that the constitution of the saline contents of different specimens of ice differs for each specimen, and is always different from that of the saline contents of sea-water. Were the salinity due to inclosed unfrozen and concentrated sea-water, we "ought to find by chemical analysis exactly the same proportion between Cl, MgO, CaO, SO_3, &c., in the ice and in the brine as in the sea-water itself." He adduces numerous examples of analyses of specimens of sea-water ice from the Baltic and from the Arctic Seas to show that this is not the case. Calling the percentage of chlorine in each case 100, he found in various sea-waters the percentage of SO_3 vary from 11 49 to 11·89. In specimens of sea-water ice it varied from 12·8 to 76·6, and in brines separating from the ice and remaining liquid at − 30° C. it varied from 1·14 to 1·16.

This argument appears conclusive. In order to explain all the phenomena observed in connexion with sea-water ice he cites Guthrie's investigations, which went to show that, in freezing saline solutions, under a certain concentration, pure ice is formed at a temperature which falls from 0° C., when the amount of salt dissolved is infinitely small, to a certain definite temperature when the solution contains a certain definite percentage of salt. Further abstraction of heat then produces solidification of the solution as a whole, in the form of a crystalline hydrate, of constant freezing- and melting-point. To such hydrates, Guthrie gave the name of cryohydrates. Pettersson quotes the following as being particularly applicable to the case of sea-water:—

The cryohydrate of	Contains per cent. of water	Solidifies at °C.
NaCl	76·39	−22
KCl	80·00	−11·4
$CaCl_2$	72·00	−37·0
$MgSO_4$	78·14	− 5·0
Na_2SO_4	95·45	− 0·7

And he refers more particularly to the cryohydrate of Na_2SO_4 forming and melting at −0°·7.

Now the bearing of Guthrie's experiments is to show that, while at sufficiently low temperatures, and with suitable concentration, the water will solidify along with one or other of the salts in solution, until this low temperature and high concentration are attained, pure ice must be the result of freezing.

The abnormal phenomena attending the formation and the melting of ice in saline solutions and sea-water, find a natural explanation in an observation which I have frequently quoted, and which Dr. Pettersson mentions in a footnote at p. 318, namely, that "a thermometer immersed in a mixture of snow and sea-water which is constantly stirred indicates −1°·8 C." If this is true, it is clear that my melting-point observations proved nothing. On repeating the experiment I found it confirmed, and took the opportunity this winter of investigating the matter more closely. The paper read before the Royal Society of Edinburgh contains the first portion of the results. It deals with the subject under two heads, namely, (*a*) the temperature at which sea-water and some other saline solutions freeze, and the chemical constitution of the solid and the liquid into which they are split by freezing; and (*b*) the temperature at which pure ice melts in sea-water and in a number of saline solutions of different strengths.

(*a*) The freezing experiments were limited to sea-water and solutions of NaCl comparable with sea-water.

Chloride of Sodium.—Four solutions were used, and they were intended to contain 3, 2·5, 2, and 1·5 per cent. NaCl respectively. Forty grammes of this solution, in a suitable beaker, were immersed in a freezing mixture of such composition as to give a temperature from 2° to 2°·5 C. below the freezing temperature expected. The temperature at which ice began to form (if necessary after adding a minute splinter of ice) was noted, and the freezing was allowed to continue with constant stirring till the temperature had fallen 0°·2 C. A specimen of the mother-liquor was removed, and the chlorine in it determined; the chlorine in the original solution had been determined before. The beaker was then removed from the freezing bath and allowed to melt. The temperature in all cases rose during melting exactly as it had fallen during freezing. In the following table are given the means of the temperature at which ice began to form in the original solution, and that of the liquid when the sample of brine was taken, and the means of the chlorine found in the original solution and in the brine sample

Mean Freezing Temp.	−1°·875 C.	−1°·63	−1°·30	−0°·975
Mean per cent. Cl.	1·87	1·60	1·30	0·98

It will be seen that, in the dilute solutions experimented with, the percentage of chlorine expresses, in terms of the Centigrade scale, the lowering of the freezing-point of the solution.

Sea-Water.—Similar experiments were made with sea-water of different degrees of concentration. In sea-water from the Firth of Clyde containing 1·84 per cent. of chlorine, ice forms at $-1^\circ{\cdot}9$ C. The following results are from means of closely-agreeing results :—

Freezing temperature	$-2^\circ{\cdot}0$	$-1^\circ{\cdot}5$	$-1^\circ{\cdot}0$	$-0^\circ{\cdot}5$
Per cent. chlorine	1·94	1·445	0·963	0·475
Difference	0·06	0·055	0·037	0·025

Sea-water resembles a chloride of sodium solution, containing the same percentage of chlorine, and the resemblance is closer the greater the dilution. When the beaker was removed from the freezing-bath, the temperature rose during melting as it had fallen during freezing. In these experiments, which had for their object the determination of the temperature at which the crystals melted, as well as that at which they began to form in the water, it was impossible to remove a sample for analysis large enough to enable the sulphuric acid to be determined in it.

For this purpose a series of observations were made, using quantities of 300 grammes of sea-water. Freezing was continued usually until the temperature had fallen $0^\circ{\cdot}3$ C. below that at which crystals began to form. The mother-liquor was then separated from the crystals by means of a large pipette with fine orifice, before removing the beaker from the freezing bath. The magma of crystals was then brought rapidly on a filter and drained by means of the jet pump. The ice, thus drained, was then melted, and the three fractions were analysed. In the following table (I.) the results of four experiments are given. In the one column (W) will be found the weight of the original water taken and of the fractions into which it was split in freezing ; in the other (R) will be found the ratio of SO_3 to Cl found by analysis, the chlorine being set down as 100 ; thus, in I, the percentage of chlorine found in the crystals, melting at the lowest temperature, was 1·497, and that of the SO_3, 0·174 ; the ratio (R) is therefore 11·62.

TABLE I.—*Freezing sea-water—Analyses of fractions.*

No. of Experiment.	I.		II.		III.		IV.	
Nature of Water...	Forth 100 %.		Mother liquor		Clyde 100 %.		Clyde 50 %.	
	W.	R.	W.	R.	W.	R.	W.	R.
Original water	300	11·83	90	11·67	300	11·58	300	11·21
Mother-liquor	170·6 (Mother-liquor and Drainings)	11·67 (Mother-liquor and Drainings)	—	11·83	102	11·57	78	11·67
Drainings			—	—	94	11·56	109	—
Crystals	106	11·62	23	11·22	97	11·67	106	11·44
,, ...	22·5	11·11	—	—	—	—	—	—

It will be seen that the ratios (R) found for mother-liquor, drainings, and ice agree with one another quite as closely as those found in samples of pure sea-water from different localities. It is to be remembered that in these experiments the water was frozen *gently*, that is, the rate of abstraction of heat was low, the temperature of the freezing bath being regulated so as to be about 2° C. below the freezing temperature of the solution. Much of the error and uncertainty about the freezing of saline solutions arises from the violence of the methods employed. Judging then by the constancy of the relation of the percentage of Cl to SO_3 we see that in sea-water, frozen at moderate temperatures, the composition of the saline contents of the original water, the mother-liquor and the ice is identical ; and we are justified in concluding that it is probable that the saltness of the ice is due to unfrozen and concentrated sea-water adhering to it. Ice forming in even very weak saline solutions closely resembles snow (which is ice forming in air), and has the same remarkable power of retaining mechanically several times its weight of water or brine.

A strict account was kept of the heat removed from the sea-water while the freezing was going on. In Table II. will be found the number of heat-units (gramme ° C.) removed during the freezing in the case of Nos. III. and IV. ; and this number, divided by 79·25, gives the weight of pure ice, which could have been formed at 0° C. by the removal of heat.

TABLE II.—*Calculation of ice formed.*

		III.	IV.
Weight of original water (grammes)	W	300	300
Per cent. Cl in ditto	c	1·836	0·923
Per cent. Cl in mother-liquor	K	2·212	1·153
Weight of mother-liquor $W\frac{c}{K}=$	L	249·0	239·3
Weight of ice $W-L=$	I	51·0	60·7
Mean freezing temperature (° C)......................	...	$-2^\circ.05$	$-1^\circ{\cdot}05$
Heat abstracted (grammes ° C)	...	4230	5193
Equivalent ice formed (grammes)	...	53·4	65·5

Sea-water, like other saline solutions, is easily cooled several degrees below its freezing-point before crystals begin to form. While cooling down to and below what was known to be its freezing-point, simultaneous observations of the temperature of the sea-water and the freezing bath were made from half-minute to half-minute. From these observations, the rate of abstraction of heat for different differences of temperature of sea-water and bath was found. At a given moment a minute splinter of ice (weighing much less than a drop of water) was introduced. Crystals immediately began to form, and the temperature rose in from ten to fifteen seconds to the freezing-point. During the freezing the temperatures of bath and sea-water were observed at regular intervals. The heat removed is thus made up of that eliminated during the few seconds when freezing began and the temperature rose to the freezing-point, which is found by multiplying the rise of temperature by the weight of liquid, and that removed during the subsequent cooling, which is deduced from the duration of the operation and the rate of loss of heat observed before freezing commenced. The specific heat of the solution is taken as unity. In the table are further given the weight of the sea-water used, the percentage of chlorine in the original water and in the mother-liquor, the weight of the mother-liquor on the assumption that it contains all the salt of the original water, and, by difference, the weight of the ice formed. The agreement between the two quantities of ice formed as calculated by the different methods is as close as could be expected.

It has thus been shown that the composition of the saline contents of the ice formed as above described is the same as that of the original water, and this of itself is almost conclusive that the salt is contained in adhering brine and not as a solid constituent of the ice. Assuming that this is so the amount of ice formed as deduced from the composition of the mother-liquor agrees well with the amount deduced from the thermal exchange taking place during the freezing.

It has, moreover, been proved by Guthrie, Rüdorff, and others, that, in solutions of the salts occurring in sea-water, ice does separate out at first, and continues to separate out until the concentration has become many times greater than that of sea-water. Assuming that in sea-water all the chlorine is united to sodium, 87 per cent. of the water would have to be removed as ice before a cryohydrate would form, and if it contained nothing but sulphate of soda in the proportion corresponding to the sulphuric acid formed in it, over 90 per cent. of the water would have to go as ice, before the cryohydrate would be formed.

In my experiments, about 15 per cent. of the weight of the water was frozen out as ice, causing a lowering of freezing-point by $0^\circ{\cdot}3$ C. In nature it is probable that the ice forming at the actual freezing surface does so at an almost uniform temperature, the local concentration produced by the formation of a crystal of ice being immediately eliminated by the mass of water below. In the interstices of the crystals there will be retained a weight of slightly concentrated sea-water at least as great as that of the ice crystals. These retain the brine in a meshwork of cells, and, as the thickness of the ice covering increases, and the freezing surface becomes more remote, the ice and the brine become more and more exposed to the atmospheric rigours of the Arctic winter. The brine will continue to deposit ice until its concentration is such that, for example, the cryohydrate of NaCl is ready to separate out. It probably will separate out until it comes in conflict with, for instance, the chloride of calcium or the chloride of magnesium, which will retain some of the water, without solidifying, even at the lowest temperatures. At the winter quarters of the *Vega* brine was observed oozing out of sea-water ice and liquid at a temperature of − 30° C. It was very rich in calcium and especially magnesium chlorides. In fact, *it is probably quite impossible by any cold occurring in nature to solidify sea-water.*

The residual and unfreezable brine which remains in considerable quantity liquid when sea-water is frozen, must also remain in greater or less quantity when fresh water is frozen. All natural waters, including rain-water, contain some foreign and usually saline ingredients. If we take chloride of sodium as the type of such ingredients, and suppose a water to contain a quantity of this salt equivalent to one part by weight of chlorine in a million parts of water, then we should have a solution containing 0·0001 per cent. of chlorine, and it would begin to freeze and to deposit pure ice at a temperature of − 0°·0001 C.; and it would continue to do so until, say, 999,000 parts of water had been deposited as ice. There would then remain 1000 parts of residual water, which would retain the salt, and would contain, therefore, 0·1 per cent. of chlorine, and would not freeze until the temperature had fallen to − 0°·1 C. This water would then deposit ice at temperatures becoming progressively lower, until, when 900 more parts of ice had been deposited, we should have 100 parts residual water, or brine as it might now be called, containing 1 per cent. of chlorine, and remaining liquid at temperatures above − 1°·0 C. When 90 more parts of ice had been deposited, we should have 10 parts of concentrated brine containing 10 per cent. of chlorine and remaining liquid at − 10° C. In the case imagined, we assume the saline contents to consist of NaCl only, and with further concentration the cryohydrate would no doubt separate out and the mass become really solid. On reversing the operations, that is, warming the ice just formed, we should, when the temperature had risen to − 10° C., have 999,990 parts ice and 10 brine containing 10 per cent. chlorine. Now, owing to the remarkable fact (which is dealt with at length in the second part of the paper) that pure ice, in contact with a saline solution, melts at a temperature which depends on the nature and the amount of the salt in the solution, and is identical with the temperature at which ice separates from a solution of the same composition on cooling, the brine liquefies more and more ice at progressively rising temperatures, until, as before, when the temperature of the mass has risen to − 0°·1 C., it consists of 999,000 parts of ice and 1000 parts of liquid water, containing 1 part of chlorine. The remainder of the ice will melt at a temperature gradually rising from − 0°·1 C. to 0° C.

The consideration of this example furnishes an easy explanation of the anomalous behaviour of ice, formed from anything but the very purest distilled water, in the neighbourhood of its melting-point. This subject has been studied with great care and thoroughness by Pettersson. The apparent expansion of all but the very purest ice, when cooled below 0° C., is ascribed by him in part to solid saline contents of the ice which exercise a disturbing and unexplained influence on its physical properties. Viewed in the light of the fact that the presence of even the smallest quantity of saline matter in solution prevents the formation of ice at 0° C. and promotes its liquefaction at temperatures below 0° C., we see that this apparent expansion of the ice on cooling is probably due to the fact that we are dealing not with homogeneous solid ice but with a mixture of ice and saline solution. As the temperature falls this solution deposits more and more ice and its volume increases. But the increase of volume is due to the formation of ice out of water and not to the expansion of a crystalline solid already formed.

In Table III. are given the volumes occupied by the ice (with inclosed brine) formed by freezing 100,000 c.c. (at 0° C.) of a water containing chloride of sodium equivalent to 7 grammes chlorine in 1,000,000 cubic centimetres (at 0° C.).

TABLE III.—*Water containing 7 parts Cl in 1,000,000.*

Temp. ° C.	Water frozen. c.c.	Ice formed. c.c.	Brine remaining. c.c.	Ice and Brine. c.c.	Pettersson III. Vol. of ice at *T*. c.c.	Diff.
T	V_1	v_1	V_2	v_2	P	$P - v_2$
− 0·07	99000	107979	1000	108979	108980	1
− 0·10	99300	108306	700	109006	109007	1
− 0·15	99533	108561	467	109028	109038	10
− 0·20	99650	108687	350	109037	109048	11
− 0·40	99825	108879	175	109054	109057	3

The volume of the ice formed on freezing this water is compared with that observed by Pettersson in freezing a sample of the distilled water in ordinary use in the laboratory.

It will be seen that the volumes observed by Pettersson agree very closely with those calculated for a water containing 7 parts of chlorine in a million.

The irregularities in the melting-points of bodies like acetic acid, to which Pettersson refers, are without doubt due to a perfectly similar cause.

Also the very low latent heat observed by Pettersson for sea-water is to be explained by the fact that the salt retains a considerable proportion of the water in the liquid state even at temperatures many degrees below the freezing-point of distilled water.

The *plasticity* of ice and the motion of glaciers receive a simple and natural explanation when we see, as in Table III., that, if the water from which this ice is produced contains no more than 7 parts of chlorine per million, it will, in the process of thawing, when the temperature has risen to − 0°·07 C., consist to the extent of 1 per cent of its mass of liquid brine or water. The water considered in Table III. is certainly not less free from foreign ingredients than rain or snow. It follows, therefore, that a glacier, in a climate where the temperature is for the greater part of the year above 0° C., must have a tendency to *flow*, owing to the power of saline solutions to deposit ice and to dissolve it at temperatures below 0° C.

(*To be continued.*)

NOTES

THE Endowed Schools Committee, of which Sir Lyon Playfair is Chairman, after sitting for a year and a half, have agreed to their Report. This is not yet issued, but it is known that the Committee have reported in favour of endowed schools being in future largely used for the promotion of scientific and technical education. The Report also recommends that local authorities should be authorised to employ local rates for founding or contributing to laboratories and workshops in such schools in order to promote practical scientific education.

LAST week an important Conference was held at Oxford for the consideration of questions connected with the University Extension Scheme. The meetings were attended by many members of the University, local delegates, and others interested in this method of University development. There can be no doubt whatever as to the good work done by University Extension lecturers. Unfortunately, however, it is hard to obtain the funds which are necessary for the complete success of the experiment. One speaker urged that "the University should lead the way by the creation of a Jubilee Fund, and so stimulate local efforts." To this Prof. Rogers replied that the University was "positively poor." Prof. Rogers added that the result of an appeal to London Companies "had not been favourable," but that the Charity Commissioners might perhaps be willing to do something for the movement.

THE American Exhibition to be opened in the Earl's Court neighbourhood on May 9 will contain much that ought to be of scientific interest. The large encampment of American Indians will be found to contain a great variety of types, and ought to prove attractive to ethnologists. The machinery department will contain many illustrations of the successful applications of science, especially in the section directed to machines for the production and application of electricity. Under mining and metallurgy there will be a large collection of minerals, ores, and stones, besides specimens of metallurgical products. In the department of education and science will be found illustrations of the varied educational appliances and apparatus used in the United States, exhibits from the many institutions and organisations which exist in the States, and a very varied collection of scientific and philosophical instruments.

A NEW scientific journal—*Centralblatt für Physiologie*—has made its appearance this month in Germany. It is edited by Dr. S. Exner, of Vienna, and Dr. J. Gad, of Berlin, who have the advantage of the co-operation of the Berlin Physiological Society. The journal will be issued once a fortnight.

A MONUMENT to Galileo has been erected in Rome, on the Via Pincio, fronting the old Medici Palace, now occupied by the French Embassy, where he was kept a prisoner, in 1637, during his prosecution by the Inquisition. The monument consists of a column with a pedestal, on which is the following inscription in the Italian language:—"Erected in memory of Galileo Galilei, who was kept a prisoner in this Palace, for having seen that the earth moves round the sun."

DR. R. MÜLLER publishes, in the April number of *Mittheilungen aus dem Gebiete des Seewesens*, the results of an investigation as to whether or not the popular idea of equinoctial gales, the existence of which was contested some time ago as regards this country by Mr. Scott (NATURE, vol. xxx. p. 353), holds good for the Adriatic Sea. For this purpose the hourly records of the anemometer at Pola, from 1876–86, were used. During this period strong winds or gales were registered on 607 days, 63 per cent. of which occurred in the winter season (October to March). The months with least wind were naturally June and July; then a tolerably regular increase in the number of days with stormy winds took place till the end of January. A considerable decrease occurred in Febuary, while March had the greatest number of stormy days. The result arrived at is that, for the Adriatic, no important influence can be attributed to the equinoctial seasons, especially during the autumnal equinox. Dr. Müller also quotes a similar investigation made by the *Deutsche Seewarte*, for the years 1878–83, for the German coasts, with nearly similar results; the percentage of storms for the winter season being 80 per cent., and for the summer season only 20 per cent. The greatest number of storms occurred in November and December, March having 14 per cent., and September 3 per cent. only.

AT a recent meeting of the Italian Meteorological Society, reported in its *Bollettino mensuale* for February last, the Committee enumerated the meteorological stations lately established by it abroad, viz. one in Tripoli, two in the Argentine Republic, three in Uruguay, one in Colombia (South America), and one in Mexico, and notified their intention of shortly establishing others on the Patagonian coasts of the Pacific, and in some of the islands near Cape Horn. Among other matters discussed was the proposed suppression of the *Bollettino decadico*—which has reached its fourteenth yearly volume, and which contains the observations made at ordinary stations, and at stations in the Alps and Apennines, for decades—as the increasing work of the Society renders its publication difficult. The monthly means of these observations appear in the *Bollettino mensuale*, but the last published are for March 1886.

ON the night of April 12, at about 11.30, a brilliant meteor was seen in Værdalen, in Norway. It appeared in the east, and went in a southerly direction. At first the colour was a pure white, but during the progress of the meteor it changed into green and yellow. The lustre of the body was very bright, and its greatest apparent size was about that of an ordinary plate. On the meteor disappearing from view behind a mountain ridge, a sudden brilliancy seemed to indicate that it had burst into fragments, but no detonation was heard. It left a faint trail of smoke behind, about a few yards in length, which remained for a few seconds in the sky, then disappeared.

ON April 13 a shock of earthquake was felt at Lisbon, and in Malta and Sicily. Considerable alarm was caused in Jersey at a few minutes past 3 o'clock on the morning of April 21 by a slight shock of earthquake, the direction of which was from south-west to north-west. There was so loud a noise that at first some persons fancied guns were being fired. About the same time a smart shock of earthquake was experienced in Guernsey. A decided tremor of the earth, lasting about three seconds, and accompanied by a rumbling noise, was felt in all parts of the island.

THE death is announced of Dr. Nathaniel Lieberkühn, Professor of Anatomy at the University of Marburg, on April 14, at the age of sixty-five; and of Herr J. B. Obernetter, well known by his researches in photographic chemistry, on April 13, at the age of forty-seven.

A NEW GUINEA Exhibition will shortly be opened at Bremen.

MESSRS. R. FRIEDLÄNDER AND SON, of Berlin, send us the first quarterly list for 1887 of their new publications. It includes many valuable works in natural history and the exact sciences.

THE scheme for the formation of a North Sea Fisheries Institute is still under the consideration of the National Fish-Culture Association and of various local authorities, by whom efforts are being made to secure the necessary funds. It is proposed to form a Fish-Culture Station at Cleethorpes, and schools at Grimsby, and to carry out scientific observations wherever the conditions seem to be most favourable. Particular attention is to be given to the culture of the oyster and cod. A meeting has lately been held in London to advance the undertaking, and another is to take place shortly at Grimsby for the same purpose.

THE list of elements whose atomic weights have been determined with great accuracy has just received two valuable additions, for although one of them, silicon, is by no means rare in its occurrence in nature, and the other, gold, is neither among the most recently discovered of metals nor rare from the chemist's point of view, yet past determinations of the atomic weights of these important elements have resulted in leaving the subject enshrouded with considerable ambiguity. Prof. Thorpe and Mr. J. W. Young, who have recently determined the atomic weight of silicon, used for this purpose the tetrabromide $SiBr_4$.

and, instead of the small quantities of material used by other experimenters, prepared upwards of half a kilogramme of this substance by passing bromine vapour over a heated mixture of pure silicon dioxide and charcoal. The product was rectified in an atmosphere of nitrogen, and portions for analysis were collected in bulbs without exposure to air; these bulbs were then broken in bottles containing pure water, and in each case the resulting turbid liquid was very slowly evaporated to complete dryness, the relation of the weight of silicon dioxide obtained to that of the tetrabromide used forming the basis of the calculations. The result of this long and difficult series of analyses fixes the atomic weight of silicon as 28·332. The instability of the salts of gold has long been a stumbling-block in the way of obtaining accurate determinations of its atomic weight, but Prof. Thorpe and Mr. A. P. Laurie have overcome this difficulty by utilising the double bromide of gold and potassium, which they prepared by digesting together pure gold, bromine, potassium bromide, and water, the salt being afterwards subjected to several recrystallisations. An unknown quantity of the pure salt was then carefully ignited, and the mixture thus obtained, of potassium bromide and gold, weighed; after removal of the potassium bromide by washing, the weight of residual gold obtained in each analysis furnished data from which one set of values averaging 196·876 was obtained. The bromine in the potassium bromide as determined by titration with silver nitrate gave a second averaging 196·837, and the weight of silver bromide formed yielded a third series of numbers, averaging 196·842. Taking Stas's value for oxygen at 15·96 the atomic weight of gold is fixed by these analyses at 196·85; but if, along with Mendelejeff, we consider oxygen 16, then gold becomes 197·28, and it is interesting to note that Mendelejeff considered the old value, 196·2, to be too low, there being no place in the periodic system for an element of this atomic weight having the properties of gold. Hence the result of the present determination has been to place gold in its proper position in the periodic classification. Prof. Krüss has just published (*Ber. Deut. Chem. Ges.* No. 2, 1887) the results of a determination of the atomic weight of gold recently made by him, according to which the probable value is 196·64. The method employed, however, was slightly different from the above, a weighed quantity of the double bromide itself being used as the basis of a portion of the analyses.

IN a paper on Electric Locomotion, read before the Society of Arts on the 20th inst., Mr. Reckenzaun pointed out that in the United States and on the European continent there are dozens of electric tramways at work to the satisfaction of everybody, while we have few opportunities of testing their advantages in England. Yet England is "the home of the dynamo-machine, the country where the electromotor has found its highest development." We have been outstripped in this matter chiefly because an Act of Parliament must be obtained before electric cars can be run, and every company has to apply for it separately.

THE other day M. Émile Rivière discovered a prehistoric station in the wood of Chaville, to the right of the Versailles road, in a part where there are comparatively few trees. Some flint implements and weapons were found, and a fragment of coarse pottery without ornament.

AT the February meeting of the Pekin Oriental Society, Mr. Owen read a paper on animal worship amongst the Chinese. He referred at considerable length to the worship paid to the fox, weasel, hedgehog, and snake, to which at Tientsin is added the rat. The first four are called the immortals. These deified animals seem to usurp the entire attention of the people, even to the exclusion of the Buddhist and Taoist gods. Dr. Edkins quoted from the Chinese to prove that animal worship was unknown in ancient times, while Dr. Dudgeon pointed out that it was a mistake to suppose that animal worship was confined to the four animals mentioned. The horse, cow, dog, insects, dragon, lion, &c., are worshipped. In the fifth month the centipede, lizard, scorpion, frog, and snake—the five poisonous animals, as they are called—are also objects of worship. Dr. Martin disputed Dr. Edkin's theory that animal worship was unknown in ancient times because it was not mentioned by Confucius; he (Dr. Martin) believed that it existed to a much greater extent in ancient than in modern times. From the observations of other speakers it is clear that animal worship occupies a very large place in Chinese superstitious observances.

THERE was an interesting Geographical Exhibition in connexion with the meeting of the Deutsche Geographentag at Carlsruhe on the 13th inst. An historical department showed the development of cartography, all the exhibits being from Baden and Würtemberg. Water-colour sketches by the well-known African traveller Paul Reichard, and some fine oil sketches by the painter Hellgreve, who was sent to East Africa by the Artists' Club at Berlin, were exhibited. In the plant department were shown cotton plants found growing wild in Togoland, wild coffee and sugar-cane from Cameroons, and tobacco and various seeds from the gardens of the German East African Society.

AN interesting case of "colour-hearing" was recently reported to a meeting of the Société de Psychologie Physiologique. In this case, colour-hearing was an hereditary peculiarity, transmitted from father to daughter.

THE third volume of the "Grande Encyclopédie" has just been published. It is expected that thirty volumes will probably be required to complete this great work. Each volume consists of 1200 quarto pages in two columns, printed in small type.

EVERYONE who takes an interest in zoology is probably acquainted with the "Zoological Record," which consists of an annual volume containing a summary of the work done in the various branches of zoology. It was begun in 1865, and for the first six years was published by Mr. Van Voorst. For the last sixteen years it has been carried on by an Association of zoologists called the "Zoological Record" Association, who have received assistance in the shape of grants from the Government Fund of the Royal Society, the British Association, and the Zoological Society of London. The "Zoological Record" Association, having been lately unsuccessful in obtaining the continuance of some of these grants, and being unwilling to carry on the publication of the "Record" any longer, have agreed, upon certain conditions, to transfer their whole stock to the Zoological Society of London, who, for the future, have determined to carry on this most useful publication. The "Zoological Record" will, therefore, beginning with the volume for the present year (which will contain the record of the zoological literature of 1886), be published by the Zoological Society of London, under the management of a Committee of the Council of that Society, and will be edited by Mr. F. E. Beddard, the Society's Prosector. The "Record" will be published for the Society by Messrs. Gurney and Jackson at the former price of 30*s.* per volume. But all members of the Society will have the privilege of receiving it, including the cost of delivery, at a subscription price of 20*s.* per annum. This subscription will be due on July 1 in every year, and the privilege of subscription will be forfeited unless the amount be paid before December 1 following. The Zoological Society, having purchased the entire stock of the "Zoological Record," are now able to supply complete sets of the first twenty-two volumes at the price of 5*l.* 10*s.*, that is 5*s.* per volume. Volumes of any single year can likewise be supplied at 10*s.* per volume. Learned Societies and Institutions and members of the former "Zoological Record" Association will be permitted to subscribe to the "Record" on the same conditions as are accorded to members of the Zoological Society.

It is intended to form a class, including beginners and advanced students, this summer, in the same way as last year, for the study of geology near London, to be conducted on Saturday afternoons, by Prof. H. G. Seeley, F.R.S., King's College. Applications for tickets should be made at once to the Hon. Secretary, W. W. R. May, 16 Bethune Road, Manor Road, Stoke Newington, N.

The additions to the Zoological Society's Gardens during the past week include two Rhesus Monkeys (*Macacus rhesus* ♂ ♀) from India, presented by Mr. W. F. Lock; a Common Fox (*Canis vulpes* ♂) British, presented by Mr. Isaac Bell, Jun.; a Bosch-bok (*Tragelaphus sylvaticus* ♂) from South Africa, presented by Capt. Travers; a Vulpine Phalanger (*Phalangista vulpina* ♂) from Australia, presented; two Turkey Vultures (*Cathartes aura*) from the Falkland Islands, presented by Mr. James H. Moore; a Common Viper (*Vipera berus*), British, presented by Mr. S. E. Gunn; a Chinese Lark (*Melanocorypha mongolica*) from China; two Common Rheas (*Rhea americana* ♂ ♀) from the Argentine Republic, received in exchange; a Burrhel Wild Sheep (*Ovis burrhel*); two White-backed Pigeons (*Columba leuconota*) from the Himalayas; a Hodgson's Partridge (*Perdix hodgsoniæ*) from Bootan, purchased; four Long-fronted Gerbilles (*Gerbillus longifrons*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

Barnard's First and Second Comets 1887.—Comet *c* 1887, discovered by Mr. Barnard on January 23, has now attained a high declination, and, though faint, may possibly be observed within the next few days. Dr. H. Kreutz gives the following ephemeris for it for Berlin midnight, derived from Dr. H. Oppenheim's elements:—

1887	R.A. h. m. s.	Decl. ° ′	log Δ	log r
April 27	1 12 46	65 40·4	0·4742	0·3989
29	1 21 49	65 52·7		
May 1	1 30 47	66 3·8	0·4827	0·4057
3	1 39 38	66 13·7		
5	1 48 22	66 22·5	0·4910	0·4125

Correction of ephemeris for April 15; in R.A. + 3m. 46s.; in Decl. *nil*.

The second comet discovered by Mr. Barnard, viz. Comet *d* 1887, discovered February 16, is scarcely likely to be seen further. Its present brightness is but one-seventh of that which it had on March 11, and having almost exactly the same R.A. as the sun it scarcely frees itself from the twilight. An ephemeris for its course throughout the month of April, based on Dr. Palisa's elements, was given by Dr. Kreutz in the *Astronomische Nachrichten*, No. 2777, and in the *Observatory* for April; but the probability of its being observed after the April full moon had passed away, except with very powerful instruments, was very slight.

Probable Re-discovery of Hesperia.—Dr. R. Luther detected a minor planet on April 11 which it appears probable is no other than the lost Hesperia, No. 69, as the magnitude and motion resembled those of the missing asteroid. Dr. Luther had previously looked for the planet in vain in 1882, 1885, and in March of the present year.

The Ellipticity of Uranus.—Prof. W. Valentiner, of the Karlsruhe Observatory, writing in the *Astronomische Nachrichten*, No. 2781, states that Herr von Rebeur, observing Uranus with the 6-inch refractor of the Observatory on the evening of April 3, noticed that the disk appeared distinctly elliptical. On the following evening Prof. Valentiner himself observed the planet, and found that the direction as estimated of the major axis of the disk, the ellipticity of which was unmistakable, agreed closely with that of the assumed equatorial diameter as read off from the position-circle of the micrometer. Prof. Valentiner brings the subject forward now in the hope that those astronomers who have the command of powerful telescopes may be induced to give some attention to it.

The Washington Observatory.—It appears from *Science*, vol. ix. No. 218, that the statement (reported in last week's Nature, p. 595) that the sum of 400,000 dollars had been appropriated by Congress for the erection of a new Naval Observatory near Washington is erroneous. The amount actually available is but 100,000 dollars, with the understanding that the entire cost of the work shall not exceed 400,000 dollars.

The Paris Conference.—The same number of *Science* states that Ensign Winterhalter, of the United States Naval Observatory, had sailed for Paris, to represent the Observatory at the Photographic Conference. It is understood that Dr. Peters, of Clinton, and Mr. Rutherfurd, of New York, will also attend the Conference.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 MAY 1–7

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 1

Sun rises, 4h. 34m.; souths, 11h. 57m. 0·2s.; sets, 19h. 20m.; decl. on meridian, 15° 4′ N.: Sidereal Time at Sunset, 9h. 58m.

Moon (Full on May 7) rises, 11h. 27m.; souths, 18h. 59m.; sets, 2h. 19m.*; decl. on meridian, 14° 0′ N.

GEOGRAPHICAL NOTES

WE are glad to know that General R. Strachey, R.E., F.R.S., has agreed to accept the presidency of the Royal Geographical Society, in succession to Lord Aberdare. The Society's honours for the present year will be conferred as follows:—The Founder's Medal to Lieut.-Colonel T. H. Holdich, R.E., for the eminent services he has rendered to geography in Afghanistan; the Patron's Medal to the Rev. George Grenfell, for the extensive explorations he has carried out during his thirteen years' residence in Africa, partly in the Cameroons country and more recently in the Congo region; the Murchison Grant to Mr. George Bourne, second in command and sole survivor of the Landsborough Expedition, which crossed the continent of Australia in 1861; the Back Premium to Sarat Chandra Das, for his researches in Tibet; the Gill Memorial to Mr. J. F. Needham, for his explorations in the Lohit Valley of the Brahmaputra. The following have been made Honorary Corresponding Members:—H.R.H. Krom Mun Damrong Rajah Nubharp, Director-General of Surveys and Minister of Public Instruction, Siam; Dr. Alfred Kirchhoff, Professor of Geography at Hallé University, and President of the Hallé Geographical Society; and Dr. E. Naumann, late Director of the Geographical and Topographical Survey of Japan.

THE paper read at the Royal Geographical Society on Monday was by General J. T. Walker, F.R.S., on the Lu River of Tibet, the Lu-Kiang, or Lu-tse-Kiang of the Chinese. This river is generally held to be the source of the Salwin, but General Walker adduced many reasons for maintaining that it is more probably that of the Irrawadi. In the course of an able paper, the result of much research, General Walker gave a most useful summary of exploration in this highly interesting hydrographical region; more particularly insisting on the value of the work of the late Abbé Krick, who ascended the Lohit in 1852, but of whom little is known in this country. General Walker made out a strong case for his position, but the leading conclusion of his valuable paper is that further exploration in this remarkable region is urgently demanded. Probably no region of the earth would yield more valuable results to scientific geography.

ACCORDING to the latest news, Mr. Stanley is well up to time in his ascent of the Congo with the Emin Pasha Expedition. He is at present on his march across country from Matadi, at the lower end of the Livingstone Falls, to Leopoldville, on Stanley Pool. It is hoped that when he reaches the Pool he will find sufficient vessels in readiness to convey his large following up the river without delay. So far the Expedition has been exceedingly fortunate.

THE statement that Baron Nordenskjöld will undertake an Antarctic expedition at the expense of the King of Sweden and Mr. Oscar Dickson is, to say the least, premature. We are informed by Mr. Dickson that Baron Nordenskjöld is "willing" to undertake such an expedition, but that if he does so neither the King of Sweden nor Mr. Dickson will find the money. No doubt Baron Nordenskjöld would be an excellent leader for such an expedition, and as Committees have been formed both in this country and in Australia to promote Antarctic exploration, would it not be wise in them to unite their forces, and place themselves in communication with the Baron? Those who are competent to give an opinion on the subject maintain that an Antarctic expedition is much less risky than one to the other Pole. There would be no difficulty in a party wintering on some part of the Antarctic continent; a vessel could cruise round the verge of the ice during the winter and watch a favourable opening, of which immediate notice could be given to the exploring party, while a third vessel could leave New Zealand at a suitable time with additional supplies. No doubt the subject will again be brought up at the next meeting of the British Association, when it is hoped a strong and active Committee will be appointed. Baron Nordenskjöld will be among the distinguished foreigners invited to the meeting, and we hope he will accept the invitation.

THE Germans continue to show great activity in the exploration of their portion of New Guinea. Freiherr von Schleinitz has recently accomplished a running survey of Huon Gulf, and besides establishing the direction of the coast-line and the positions of reefs, has laid down eight hitherto unknown harbours and discovered nine new rivers. Some of them, especially the Markham River, would form excellent routes for the exploration of the interior; the broad valley of the latter extends for miles between high ranges of mountains. The south coast of Huon Gulf consists exclusively of primitive and metamorphic rocks, with older sedimentary rocks and volcanic formations. At a later date a further survey was made of the coast from Astrolabe Bay to the mouth of the Empress Augusta River, and led to the discovery of a series of bays, harbours, islands, and rivers.

M. GRIMAILO, in company with his brother, an engineer, and six Cossacks, has set out for a further exploration of the Pamir.

DR. LABONNE left Cherbourg a few days ago for a further exploration of the geysers and glaciers of Iceland.

PRELIMINARY NOTE ON THE FOSSIL REMAINS OF A CHELONIAN REPTILE, CERATOCHELYS STHENURUS, *FROM LORD HOWE'S ISLAND, AUSTRALIA*[1]

THE interesting remains of which I propose to give a brief notice in the present communication are contained in a friable sandstone (apparently formed of concreted blown sand), and they have a very recent appearance. The age of the deposit in which they are found is unknown, but it is probably Quaternary. The specimens have been for some years in the palæontological collection of the British Museum, and, for the most part, they have not yet been submitted to careful examination. But I learn that the greater number of them were long since rightly determined to be Chelonian by Mr. Davis, and set aside as such.

Several of the most important of these numerous and, in general, very fragmentary bones were originally found imbedded close together in the same block of sandstone. They consist of a great part of a pelvis, a caudal vertebra, and an imperfect skull. Of the pelvis, a right ischium and a pubis are imbedded in the rock, while an imperfect right ilium, which fits well on to the ischium, is separate; all these bones are unmistakably Chelonian. The caudal vertebra has remarkable peculiarities. It resembles an ordinary Chelonian caudal vertebra from the anterior half of the tail, in its general characters; but it is strongly opisthocœlous, the centrum having a deep cup behind and a correspondingly curved articular head in front. From the posterior part of the ventral face two stout processes diverge, and present terminal rounded facets for the rami of the large chevron bone which must have articulated with them. As a general rule, the caudal vertebræ of Chelonia are procœlous—but *Chelydra* and *Gypochelys* (perhaps also *Staurotypus* and *Platysternum*) form well-known exceptions,[2] in so far as the vertebræ behin the third and fourth are strongly opisthocœlous. In fact, the vertebra in question closely resembles the sixth or seventh of *Chelydra* or of *Gypochelys* (see Figs. 1 and 2). In the first, however, the transverse processes are very much stronger, and the pentagonal platform into which the upper surface of the neural arch expands, in place of a neural spine, is as long as the vertebra, instead of being only about half as long. The stout pre-zygapophysis of the right side is broken off, leaving only the base visible in the fossil.

[1] Paper read at the Royal Society, by Prof. Thomas H. Huxley, F.R.S., on March 31.

[2] The opisthocœlous character of most of the caudal vertebræ of *Chelydra* was first pointed out by Von Meyer in his description of the Œningen *Chelydræ*. Baur ("Osteologische Notizen," *Zool. Anzeiger*, No. 238, 1886) has gone fully into the question, and has pointed out the exceptional nature of their structure among the Chelonia. Since the above paragraph was written, Dr. Günther has kindly enabled me to examine a spirit specimen and a skeleton of *Platysternum*. The caudral vertebræ resemble those of *Chelydra*, except that the last nine are procœlous, while that between these and the more anterior opisthocœlous vertebræ is nearly flat at the ends. In this, as in other respects, *Platysternum* presents characters intermediate between *Chelydra* and the ordinary *Emydæ*. Prof. Cope ("Vertebrata of the Tertiary Formations of the West," 1883, p. 111) ascribes opisthocœlous caudal verebræ to the *Bænidæ*, but no figures or descriptions of such vertebræ are given. Of the opisthocœlous Chelonian vertebræ figured in Plate XXIV. of the "Report of Extinct Vertebrata obtained in New Mexico" (1887), it is expressly stated that their "correct reference cannot now be made" (p. 43).

Two other caudal vertebræ, having the same structural features, occur among the detached remains, and belong, like the first, to the second fourth of the tail. Another tolerably complete vertebra, with a considerably longer centrum, corresponds very closely with a caudal vertebra of *Gypochelys* from the third fourth of the tail. In this, as in one of the foregoing vertebræ, the chevron bones are anchylosed with the centrum. I conceive, then, that there can be no doubt that the pelvic bones and these caudal vertebræ belonged to a Chelydroid Chelonian, of about the size of the largest "snapping turtles" which are met with in North America at the present day.

Primâ facie, the skull found in the same block might also be expected to be that of a Chelydroid; and, in fact, it is so. I do not base this interpretation on the Chelonian character of the upper jaw, as there are various extinct Saurian reptiles which closely approximate to Chelonia in this part of their structure. The diagnostic characters lie in the back part of the skull; and especially in the auditory region, which is altogether Chelonian. Not only so, but when this fragmentary skull is compared with that of *Chelydra*, the correspondence between the two is singularly exact (Figs. 3 and 4). In two respects, however, the fossil differs from *Chelydra* and *Gypochelys*.

(1) The roof over the temporal fossa formed by the parietal, post-frontal, and other bones, which leaves the auditory region uncovered in the recent genera,[1] extends back, beyond the occiput, in the fossil, and sends down a broad vertical rim from its margin.

(2) The upper surface of the cranial shield is, at most, rugose

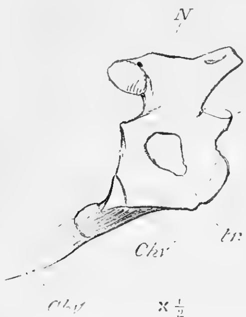

FIG. 1.—Caudal vertebra of *Ceratochelys*. *N*, platform on the neural arch; *pz*, pre zygapophysis mutilated; *tr*, broken transverse process; *Chv'*, processes for the chevron bone; *Chv*, chevron bone.

FIG. 3.

FIG. 2.—Caudal vertebra of *Chelydra*. Letters as in Fig. 1.

FIG. 4.

FIGS. 3, 4.—Skulls of *Ceratochelys* (Fig. 3) and *Chelydra* (Fig. 4); the latter of the natural size, the former much reduced. The portion of the skull of *Chelydra* which corresponds with the fossil is shaded.

in the recent *Chelydridæ*; in the fossil, three strong conical processes, like horn-cores, of which the middle is the longest, are developed from its posterior and lateral region.[1]

This skull is described and figured in the Philosophical Transactions for 1886 (Plate 30, Fig. 1) by Sir R. Owen, under the generic or sub-generic name of *Meiolania*, and is said to belong to a Saurian reptile closely allied to the "*Megalania prisca*" described in earlier communications. But the skull is assuredly that of the Chelydroid Chelonian to which the pelvis and caudal vertebra belong. What *Megalania prisca* may be I do not pretend to say; but the remains which I have described can have nothing to do with any Saurian reptiles; and I propose to confer on the genus of Chelonia to which they belong the name of *Ceratochelys*.

The singular osseous caudal sheaths described by Sir R. Owen, in the same memoir, also appertain to *Ceratochelys*. They formed part of the series of remains sent to the British Museum along with the foregoing, in which none but Chelonian bones have yet been discovered; and the remains of vertebræ left in these sheaths are similar to the caudal vertebræ of the terminal fourth of the tail in the *Chelydridæ*. The snapping turtles are noted for the length and strength of the tail and for the strong, laterally-compressed, acuminated "scales" which form a crest along the median dorsal line, while others, less strongly keeled, lie at the sides of the tail. In many Chelonia, the extremity of

[1] It is possible that these may be dermal bones coherent with the proper cranial shield.

[1] The "roof" extends much further back in *Platysternum*.

the tail is enveloped in a continuous sheath. These and other scale-like structures in the Chelonia are usually spoken of as if they were entirely epidermal. But, a day or two ago, Dr. Günther informed me that in the Australian tortoise, *Manouria*, the great imbricated scales of the limbs contain bony scutes; and that similar scutes are to be found in *Testudo græca*. This, of course, suggested the examination of the caudal scales of *Chelydra* and *Gypochelys*; and, having been enabled by Dr. Günther's kindness to examine the caudal scales of a good-sized specimen of the latter, I have found that those of the crest contain bony scutes.[1] The bony scute corresponds very closely in form with the whole "scale," but the recurved apex of the latter is formed only by epidermal substance (Figs. 5 and 6).

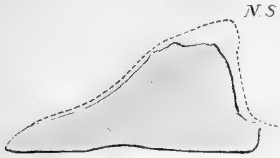

Fig. 5.

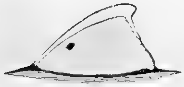

Fig. 6.

Figs. 5, 6.—Sectional views of a scute of the tail-armour of *Ceratochelys* (Fig. 5), and of one of the crest plates of *Gypochelys*, both of the natural size.

The living *Chelydra*, therefore, has a caudal armature which, in principle, is similar to that of *Ceratochelys*, but the osseous elements are relatively atrophied. There is exactly the same relation between the armour of species of living *Crocodiles* and *Alligators*, on the one hand, and those of *Jacare* and *Caiman* and the extinct *Teleosauria*, on the other. In the former, the epidermal scales remain well developed on the ventral side of the body, while the corresponding osseous scutes, fully developed in *Jacare*, *Caiman*, and *Teleosauria*, have vanished.

Among the detached fragments to which I have referred, there are remains of ribs, with their costal plates; marginal and other plates of the carapace; parts of the plastron; part of a scapula; sundry limb bones; and several of the cranial processes called "horn-cores." They all agree, so far as they can be compared, with the determination already arrived at; which, to sum it up in a few words, is that the remains of crania and caudal sheaths from Australia, hitherto referred to Saurian reptiles, under the names of *Megalania* and *Meiolania*, appertain to a hitherto unknown species of Chelonian, *Ceratochelys sthenurus*, closely allied to the living *Chelydra*, *Gypochelys*, and *Platysternum*.

The evidence of this fact offered in the present note appears to me to be conclusive, but it may be desirable hereafter to figure the parts mentioned and to describe them at length.

The interest which attaches to the discovery of this singular Chelonian arises partly from the fact that the group of Chelonia to which it belongs is wholly unrepresented in the fauna of Australia, as at present known. *Platysternum* is usually said to be found in China. Dr. Günther, however, informs me that Upper Burmah is its proper habitat; otherwise, North America, east of the Rocky Mountains, is the nearest region in which the *Chelydridæ* are to be found. But *Chelydridæ*, and, indeed, species of the genus *Chelydra*, occur in Upper Miocene (Œningen) and in Eocene formations in Europe. Moreover, *Platychelys*, of the Upper Jurassic series of Bavaria and Switzerland, is regarded by Rütimeyer as an early form of the group.

Lord Howe's Island is about 200 miles from the nearest Australian mainland, and something like 400 miles, as the crow flies, from the Darling Downs, in which the caudal armour, which has been ascribed to *Megalania*, was found. The discovery of *Ceratochelys*, therefore, has an interesting bearing on the question of the former extension of Australia to the east ward, on the one hand; and of the possible derivation of such forms as *Ceratochelys* from Asia, on the other hand. An elevation of the sea-bottom of 6000 feet would place Norfolk Island and Lord Howe's Island on a peninsula extending from the region of the present Barrier Reef to New Zealand; and the floræ and faunæ of those islands are known to have special affinities with those of New Zealand, and none with those of Australia.

Speculations respecting the origin of the Chelonian carapace are suggested by the discovery of osseous scutes in the vertebral region of the tail, and their coalescence in *Ceratochelys* to form a sort of caudal carapace, ridged in a manner resembling that of *Chelydra* and *Platychelys*. But the consideration of these points would take me beyond the limits of the present note.

[1] The fact is noted by Rütimeyer (Lang and Rütimeyer, "Die Fossilen Schildkröten von Solothurn," *Denkschriften der Allg. Schweiz. Gesellschaft*, vol. xxii.). The armature of the tail in *Platysternum* is for the most part arranged in zones, of four plates in each zone; but I have not yet been able to find any bone in them.

THE WORK OF THE IMPERIAL INSTITUTE[1]

I.

THE Colonial and Indian Exhibition, which owes not only its conception, but also its brilliantly successful realisation to your Royal Highness, will be pre-eminently remarkable in times to come, for having achieved many results of vital importance and highest benefit to Her Majesty's subjects in all parts of her vast realms.

The collection of all that is commercially valuable and scientifically interesting of the natural products of the great Indian Empire and of the Colonies in one Exhibition, embracing as it also did very comprehensive illustrations of the development of commerce, of the arts, and of certain industries, in the many countries beyond the seas which combine with the United Kingdom to constitute our vast Empire, afforded those at home an opportunity, surpassing all previous conception, of studying and comparing the natural history and resources of those distant lands, of which, attached though we might be individually to one or more of them by ties of friendship or of interest, the knowledge of many of us was of a very vague or partial character.

To the Colonists who visited us last year, the Exhibition has been of inestimable value, in affording them a most favourable and appropriate opportunity of becoming acquainted or renewing their old friendship with the mother country, and of examining the progress there made in industrial, educational, and commercial development; in leading to the cultivation of intimacy between Colonists from different sections of the Queen's Dominions; and in affording them invaluable opportunities of comparing the resources and state of development of their respective countries with those of other parts of Europe. No more convincing illustrations than were provided by this great Exhibition could have been conceived of the importance to the home country, to each Colony, and to India, of fostering intimate relationship and unity of action. No more encouraging proof could have been afforded of the desire of all classes of Her Majesty's subjects at home to cultivate a knowledge of those far-off countries which the enterprise and perseverance of the British, and men of British offspring, have converted into prosperous and important dominions, chiefly during the period of the Queen's reign, than was furnished by the interest which the thousands upon thousands, who came from all parts, displayed in the study of the instructive collections in the galleries at South Kensington.

It was the success of the Exhibition which led to the definite formulation of the suggestion first made by your Royal Highness in a letter addressed by you in the autumn of 1884 to the Agents-General of the Colonial Governments, that a permanent representation of the resources of the Colonies and India, and of their continually progressing development, might, with great benefit to the Empire at large, be established in this country. That the realisation of this idea upon a sufficiently comprehensive basis might constitute a worthy memorial of the accomplishment of fifty years of a wise and prosperous reign; a memorial not personal in its character excepting so far as it constituted an emblem of the love and loyalty of Her Majesty's subjects, but tending, as she would most desire, to serve the interests of the entire Empire; this had only to be pointed out by your Royal Highness to be heartily concurred in by the official representatives of the Colonies and India, who

[1] Lecture (abridged) delivered at the Royal Institution, on Friday, April 22, by Sir Frederick Abel, C.B., F.R.S.: H.R.H. the Prince of Wales, K.G., F.R.S., Vice-Patron, in the Chair.

were so intimately identified with the triumphs of the recent Exhibition.

The Committee to whom you, Sir, intrusted the elaboration of a scheme for carrying this conception into effect, became persuaded by a careful consideration of the subject that such an Institution as your Royal Highness desired to see spring into life, to be a memorial really worthy of the Jubilee of Her Majesty's reign, and to fulfil the great purposes which you had in view, must not be confined in its objects to particular portions of Her Majesty's Dominions, but must be made thoroughly representative of the interests and of the unity of the whole Empire.

The outline of the scheme for the establishment of an Imperial Institute for the United Kingdom, the Colonies, and India, which met with the cordial approval of your Royal Highness, was necessarily concise in dealing with the very wide extent of ground which the operations of the Institute are intended to cover; but those who have carefully considered it, and rightly interpreted its proposals, have not failed to realise that it aims at very much more than the creation and maintenance of collections illustrative of the natural resources of our Colonies and of India, and of the development and present condition of the chief industries of different parts of the Empire.

One of the primary objects of the Institute will certainly be the establishment of thoroughly well selected, carefully arranged, and efficiently maintained representations of the natural products which constitute the treasures, and are emblematic of the important positions in the Empire, of those great colonial possessions which, during the fifty years of Her Majesty's reign, have, in many instances, experienced a marvellous development in extent, in commercial, social, and even in political importance.[1] The recent Exhibition not only afforded conclusive demonstration of the great interest and value to the United Kingdom which must attach to such collections if properly organised; it also served, by such illustrations as the magnificent collections of valuable woods, from nearly every colony, many quite unknown in England, and the great variety of valuable economic products from India, of the existence of which we at home had little idea, to convince us that our knowledge of the great countries which constitute the chief portion of the Empire is very limited and imperfect, and that their resources are in many directions still in the infancy of development. Our Colonial brethren cannot, on their part, fail to be greatly benefited by being thoroughly represented in a well-selected and carefully organised assemblage of illustrations of the sources of prosperity which constitute the sinews of their commerce, and upon a continued exploration and cultivation of which must depend the maintenance of their influence upon industrial and social progress. Neither can they fail to reap substantial advantages by pursuing a friendly rivalry with each other in demonstrating the advances made from time to time in the development of the resources of the respective portions of the Empire in which their lot is cast.

The hearty co-operation and important material support to which the great Colonies, through their representatives in London, pledged themselves when the scheme for the proposed Imperial Institute was in the first instance limited to this branch of the great work which it is now contemplated to accomplish, afforded conclusive evidence of their earnest desire to be in all respects thoroughly represented in the mother country, and to take their places permanently in our midst as fellow-labourers in the advancement of the prosperity of the Empire. In furtherance of this important end, a notable feature of that building which, in its character, will, it is hoped, be worthy of the momentous epoch which it is to commemorate, will be the attractions and conveniences presented by it, as a place of resort and a *rendezvous* for Colonists visiting England, and, it is also anticipated, for the important Societies which represent the Colonies and Asiatic possessions in this country, and the facilities which it will afford for reference to literature concerning the Colonies and India, for conferences on matters of common interest and value to the Colonists and those at home, for the interchange of information between the British manufacturer and those in the Colonies who are directly interested in meeting his requirements, and generally for the cultivation of intimate relations and good fellowship between ourselves and our brethren from all parts of the Empire.

The Institute will, however, not only operate actively under its own roof in promoting the cultivation of a better knowledge of the geography, natural history, and resources of our Colonies, and for the advancement of the interests of the Colonists in this country; it is also contemplated that representative collections of the natural products of the Colonies and India, carefully identified with the more elaborate collections of the head establishment, shall be distributed to provincial centres, and that the provinces shall be kept thoroughly conversant with the current information from the Colonies and India, bearing upon the interests of the commercial man, the manufacturer, and the intending emigrant.

Although the formation and maintenance up to date of collections illustrative of the development and present condition of the important industries of the Empire also forms, as I have stated, a part of the programme of the Institute, the scope of its activity in relation to industry will be of a much more comprehensive character; indeed, it is to be hoped that the work which it will achieve in furtherance of the development and progress of industries and their future maintenance in the United Kingdom at least upon a footing of equality with their conditions in the great Continental States, will be most prominent in securing to the Imperial Institute the exalted position which it should occupy as the National Jubilee Memorial of Her Majesty's reign.

There is no need for me to recall to the minds of an audience in the Royal Institution the great strides which have been made during the last fifty years in the applications of science to the purposes of daily life, to the advancement of commerce, and to the development of the arts and manufactures. Nor is it necessary to dwell upon the fact that this country is the birth-place of the majority of the great scientific and practical achievements which have revolutionised means of intercommunication, and have in other ways transformed the conditions under which manufactures, the arts, and commerce are pursued. These very achievements, of which we as a nation are so justly proud, have led, however, by many of their results, to our becoming reduced to an equality of position with other prominent nations in regard to important advantages we so long derived from the possession in this country of great material resources easy of access and application, and from the consequent pre-eminence in certain branches of the trade and industry which we so long enjoyed.

In 1852, Sir Lyon Playfair was impelled by the teaching of the preceding year's Great Exhibition to point out that "the raw material, formerly our capital advantage, was gradually being equalised in price and made available to all by the improvements in locomotion," and "that industry must in future be supported, not by a competition of local advantages, but by a competition of intellect." If this was already felt to be the state of the case six-and-thirty years ago, how much more must we be convinced of the full truth of this at the present day, by the conditions under which the British merchant and the manufacturer have to compete with their rivals on the Continent and in the United States.

It is still within the recollection of many that almost the whole world was in very great measure dependent upon Great Britain for its supplies of ordinary cast iron. Even as lately as 1871, the United States of America received from Great Britain nearly one-fifth of its total produce of pig iron; but from 1875 all importation of British iron ceased for over three years, and it was only in consequence of requirements in the States exceeding the capabilities of production, that some small demands arose in 1879, which were for some time maintained.

Within three years, however, the make of iron in the United States increased by 70 per cent., and although, since 1882, the actual make has not increased, the *capacity of production* has risen enormously, it being at present estimated at nearly 300 per cent. greater than it was in 1879. Looking nearer home, we find that the iron of France, Belgium, and Germany not only competes with ours in the open market, but that Belgian and German iron is actually imported into this country to a moderate extent.

From time to time the ground which we have lost through the development of the resources of other countries has been more than retrieved temporarily by improvements effected through the more thorough comprehension and consequent better application of the scientific principles underlying processes of manufacture, but the ultimate effect of advances of importance has not unfrequently been to improve the position, in relation to the manufactures concerned, of other nations less favourably circumstanced than Great Britain.

The history of the development of steel manufacture during the last twenty-five years affords a most instructive illustration of the

[1] Statistical statements illustrating the development of the colonies during the Queen's reign are appended.

fluctuations which may ensue in the value of our natural resources, and the consequent condition of one or other of our important industries, arising out of continued advances made in the application of science to the perfection or transformation of manufacturing processes, and of the stimulating effects of such fluctuations upon the exertions of those who are able to bring scientific knowledge to bear upon the solution of problems in industrial operations which entirely baffle the ordinary manufacturer. Within that period the inventions of Bessemer and of Siemens have led to the replacement of iron by steel in some of its most extensive applications. This important change in our national industry was, ere long, productive of a serious crisis therein, and for the reason that the pig iron produced from a large proportion of those ores which, from their abundance and the cheapness of their treatment, have been greatly instrumental in placing Great Britain in her high position as an iron-producing nation, could not be applied to the production of marketable steel by means of the Bessemer converter. Hence the application of this rapid steel-making process had to be chiefly restricted to particular kinds of ores, free from the impurity, phosphorus, which it was powerless to eliminate; the supplies of such ores being limited to a few districts in this country. These had to be largely supplemented by importations from other countries; nevertheless the cheapness of production and superiority in point of strength, durability, and lightness of the steel rails thus sent into the market from the Bessemer converter combined to maintain a supremacy of them over iron rails, &c., manufactured by the old puddling process from the staple ores of the country.

The advantages presented by steel over the wrought iron of the puddling furnace for constructive purposes speedily became evident, and the effect of the rapid displacement of malleable iron by steel produced from ores of a particular class has been that at least 85 to 90 per cent. of the iron ores of Great Britain could no longer be applied to the production of material for rails, for ships, and for other important structures. Great has been the apprehension among the owners of those ores that the demand for iron which they can furnish could not revive, but the scientific metallurgist has successfully grappled, from more than one direction, with the great problem of restoring their commercial importance; and a simple alteration of the method of carrying out the Bessemer process has within the last few years led to really triumphant results, with the employment of those ores which before could only be dealt with by the searching operation of the old puddling furnace. A new era has thus been established in steel manufacture, there being now but very few restrictions to the application of the quick processes to iron produced from all varieties of ores. Indeed, the treatment is actually being applied profitably to the recovery of iron from the rich slag forming the refuse-product of the puddling furnace in the production of malleable iron, which before had been condemned to limited usefulness as a material for road-making. Yet another most interesting and valuable result has been achieved by this simple application of scientific knowledge. The slag or refuse-product of the so-called *basic treatment* of iron contains, in the form of phosphates of lime and magnesia, the whole of the phosphorus which it is the main function of that treatment to separate from the metal; it was soon found that the phosphoric acid was there presented in a condition as readily susceptible of assimilation by plants as it is in the valuable artificial manure known as superphosphate; this refuse-slag, simply ground up, constitutes therefore a valuable manure which already commands a ready sale at very profitable prices.

The origination of this latest advance in the development of steel manufacture dates back only nine years, and already the year's product of the basic process amounts to over 1,300,000 tons of steel. But although it is to Englishmen that the owner of iron property and the steel-maker are again indebted for these important results, and to English manufacturers that the first practical demonstration of the success of this process is due, its application has been far more rapidly elaborated upon the Continent than here; in Germany the importance of the subject was at once realised, and it is there that considerably the largest proportion of steel is produced by the basic treatment; it is in Germany also that the value of the slag for agricultural purposes has been developed, the first steps in its utilisation here being but just now taken, in Staffordshire.

I have already referred to the remarkable strides which have been made in the extension of iron manufacture in the United States; the development there of steel production has been no less marvellous, and the causes of this are evident; the resources of the country in ore and fuel are gigantic, and the systematic technical training of the people has made its influence felt upon the development of this as of every other branch of industry which our friendly rivals pursue. But it is not only in the United States that the development in the production of iron and steel has greatly increased of late years; thus, in Germany the increase in the production of pig iron alone, during the last twenty-one years, has been 237 per cent., while with us it has been 75 per cent.

Although, however, the increase in actual production of iron and steel in Great Britain has not kept pace with that of some other countries, it is satisfactory to know that our *productive power* has very greatly increased in late years, and there is probably no one branch of our industries in which we have maintained our position so satisfactorily in regard to quality of product as that of iron and steel manufacture, even though, every now and then, we have indications that in the struggle with other nations for superiority of product and for pre-eminence in continuity of progress, we have to look to our laurels.

There are, however, other important branches of industry, for a time essentially our own, the present condition of which, in this country, we cannot contemplate with equal satisfaction. Several instructive illustrations might be quoted, but I will content myself with a brief examination of one of the most interesting.

In illustrating the advances which were being made, thirty-five years ago, as demonstrated by the Exhibition of 1851, Playfair referred to the great development of the value of the evil-smelling coal-tar, which was then made to furnish the solvent liquids benzene and naphtha, and the antiseptic creosote, the residual material being utilised for pavements and for artificial fuel. The chemist little dreamt then that between 1851 and the year of the next great Exhibition, 1862, coal-tar would have become a mine of wealth equally to science, the manufactures, and to the arts, in which fresh workings have ever since continued to be opened up, and still present themselves for exploration. Hofmann, in his valuable report on the chemical products and processes elucidated by that Exhibition, dwells with the enthusiasm of the ardent worker in science upon the brilliant products obtained from coal-tar which had resulted from the labours of the scientific chemist, and had already acquired an almost national importance, although this great industry was then still in its infancy. From the year 1856, when the first colouring-matter, known as *mauve*, was discovered and manufactured by one of Hofmann's most promising young pupils, Mr. Perkin, down to the present time, the production of new coal-tar colours, or of new processes for preparing the known colours in greater purity, has progressed uninterruptedly, this industry having long since become one of the most important, and also one of the most remarkable, as illustrating by each stage of its development the direct application of scientific research to the attainment of momentous practical results.

The difficulties to be overcome before mauve could be produced upon a manufacturing scale were very great, and were only solved by a steady pursuit of scientific research, side by side with practical experiments suggested by its results. Aniline—the parent of the first coal-tar colour, a liquid organic alkali—a most fertile source of interesting and important discoveries in organic chemistry, was produced with difficulty by various methods in very small quantities, so as to be almost a chemical curiosity at the time of the discovery of mauve. Among the substances from which it had been prepared was the volatile liquid known as *benzene*, first discovered in the laboratory of this Institution in 1825 by Faraday, in the liquid products condensed from oil gas, but afterwards obtained by Mansfield, in the College of Chemistry, from coal-tar naphtha. The conversion of benzene into aniline was accomplished as a manufacturing process after many difficulties by Perkin; and within a year after the discovery of mauve by him, it was in the hands of the silk dyer. Perkin's success led other chemists at once to pursue researches in the same direction, especially in France, where the next important coal-tar colour, *magenta* or fuchsine, was obtained, by M. Verguin, the successful manufacture of which in a pure state was, however, first accomplished by English chemists. In 1861 beautiful violet and blue colours were produced, again by French chemists, but were manufactured shortly afterwards in a pure state in England.

The six years succeeding those which formed the first period (1854–62) of existence of this industry were fruitful, not only of many beautiful new dyes, first produced in England, but also of important progress made here, as well as on the Continent, in the development of the manufacture, and of our knowledge of the constitution, of the parent colours.

In the next period of six years (1868–74) another great stride was made in the coal-tar colour industry, due to important scientific researches carried out by two German chemists, Graebe and Liebermann, which led them, in the first place, to obtain an insight into the true nature of the colouring-matter of one of the most important staple dye-stuffs, namely the madder-root. They found that this colouring-matter which chemists call *alizarine* was related to *anthracene*, one of the most important solid hydrocarbons formed in the distillation of coal, a discovery which was speedily followed by the artificial formation of the madder-dye, alizarine, from that constituent of coal-tar. At first, this achievement of Graebe and Liebermann was simply of high scientific interest; but Perkin, and Graebe, and Liebermann, were not long in discovering methods by which the conversion of anthracene into the madder-dye could be accomplished on a large scale, and the manufacture of alizarine was soon most actively pursued in this country, with very momentous results, as regards the market value of the madder root. The latter has long been most extensively cultivated in Holland, South Germany, France, Italy, Turkey, and India, the consumption of madder in Great Britain having attained to an annual value of as much as 1,000,000*l.* sterling. Playfair pointed out in 1852 that important improvements had lately been attained in the extraction of the red colour or alizarine from the madder-root, but those results, most valuable at the time of the first Great Exhibition, became insignificant when once the dye was artificially manufactured from anthracene; the price paid for madder in 1869 was from 5*d.* to 8*d.* per pound, but now the equivalent in artificial madder-dye, or alizarine, of one pound of the root, can be obtained for one-halfpenny.

With the discovery of artificial alizarine the truly scientific era of the coal-tar industry may be said to have commenced, most of the commercially valuable dye-products, obtained since that time, being the result of truly theoretical research by the logical pursuit of definite well-understood reactions. The wealth of discovery in this direction made during the last thirteen years is a most tempting subject to pursue; but I must content myself with mentioning that one of the results was the production of very permanent and brilliant scarlet and red dyes, the manufacture of which has greatly reduced the market value of cochineal; that the careful study of the original coal-tar colours led to their production in a state of great purity by new and beautifully simple scientific methods; and that even the well-known vegetable colouring-matter, *indigo*, one of the staple products of India, now ranks among the colours synthetically obtained by the systematic pursuit of scientific research, from compounds which trace their origin to coal-tar.

The rapid development of the industry has also not failed to exercise a very important beneficial influence upon other chemical manufactures; thus, the distillation of tar, which was a comparatively very crude process, when, at the period of the first Exhibition, benzene, naphtha, dead-oil, and pitch were the only products furnished by it, has become a really scientific operation, involving the employment of comparatively complicated but beautiful distilling apparatus for the separation of the numerous products which serve as raw materials for the many distinct families of dyes. Very strong sulphuric acid became an essential chemical agent to the alizarine manufacturer, and, as a consequence, the so-called anhydrous sulphuric acid, the remarkable crystalline body which was for many years prepared only in small quantities from green vitriol, is now made at a low price upon a very large scale by a beautifully simple process worked out in England. The alkali- and kindred chemical trades have been very greatly benefited by the large consumption of caustic soda, of chlorate of potash, and other materials used in the dye manufactures, and the application of constructive talent, combined with chemical knowledge, to the production of efficient apparatus for carrying out on a stupendous scale the scientific operations developed in the investigator's laboratory, has greatly contributed to the creation of a distinct profession, that of the chemical engineer.

One of the most beneficial results of the rapid development of the coal-tar colour industry has been its influence upon the ancient art of dyeing, which made but very slow advance until the provision of the host of brilliant, readily-applicable colours completely revolutionised both it and the art of calico-printing.

I venture to think that it will be interesting at this point to quote some words of prophecy included in Prof. Hofmann's important "Report on the Chemical Section of the Exhibition of 1862," and to inquire to what extent they have been verified. In commenting upon one of the features of greatest novelty in that world's show, the exhibition of the first dye-products derived from coal-tar, he says:—

"If coal be destined sooner or later to supersede, as the primary source of colour, all the costly dye woods hitherto consumed in the ornamentation of textile fabrics; if this singular chemical revolution, so far from being at all remote, is at this moment in the very act and process of gradual accomplishment; are we not on the eve of profound modifications in the commercial relations between the great colour-consuming and colour-producing regions of the globe? There is fair reason to believe it probable that, before the period of another decennial Exhibition shall arrive, England will have learnt to depend, for the materials of the colours she so largely employs, mainly, if not wholly, on her own fossil stores. Indeed, to the chemical mind it cannot be doubtful that in the coal beneath her feet lie waiting to be drawn forth, even as the statue lies waiting in the quarry, the fossil equivalents of the long series of costly dye-materials for which she has hitherto remained the tributary of foreign climes. Instead of disbursing her annual millions for these substances, England will, beyond question, at no distant day become herself the greatest colour-producing country in the world; nay, by the strangest of revolutions, she may ere long send her coal-derived blues to indigo-growing India, her tar-distilled crimson to cochineal-producing Mexico, and her fossil substitutes for quercitron and safflower to China, Japan, and the other countries whence these articles are now derived."

So far as concerns the displacement of madder, cochineal, quercitron, safflower, and other natural dye-materials from their positions of command in the markets of England and the world, Hofmann's predictions have been amply fulfilled, and it appeared in the earlier days of the coal-tar colour industry as though he would be an equally true prophet in regard to England becoming herself the greatest colour-producing country in the world. But, although Germany did little in the very early days of this industry, beyond producing a few of the known colours in a somewhat impure condition, many years did not elapse ere she not only was our equal in regard to quality of the dyes produced, but, moreover, had outstripped us in the quantities manufactured and in the additions made to the varieties of valuable dyes sent into the market. So far back as 1878 the value of the make of colours in England was less than one-fourth that of Germany, and even Switzerland, which, in competing with other countries industrially, is at great natural disadvantages, was not far behind us, ranking equal to France as producers. The superior position of Germany in reference to this industry may be in a measure ascribable to some defects in the operation of our Patent Laws and to questions of wages and conditions of labour; but the chief cause is to be found in the thorough realisation, by the German manufacturer, of his dependence for success and continual progress upon the active prosecution of scientific research, in the high training received by the chemists attached to the manufactories, and in the intimate association, in every direction, of systematic scientific investigation with technical work.

The young chemists whom the German manufacturer attracts to his works rank much higher than ours in the general scientific training which is essential to the successful cultivation of the habit of theoretical and experimental research, and in the consequent power of pursuing original investigations of a high order. Moreover, the research laboratory constitutes an integral part of the German factory, and the results of the work carried on by and under the eminent professors at the universities and technical colleges are closely followed and studied in their possible bearings upon the further development of the industry.

The importance attached to high and well-organised technical education in Germany is demonstrated not only by the munificent way in which the scientific branches of the universities and the technical colleges are established and maintained, but also by the continuity which exists between the different grades of education; a continuity, the lack of which in England was recently indicated by Prof. Huxley with great force.

The important part taken by the German universities in the training of young men for technical pursuits has often been dwelt upon as constituting a striking feature of contrast to our university systems. The national appreciation of the opportunities there presented for scientific training is demonstrated by the large number of students which are always working in the university laboratories, while the expenditure of 30,000*l.* upon the physical laboratory, and 35,000*l.* upon the chemical department, of the New University of Strasburg, serves to illustrate the unsparing hand with which the resources of the country are devoted to the provision of those educational facilities which are the very life-spring of the industrial progress whence those resources are derived.

In France, higher education had been allowed to sink to a low ebb after the provincial universities had been destroyed in the great Revolution, and the University of Paris had been constituted by the first Napoleon the sole seat of high education in the country. Before the late war, matters educational were in a condition very detrimental to the position of the country among nations. There was no lack of educational establishments, but the systems and sequence of instruction lacked organisation, but since the war, France has made great efforts to replace her educational resources upon a proper footing. The provincial colleges have been re-established at a cost of 3,280,000*l.*, and the organisation of industrial education has now been greatly developed, though still not on a footing of equality with that of Germany. Every large manufacturing centre has its educational establishment where technical instruction is provided, with special reference to local requirements; and, in order to render these colleges accessible to the best talent of France, more than 500 scholarships have been founded, at an annual cost of 30,000*l.* The Ecole Centrale des Arts et Manufactures, of Paris, still maintains the reputation as the great technical university of the country which it earned many years ago, and receives students from the provincial colleges, where they have passed through the essential training preliminary to the high technical education which that great institution provides.

Switzerland has often been quoted as a remarkable illustration of the benefits secured to a nation by the thoroughly organised education of its people. Far removed from the ocean, girt by mountains, poor in the mineral resources of industry, she yet has taken one of the highest positions among essentially industrial nations, and has gained victories over countries rich in the possession of the greatest natural advantages. Importing cotton from the United States, she has sent it back in manufactured forms, so as to undersell the products of the American mills. The trade of watch-making, once most important in this metropolis, passed almost entirely to Switzerland years ago; the old-established ribbon trade of Coventry has had practically to succumb before the skilled competition of Switzerland; and although she has no coal of her own, Switzerland is at least as successful as France in her appropriation of the coal-tar colour industry and her rivalry in rate of production with England, the place of its birth and development. Comparative cheapness of labour will not go very far to account for these great successes; they undoubtedly spring mainly from the thoroughly organised combination of scientific with practical education of which the entire people enjoys the inestimable benefit.

Holland furnishes another brilliant example of the success with which a nation brings the power of systematic technical education to bear in securing and maintaining industrial victories in the face of most formidable disadvantages, while the United States of America, so rich in natural resources, have long since realised the immensity of additional advantages to be gained over European nations in the war of industry by a wide diffusion and thorough organisation of technical education. So long as forty years ago the States already possessed several excellent educational institutions established upon the basis of the Continental polytechnic schools, but it was not until about fifteen years later that the country became thoroughly impressed with the great advances achieved by Germany in technical education, and that the subject was made a thoroughly national one. It is now just upon a quarter of a century ago since Congress ordained that each State should provide at least one college, having for its leading objects the diffusion of scientific instruction in its relations to the industry of the country, and decreed that public lands should be granted to the States and Territories providing such colleges. The combined effect of this State action, and of great private munificence, was a remarkably rapid development of scientific and technical education throughout the country; besides some fifty colleges, with eight or nine thousand students, which sprang out of the Land Grant Act for Industrial Education, there are now in the States about 400 other universities and colleges, in a large proportion of which efficient instruction in applied science is provided. To the useful work accomplished within a few years by these and many other highly important educational institutions, which have placed the acquisition of scientific knowledge within the reach of the very humblest, the enormous strides made by the United States in the development of home industries must unquestionably be in the main ascribed.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—There are only a few alterations and additions to the usual scientific lecture-list to report, as most of the courses are in continuation of those given last term. Prof. Sylvester is to lecture on the theory of numbers; in the Chemical Department, Mr. Wyndham Dunstan lectures on organic chemistry in relation to medicine and physiology; Prof. Prestwich is to have his usual summer geological excursions; Dr. Tylor continues his exposition of the development of arts, as illustrated in the Pitt-Rivers Museum.

The Sibthorpian Professorship of Rural Economy has been filled up by the re-election of Dr. Gilbert. The Radcliffe Travelling Fellowship has been awarded to Mr. W. Overend, B.A., of Balliol. The statutes of the University Commissioners, which limited the competition for most college scholarships to candidates under nineteen, seem to be having an unfortunate, though not unexpected, effect, as several colleges have lately found it impossible to award scientific scholarships, owing to the want of sufficiently qualified candidates.

There is a good deal of strong feeling in the University with regard to the approaching appointment of a Reader in Geography, and the action of the Delegates of the University Fund in transferring a Readership from History to Geography, just after the offer of the Royal Geographical Society for a similar purpose had been refused, is the subject of much unfavourable comment. There is no thought of opposition to the study of geography, even of scientific geography, but history lecturers not unnaturally complain that the only University appointment open to them should be abolished to make a post for a lecturer in another subject.

CAMBRIDGE.—Among the seven courses on chemistry being delivered this term are lectures on gas analysis and on aromatic bodies, by Dr. S. Ruhemann. Prof. Dewar and Dr. Ruhemann also superintend laboratory practice specially directed to research.

The course given by Mr. Lyon, the Superintendent of the Mechanical Workshops, this term is on machine construction.

Mr. Langley is giving a special course on the central nervous system, with demonstrations and practical work.

Prof. Macalister's lectures this term are on the history of human anatomy. It is to be hoped that he will publish them.

Mr. M. A. Fenton is lecturing on elementary comparative osteology: Dr. Gadow on the morphology of Mammalia, recent and extinct, and on the palæontology of the Vertebrata.

Dr. Vines has a course of advanced embryology of plants, and Mr. F. Darwin is giving advanced demonstrations in the physiology of plants.

In geology, Prof. Hughes is taking the geology of the neighbourhood of Cambridge, by lectures and field excursions; Mr. Marr, foreign stratigraphy; and Mr. Roberts, the Trilobites.

Prof. Roy has classes for general pathology, morbid anatomy, and practical morbid histology, bacteriology, &c.

The lectures mentioned above are only a selection of the more interesting courses. The lists from which the above are selected announce about seventy-five courses of lectures and practical work.

Candidates for the John Lucas Walker Studentship, the holder of which must devote himself or herself to original research in pathology, should send their applications to Prof. Roy, Trinity College, Cambridge, not later than May 31 next. The Studentship is of the annual value of 250*l.*, and is tenable under certain conditions for three years.

SCIENTIFIC SERIALS

The American Journal of Science, April.—Contributions to meteorology, twenty-second paper, by Elias Loomis. In this communication the author treats of areas of high pressure, their magnitude and direction of movement, and their relation to areas of low pressure. The latter subject is illustrated with a plate giving the isobars for December 15, 1882, in the northern hemisphere, and it is shown generally that the movement of areas of high pressure depends upon very different causes from that of areas of low pressure, which seem to be endowed with a power of locomotion residing within themselves. Areas of high pressure exhibit no such power, their movement seeming to depend entirely on external forces.—The faults of South-West Virginia, by John J. Stevenson. Here is given a summary of the information communicated by the author in several memoirs read before the American Philosophical Society (1880-84) on a reconnaissance made by him of the faulted region in Virginia from the Tennessee line to nearly twenty miles beyond New River, a total distance of 150 miles.—On Taconic rocks and stratigraphy, with a geological map of the Taconic regions, part 2, by James D. Dana. The general facts are here detailed which bear on the geographical distribution of the limestone and other rocks. A description is given of Williamstown, regarded as the birthplace of the Taconic system, and it is shown generally that the great quartzite formation, forming the foundation of the Palæozoic of the region, derived its material from Archæan formations of the vicinity and not from the fabled "Atlantis" as some geologists have supposed.—Irish esker drift, by G. H. Kinahan. It is pointed out that, in common with some other observers, Prof. Carvill Lewis confounds true esker drift and ridges of esker-like drift. His statement in the December number of the *American Journal of Science* that the Irish eskers appear to be adjuncts of the melting of the ice-sheets is shown to be impossible.—Physical characteristics of the northern and north-western lakes, by L. Y. Schermerhorn. The results are given of the lately completed surveys made by the United States of all the great lakes draining through the St. Lawrence to the Atlantic. The total water-area is 95,275, and the total area of the lacustrine basin over 270,000, square miles. The length of shore-line with connecting rivers is about 5400 miles, the extreme depth of Superior 1008 feet, or over 406 below sea-level, the mean annual rainfall of the whole basin 31 inches, the volume of water in the lakes about 6000 cubic miles, and the discharge of Ontario at St. Lawrence River 300,000 cubic feet per second.—Mineralogical notes from the laboratory of Hamilton College, by Albert H. Chester. Specimens are described and analysed of fuchsite, pink celestite, zinkenite, brochantite, pectolite, crystals of barite, scorodite, and bismuthite.—The topography and geology of the Cross Timbers and surrounding regions in Northern Texas, by Robert T. Hill. This wooded zone penetrating in two belts from Indian territory through the surrounding prairie southwards to 32° N. lat., is explained by the detritus of arenaceous strata which occupy well-defined horizons in the geological series, and which have been exposed by the denudation of the overlying strata.—American Jurassic mammals, by Prof. O. C. Marsh. In this paper are described the remains of several hundred individuals which have come to light since the appearance of the author's previous papers on the subject. Although fragmentary, the remains are usually well preserved, comprising the lower jaws, teeth *in situ*, various portions of the skull, vertebræ, and other parts of the skeleton. Placental as well as marsupial mammals occur in the oldest formations, whence the inference that the former do not derive from the latter evolutionally, as is supposed, but that both of these orders descend in independent lines from a common ancestor.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 24.—"On the Magnetisation of Iron in Strong Fields." By Prof. J. A. Ewing, University College, Dundee, and William Low.

The behaviour of iron and steel when subjected to very strong magnetising forces is a matter of considerable practical and very great theoretical interest, especially from its bearing on the molecular theory of magnetisation, which assigns an upper limit to the intensity of magnetism that a piece of iron can acquire, and even suggests that the metal may become diamagnetic under the influence of a sufficiently great force. All experiments hitherto made, by magnetising iron in the field of an electric solenoid, have shown that the intensity of magnetism, $\mathfrak{I}$, as well as the induction, $\mathfrak{B}$, is increasing with the highest values actually given to the magnetising force, $\mathfrak{H}$. It is scarcely practicable, however, to produce by the direct action of a magnetising solenoid, a field whose force exceeds a few hundreds of C.G.S. units.

In the space between the pole-pieces of a strong electro-magnet we have a field of force of much greater intensity than it is practicable to produce by the direct action of the electric current. This field is not well adapted for experiments whose object is to determine with precision the relation of magnetisation to magnetising force, on account of the distortion which it undergoes when the piece of iron to be magnetised is introduced into it. It is, however, well suited for experiments whose object is to determine how much magnetism the metal can be forced to take up.

In the authors' experiments, bobbins of Lowmoor and Swedish wrought-iron and cast-iron were magnetised by placing them between the pole-pieces of a large electro-magnet. The bobbins consisted of a short narrow central neck with conical ends. The magnetic induction in the neck was measured ballistically by means of an induction coil, consisting of a single layer of fine wire, wound on the neck; and the magnetic field in the air-space immediately contiguous to the neck was also measured by means of a second induction coil wound over the first, and of slightly greater diameter. This enabled the non-ferrous space under the inner induction coil to be corrected for, and also gave an approximation to the value of $\mathfrak{H}$, the magnetic force acting on the metal. The magnetic force varied up to about 11,000 C.G.S. units, and the highest induction observed (in a sample of Lowmoor wrought-iron) was 32,880 C.G.S. units. In some instances the magnetic induction was observed by withdrawing the bobbin; in others the bobbin was turned round suddenly so that its magnetism was reversed. The following results refer to Lowmoor wrought-iron and to cast-iron.

Lowmoor wrought-iron

Field round iron neck per sq. cm.	Magnetic induction in the metal	Current in field magnets, amperes	$\frac{\mathfrak{B} - \text{outside field}}{4\pi}$	$\frac{\mathfrak{B}}{\text{outside field}}$

The magnetic force within the metal ($\mathfrak{H}$) differs from the field in the surrounding space by an amount which cannot be estimated without a knowledge of the distribution of free magnetism on the pole-pieces and conical faces of the bobbin. It appears probable that, with the dimensions of the various parts used in these experiments, the magnetic force within the metal is less, but not very greatly less, than the outside and closely neighbouring field. In the absence of any exact knowledge of $\mathfrak{H}$, it is interesting to examine the relation of $\mathfrak{B}$ to the outside field. Thus, ($\mathfrak{B}$ – outside field)/4π gives a quantity which is probably not much less than the intensity of magnetism, $\mathfrak{I}$. The values of this quantity and also of the ratio $\mathfrak{B}$/outside field for Lowmoor wrought-iron and cast-iron are stated in the tables above.

Curves are given showing the relation of $\mathfrak{B}$ to $\mathfrak{B}$/outside field for Lowmoor iron and for cast-iron, in the manner introduced by Rowland for showing the relation of $\mathfrak{B}$ to μ (the permeability). The curves have the same kind of inflection that a curve of μ and $\mathfrak{B}$ begins to have when the magnetising force is raised sufficiently high. The range through which the permeability of iron may vary is well shown by comparing the values reached here (probably in the extreme case less than 3) with the value 20,000, which was found by one of the authors in the case of a soft wire exposed to a very small magnetising force and kept at the same time in a state of mechanical vibration.

The experiments give no support to the suggestion that there is a maximum of the induction, 𝔅. The value of 𝔅 capable of being reached by the method here employed depends mainly on the scale of the experiments. Larger field magnets with pole-pieces tapering to a narrow neck should yield values of 𝔅 greatly in excess even of those that were observed.

Linnean Society, April 7.—Mr. William Carruthers, F.R.S., President, in the chair.—Mr. Hunter J. Barron, Mr. Jas. H. Dugdale, and Mr. Edwd. B. Poulton were elected Fellows of the Society.—Fresh specimens were exhibited of a pure white variety of primrose, which had been gathered, growing wild, near Biarritz, France, by Mr. W. D. Godolphin Osborne.—A large series of instantaneous photographs of storks nesting, &c., were exhibited for Mr. E. Bidwell. These had been taken in Germany, and were specially interesting as showing the peculiar attitudes assumed in flight, &c.—Some malformed trout in an early stage of development were shown and commented on by Dr. F. Day.—A paper was read by Prof. Huxley on "The Gentians; Notes and Queries." Taking the flower as a basis, he divides the Gentianeæ into two great series, each of which is characterised by a peculiar disposition of the nectarial organs, and a gradation of forms of the corolla from the deeply cleft rotate or stellate condition, through the campanulate to the extreme infundibulate kind. In one series termed (I.) Perimelitæ, the nectarial cells are aggregated in a single or two patches; in the other series (II.) Mesomelitæ, the distinguishing characters are a zone of secreting cells encircling the ovary, or absence of such, with presence of a honey-secreting surface which may exist in the central parts of the flower. He assumes, on morphological grounds, a hypothetical ancestral flower or Ur-Gentian = Haplanthe. As a starting-point, this would lead, on the one hand, to the series of Perimelitæ, with four subsidiary types; and on the other to the Mesomelitæ, also with four subsidiary types of floral structure. The Perimelitæ comprise the groups:—1. Actinanthe, 2. Keratanthe, 3. Lophanthe, and 4. Stephananthe; the Mesomelitæ comprise:—1. Asteranthe, 2. Limnanthe, 3. Lissanthe, and 4. Ptychanthe. The one series appears to bear a certain progressive relation in its evolution to the leading morphological modifications of the opposite series. In treating of the geographical distribution of the gentians, Prof. Huxley adopts the lines previously followed by him on animal distribution. Under (I.) Arctogea he includes Europe, Africa, Asia, and North America as far as Mexico; South Africa, Madagascar, Hindostan, and Indo-China forming a sub-province = South Arctogea; the remainder = North Arctogea. (II.) Austro-Columbia comprises South America, isthmus and islands as far north as Mexico. (III.) Australia is another province; and (IV.) New Zealand with adjoining islands. Species of the Gentianeæ are found in all these provinces, the head-quarters being North Arctogea and Austro-Columbia. The Ptychanthe are predominant in North Arctogea; the Lissanthe in South Arctogea; and Actinanthe, Lophanthe, and Lissanthe in Austro-Columbia. In Australia and New Zealand there is a paucity of species. He considers that the present distribution of the Gentianeæ is not to be accounted for by migration from any given centre, whence diffusion to their present localities. Borrowing analogy from zoological distribution, he likens the gentians to the tapirs, at present only represented in South America and the Indo-Malayan region. Yet the Tapiridæ in the Middle Tertiary epoch were distributed everywhere in the intermediate areas. Though fossil remains of gentians are not yet known, Prof. Huxley nevertheless suggests that in Pliocene and Miocene times their distribution may have been substantially similar to what is now extant. He further throws out the hint that, could the age of the first appearance of dipterous, hymenopterous, and lepidopterous insects provided with long haustra be indicated, we should then be in a position to guess approximately when specialisation of the types of the gentians and their ultimate distribution occurred.

Geological Society, April 6.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—On the rocks of the Malvern Hills, part 2, by Mr. Frank Rutley. The details of the microscopic examination of the rocks constituted the principal part of the present paper. The author concluded that the rocks of the Malvern Hills represent part of an old district consisting of plutonic and, possibly, of volcanic rocks associated with tuffs, sedimentary rocks composed mainly or wholly of eruptive materials, and grits and sandstones; that the structural planes in these rocks (sometimes certainly, at others possibly) indicate planes of stratification, and that the foliation, in many cases if not in all, denotes lamination due to deposition either in water or on land surfaces, probably more or less accentuated or altered by the movements which produced the upheavals, subsidences, and flexures prevalent in the range.—On the alleged conversion of crystalline schists into igneous rocks in County Galway, by Dr. C. Callaway.—A preliminary inquiry into the genesis of the crystalline schists of the Malvern Hills, by Dr. C. Callaway. The author's researches amongst the crystalline rocks of Connaught had suggested certain lines of investigation which had subsequently been followed out in the Malvern district. He had satisfied himself that many of the Malvern schists had been formed out of igneous rocks; but at present he limited himself to certain varieties. The materials from which these schists were produced were diorite (several varieties), granite, and felsite. The metamorphism had been brought about by lateral pressure. Evidence of this was seen in the intense contortion of granite-veins and in the effects of crushing as observed under the microscope. The products of the metamorphism were divided into two groups:—(1) Simple schists, or those formed from one kind of rock. (2) Injection schists, formed by the intrusion of veins, which had acquired parallelism by pressure. Veins of diorite in diorite produced *duplex diorite-gneiss*, and veins of granite in diorite originated *granite diorite-gneiss*. It was further noted that (1) generally the particular varieties of schist occurred in the vicinity of the igneous masses to which they were most nearly related in mineral composition; (2) the mineral banding of the rocks in the field was more like vein-structure than stratification. The author accepted the received view of the age of the schists. The parallel structure was clearly antecedent to the Cambrian epoch, and the occurrence of similar rocks as fragments in the Uriconian conglomerate of Shropshire seemed to indicate that the Malvernian schists were older Archæan. The reading of this paper was followed by a discussion in which the President, Mr. Teall, Dr. Hicks, Colonel McMahon, Dr. Callaway, and Mr. Rutley took part.

Entomological Society, April 6.—Dr. David Sharp, President, in the chair.—Mr. Francis Galton, F.R.S., Mr. J. H. Leech, B.A., F.L.S., and Mr. G. S. Parkinson, were elected Fellows.—Mr. S. Stevens exhibited specimens of *Arctia mendica*, collected in the county of Cork. The peculiarity of the Cork form of the species is that the majority of the males are as white as the female of the English form, and the typical black or English form appears to be unknown in Cork.—Mr. McLachlan exhibited a zinc box used by anglers for the purpose of keeping living flies in, which he thought might be adapted to practical use in the field by entomologists.—Mr. G. T. Porritt exhibited specimens of *Hybernia progemmaria*, from Huddersfield. All the females and a large proportion of the males were of the dark variety *fuscata*, which formerly was almost unknown in Yorkshire, but which now seemed likely to replace the original type. Mr. Jenner-Weir and Lord Walsingham both remarked that the number of melanic forms appeared to be on the increase in the north, and suggested explanations of the probable causes of such increase.—Mr. Gervase F. Mathew, R.N., exhibited several new species of Rhopalocera taken by him in the Solomon Islands during the visits to those islands of H.M.S. *Espiègle* in 1882 and 1883. Amongst them were species of *Euplœa*, *Mycalesis*, *Messarus*, *Rhinopalpa*, *Cyrestis*, *Diadema*, *Parthenos*, *Pieris*, *Papilio*, &c.—Mr. E. B. Poulton exhibited a large and hairy lepidopterous larva brought from Celebes by Dr. Hickson, and made remarks on the urticating properties of the hairs of the species, which were said by the natives to produce symptoms similar to those of erysipelas if the larva was handled. Lord Walsingham, Mr. McLachlan, Dr. F. A. Dixey, Mr. Jenner-Weir, Dr. Sharp, Mr. Slater, and Mr. Poulton, took part in a discussion as to whether urtication was due to the mechanical action of the hairs in the skin, or to the presence of formic acid, or some other irritant poison, in glands at the base of the hairs. There appeared to be no doubt that in some species the irritation caused by handling them was merely due to the mechanical action of the hairs.—Mr. P. Crowley exhibited a collection of Lepidoptera recently received from West Africa, including several new or undescribed species of *Mylothris*, *Diadema*, *Harma*, *Rhomaleo-*

soma, &c.—Mr. H. Goss announced the capture by Mr. G. D. Tait, at Oporto, of a specimen of *Anosia plexippus*, and remarked that, although some twenty specimens had been caught in the South of England, only two specimens had been previously recorded from the continent of Europe.—Lord Walsingham read a paper entitled "A Revision of the Genera *Acrolophus* (Poey) and *Anaphora* (Clem.)"; and exhibited about twenty new species of these and allied genera. Mr. Stainton made some remarks on the genera, and said he was glad Lord Walsingham was working at them and their allies.—Mr. Poulton read "Notes in 1886 on Lepidopterous Larvæ." In the discussion which ensued, Lord Walsingham referred at some length to instances of protective resemblance in larvæ, and alluded to the existence in certain species, especially of the genus *Melitœa*, of prothoracic glands.—Dr. F. A. Dixey remarked on the extraordinary powers of contraction which appeared to be possessed by the retractor muscle of the flagellum in *D. vinula*, and inquired whether any corresponding peculiarities of minute structure had been observed in it. The discussion was continued by Mr. G. F. Mathew, Mr. W. White, Dr. Sharp, Mr. Porritt, and others.

PARIS

Academy of Sciences, April 18.—M. Janssen, President, in the chair.—On an absolute unity of time; electric standards of time and chronoscopes of their variations, by M. Lippmann. It is shown that from the study of certain electric phenomena an absolute invariable unity of time may be obtained. The electric apparatus here described yields more accurate results than the best constructed astronomical clock. It has the further advantage of indicating, recording, and, where needed, automatically correcting, its variations of velocity.—Solar observations made at Rome during the first quarter of the year 1887, by M. Tacchini. The period of minimum activity for the spots and faculæ, as recorded in November 1886, has continued throughout the first three months of 1887. The protuberances also continued to decline during the same period.—On antipyrine, an antidote against pain, by M. Germain Sée. Antipyrine, with the formula $C_{11}A_{12}N_2O$, discovered by Knorr in 1884, is shown to be not only a good febrifuge, but also a most efficacious remedy for gout, rheumatism, and similar affections.—On the earthquake of February 23, by M. J. L. Soret. Certain derangements of the telephonic apparatus in the central office at Cannes seem to show that the violent shock which occurred at 5.50 a.m. was accompanied by strong electric discharges.—On a special circumstance connected with the production of the bicarbonate of soda, by M. Paul de Mondésir. An experiment here described shows that the carbonate of soda, combined with a single equivalent of water, scarcely absorbs carbonic acid at the ordinary temperature at all. But when it is mixed with a slight portion of dry bicarbonate the reaction on the contrary begins at once, and with an energy in direct proportion to the quantity of the bicarbonate and the thoroughness of the mixture.—Method of determining the relative value of the four unities of chemical action of the atom of carbon, by M. Louis Henry. At the base of the doctrines of organic chemistry as now understood lie the two principles of the quadrivalence of the atom of carbon, and the identity in value of its four unities of chemical action. The former is an accepted fact proved by experiment, while the latter is far from possessing the same degree of objective certainty. The author here proposes a method by means of which its truth may be rigorously determined.—Artificial reproduction of rose-red spinel (balas ruby), by M. Stanislas Meunier. The author, who has been for several years incidentally occupied with the synthesis of spinel, has lately again attacked the problem in a way quite different from his first method. He now crystallises the aluminate of magnesia, tinted a rose colour by traces of chromium, the result being a stone absolutely identical with the balas ruby of nature. The experiment here described has already been varied in several ways, yielding a series of products, such as the aluminates of zinc, iron, &c., besides secondary compounds, whose study is still in progress.—On the functions of the semicircular ducts, by M. J. Steiner. From experiments made on Crustaceans at the Zoological Station at Naples, the author shows that these organs exercise little or no influence on the locomotion of the lower animals, as supposed by Delage, Viguer, and others.—On a station of the Stone Age discovered at Chaville, by M. E. Emile Rivière. This station of Chaville lies on the skirt of the wood of like name on the right side of the road between Paris and Versailles. Here the author has just discovered a large number of flint implements of the Neolithic epoch, scrapers, knives, arrow-heads, and the like. All lay on or near the surface, and were of a more or less deep gray colour, some showing clear traces of the action of fire. They closely resemble the objects found by the author at the Neolithic station of Trou-au-Loup, Clamart, in 1884-85. Amongst them was a small fragment of black, siliceous pottery without any ornamentation, and also perfectly analogous to the pottery of the Neolithic beds in the same neighbourhood.—The members of the International Conference on Celestial Photography were present at the sitting, and were welcomed by the President in an appropriate address dwelling especially on the importance for astronomy of the photographic labours of MM. Henry, of Paris.

BOOKS, PAMPHLETS, and SERIALS RECEIVED

Hyderabad, Kashmir, Sikkim, and Nepal: Sir R. Temple and Capt R. C. Temple (Allen).—Geology of England and Wales, 2nd edition: H. B Woodward (Philip).—An Elementary Treatise on the Mathematical Theory of Perfectly Elastic Solids: W. J. Ibbetson (Macmillan).—Dynamics for Beginners: Rev. J. B. Lock (Macmillan).—Catalogue of Lizards, 2nd edition, vol. iii.: G. A. Boulenger (British Museum).—Mineral Resources of the United States, 1885 (Washington).—Photography of Bacteria: E. M. Crookshank (Lewis).—Chemistry for Beginners: R. L. Taylor (Low).—Woodland Tales: J. Stinde (Unwin).—Geological and Natural History Survey of Minnesota, 13th and 14th Annual Reports: W. H. Winchell (St. Paul).—Longmans' New Geographical Readers, Standard VII. (Longmans).—The Prevention of Consumption: C. Candler (K. Paul).—Pictographs of the North American Indians: G. Mallery (Washington).—Der Bau des Menschen: Dr. R. Wiedersheim (Williams and Norgate).—Thomas Young: Prof. Tyndall.—Oberpliocän-Flora aus den Baugruben des Klärbeckens bei Niederrad und der Schleuse bei Höchst A. M.: Drs. Geyler and Kinkelin (Frankfort).—The Eruption of Krakatão: E. D. Archibald.—City Government of St. Louis: M. S. Snow (Baltimore).—Notes to Accompany a Geological Map of Northern Canada: G. M. Dawson (Montreal).—Étude Numérique des Concours de Compensation de Chronomètres: G. Cellérier (Genève).—Journal of the Royal Statistical Society, March (Stanford).—Zeitschrift für Wissenschaftliche Zoologie, xlv. Band, 2 Heft (Leipzig).—Bulletin de l'Académie Royale des Sciences de Belgique, No. 3 (Bruxelles).
